The Mk 56 was a program to provide a thermonuclear warhead for Weapon System WS-133A, whose vehicle was a three-stage, solid-propellant, intercontinental ballistic missile called MINUTEMAN, designed and manufactured by Boeing Airplane Company for the United States Air Force.

The MINUTEMAN missile was a second-generation system with more advanced characteristics than ATLAS and TITAN. A study group had suggested in 1956 that improvements could be made through the use of solid-propellant engines, which would reduce missile size, ground support equipment, numbers of operating personnel, and would increase missile readiness.

(b)(1), (b)(3)

The MINUTEMAN would be about 5-1/2 feet in diameter, 57 feet long, and weigh 65,000 pounds. It would be launched vertically from an unmanned, underground silo-type launcher, and missile stability provided by controlling the rocket nozzle direction.

(b)(1), (b)(3)

Development of the missile was approved by the Department of Defense February 28, 1958, and a study was released March 11, 1958.

This study indicated that two sizes of re-entry vehicles (and nuclear warheads) would be needed to achieve operational flexibility, and the Assistant Secretary of Defense, April 4, 1958, requested the United States Atomic Energy Commission

to cooperate with the Department of Defense and the Air Force in a feasibility study of two MINUTEMAN warheads, one weighing in the neighborhood of 330 and the other 550 pounds. It was noted that these warheads would be required in large quantities. It was requested that the yields be the maximum achievable in the weights specified and that the systems have an operational deployment date of mid-1962.[1]

The feasibility study group met May 5, 1958 and, having been requested to quickly complete the task, finished the study in one day. It was felt that the lighter device could be developed as a modification of the Mk 50 NIKE ZEUS warhead of the Los Alamos Scientific Laboratory and that a heavier design could be provided by partial rework of the XW-47 POLARIS warhead of the University of California Radiation Laboratory. There appeared to be no unusual interprogram effects concerning application of either design to the MINUTEMAN missile, and it was felt that the operational deployment date could be met.[2]

Little action was taken during much of 1958, due to lack of MINUTEMAN funding.

(b)(1), (b)(3)

Results of this second feasibility study were published March 2, 1959. It was reported that the weight of the XW-47 could be reduced, and that several other Radiation Laboratory designs could be considered for an operational availability date of mid-1963. It was noted that the United States had suspended nuclear testing October 31, 1958 and, as a result, heavy emphasis was placed on designs that could be certified without full-scale test.[3]

The Air Force Special Weapons Center sent a teletype to Sandia March 15, 1959, noting that the Air Staff was considering possible acceleration of the MINUTEMAN

program and requesting the earliest availability date of a MINUTEMAN warhead.[4] Sandia replied, March 20, 1959, stating that the most serious restraint on warhead availability would be the requirement for completion of a group of six successful missile-warhead flight tests about a year before the warhead could be stockpiled. If the XW-47 Warhead were used without change, these flight tests could be completed by December 1959, but if the warhead were modified, the flight tests might extend for another year.

(b)(1), (b)(3)

Subsequently the Joint Chiefs of Staff, August 5, 1959, established a requirement for a MINUTEMAN warhead with a diameter of 20 inches, length of 60 inches, weight of 600 pounds, and the highest yield obtainable within these parameters.

(b)(1), (b)(3)

AVCO Manufacturing Corporation would design and produce the re-entry vehicle.

(b)(1), (b)(3)

The Military Liaison Committee released a set of warhead military characteristics September 15, 1959. The weapon would provide air or ground burst, be sealed, and require a minimum of servicing and component replacement. It would be capable of being left unattended for long periods of time, and its storage life would be at least 3 years.

(b)(1), (b)(3)

The warhead would contain no primary source of power, unless the use of a ferromagnetic X-unit became necessary. At least one arming device that would serve as a safety feature was required to sense the postlaunch environment, and this component would be installed in the warhead so as to minimize the possibility of nuclear detonation by sabotage.[3]

The following priorities would be observed: Safety from nuclear disaster to friendly installations, acceptable reliability, operational simplicity, ease of maintenance, and invulnerability to ~~neutron radiation~~ nuclear countermeasures. If the warhead system were such that, when armed, energy was stored awaiting a firing signal for detonation, a device would be required to safely dissipate the energy in a minimum time, not over 10 minutes, and not to interfere with the normal arming/firing sequence.

(b)(3)

The Division of Military Application, in forwarding the development request, suggested that the program be assigned to the Lawrence Radiation Laboratory.[7]

(b)(1), (b)(3)

If this test proved successful, weaponization would be completed in about another 2 years. It was felt that sufficient confidence in the design might be generated to warrant its stockpiling without full-scale detonation.

(b)(1), (b)(3)

Lawrence Radiation Laboratory and Sandia-Livermore notified the Division of Military Application, October 29, 1959, that in view of the existing heavy weapon work load, it was important that the MINUTEMAN warhead be scheduled no earlier than required by missile production. The desired date appeared feasible, but its accomplishment would depend on the schedule set by the re-entry vehicle program.

(b)(1), (b)(3)

Sandia issued a development program definition for the XW-56 December 24, 1959.[11]

(b)(1), (b)(3)

The nonnuclear components of the XW-56 would weigh less than those of the XW-47, and it was felt that the gross warhead weight would be about 670 pounds. (b)(1), (b)(3)

(b)(1), (b)(3)

The 16 flight tests required would start about May 1961 and furnish structural, environmental and systems operational data. Pilot-production release was scheduled for early 1961, with complete engineering release by the middle of the year. Early production would be achieved by mid-1962.

The firing system would contain an inertial generator, X-unit and environmental sensing devices, with a ferromagnetic design as alternate. The warhead would not be structurally integrated with the re-entry vehicle, but would be supported near the warhead midpoint. This type of support would simplify the missile interface problems.

(b)(3)

The MINUTEMAN missile had a diameter of 5.5 feet, length of 58 feet, launch weight of 65,000 pounds, re-entry vehicle weight of 915 pounds, range of 2,000 to 5,500 nautical miles, maximum velocity of 24,000 feet per second, impact velocity of 600 to 800 feet per second, and a three-stage solid-fuel propulsion system. Launching facilities included a fixed underground silo complex or a mobile platform.

No new materials would be required by the program, and all weapon components were used in other projects.

(b)(1), (b)(3)

The Division of Military Application sent a teletype to Albuquerque Operations Office May 2, 1960, proposing three possibilities for warhead development.

(b)(1), (b)(3)

Sandia-Livermore was asked whether development of the modified XW-56 would delay the operational availability date of June 1962, and the Division of Military Application was informed that design was in progress and that the date would be met.[15]

By May 1960 a decision was made to use a ferromagnetic transducer in the XW-56 system. It would be necessary to include diodes in the arming and surface-burst fire lines for isolation. Due to current requirements, silicon rectifier diodes appeared to be the only practical type, and development was under way on an arming-line diode that could handle surge currents and have sufficient resistance to radiation.[16]

A decision had been made to use fuse-actuated switches. Four of these would be mounted on a printed circuit board and packaged in a switch pack, with two switches protecting exciting-current input lines to the ferromagnetic transducer and two others protecting fire-signal input lines. Closure of the switches in the current input lines would provide one of the two required independent arming signals.[17]

(b)(1), (b)(3)

(b)(1), (b)(3)

Field Command noted that there was no apparent advantage to a mixed arsenal of tested and untested warheads, as the best design should be selected. The Radiation Laboratory saw some benefit in a mix of lower-weight, lower-yield tested warheads for the XW-56 until the XW-56-X1 design became available, as the reduced weight would extend the range of the MINUTEMAN to more targets.

At the request of the Division of Military Application, the Radiation Laboratory provided additional information August 25, 1960.

(b)(1), (b)(3)

(b)(1), (b)(3)

Field Command, in a teletype to Sandia September 7, 1960, noted that it would be at least theoretically possible to design a weapon containing a Los Alamos primary and a Radiation Laboratory secondary.

(b)(1), (b)(3)

Meanwhile, Sandia had originated Report SC4819(WD), Proposed Ordnance Characteristics of the XW-56 Warhead.

(b)(1), (b)(3)

The report stated that early mechanical interface designs included various forward and rear supports of the warhead. The design was changed to a single

mechanical interface flange, which provided a cantilevered support of the warhead in re-entry vehicle and avoided differential thermal expansion problems between warhead and re-entry vehicle structure.

The warhead would have an explosive ferromagnetic transducer. The system would contain dual arming and firing circuits, and environmental sensing devices would prevent inadvertent signals from activating the warhead. The system would detonate the weapon by either air-burst or contact-burst firing signals supplied by the re-entry vehicle arming and fuzing package.[23]

Field Command notified Sandia, September 23, 1960 that the ordnance characteristics report had been reviewed in coordination with representatives of the three Services. The report noted that the use of a reversible arm/safe operation solely for the purpose of receiving power and/or signals for safing appeared to be neither practical nor feasible. Additionally, in view of recent warhead design changes, no firm time interval for full arming could be established. Both these conditions were accepted, and the review established that the design met all requirements of the approved military characteristics. However, it was requested that positive means be provided to prevent transfer of boosting gas into the pit in event of external fire.[24]

The Director of Defense Research and Engineering, in a letter dated October 13, 1960, approved the 600-pound XW-56-X1 design for the MINUTEMAN warhead.[13]

(b)(1), (b)(3)

(b)(1), (b)(3)

An operational availability date of July 1, 1962 was requested for a normal-version warhead, as well as a maximum-yield 600-pound warhead with an availability date of July 1963.

(b)(1), (b)(3)

This latter design would have the maximum yield possible without nuclear test and would be compatible with advanced design re-entry vehicles.

(b)(1), (b)(3)

The XW-56-X1 would be called, in production, the Mk 56 Mod 1 Warhead.[28]

Lawrence Radiation Laboratory and Sandia-Livermore forwarded the development program definition of the XW-56-X1 to Albuquerque Operations Office March 24, 1961. A series of 10 warhead flight tests would start by July 1962. Engineering release was planned for mid-1962 and early production for May 1963.

(b)(1), (b)(3)

(b)(1), (b)(3)

Environmental safing devices would provide warhead safety before the warhead was mated to the arming/fuzing package. The warhead would be sealed. A single flange would be provided for attachment to the re-entry vehicle structure.

(b)(1), (b)(3)

No materials or components were expected to present any unusual procurement or manufacturing problems.[29]

In June 1961 the Division of Military Application requested operational availability by April 1963, and it was agreed that, with increased effort, this date could be met.[30] In September 1961 Albuquerque Operations Office requested a first-production-unit date of February 1963 and increased quantities of warheads in the early months of production.[31] The difficulties in supporting such effort were discussed, and this additional acceleration was canceled. Production was authorized in September 1961 and the Division of Military Application subsequently notified the Military Liaison Committee that early units would be available by March 1963.[32]

(b)(1), (b)(3)

The design was accordingly

changed, January 18, 1962, to use external initiators and a chopper-converter firing set.[33] The XW-56-X1 was redesignated XW-56-X2, but retained production nomenclature of Mk 56 Mod 1.[34]

(b)(1), (b)(3)

The Mk 56 Mod 1 Warhead was design-released in May 1962.

(b)(1), (b)(3)

The report was accepted by the Design Review and Acceptance Group December 18, 1962.[37]

Previously, Sandia-Livermore had notified Albuquerque Operations Office that a reasonable degree of radiation hardening could be accomplished with little effect on the yield, weight and operational availability date. Existing hardening methods would, however, impose limitations on low-temperature, long-term storage, and techniques to avoid this limitation were under study.

(b)(1), (b)(3)

Sandia-Livermore sent a teletype to the Division of Military Application December 20, 1962, noting that efforts had been made to increase the resistance of the warhead to blast effects produced by antimissile defense systems and stating that the method of mating warhead to re-entry vehicle would be changed. Instead of a single-flange cantilevered mounting system, paper honeycomb would be placed between warhead and re-entry vehicle to provide area loading.

This design change would be called the XW-56-X3 and would become, in production, the Mk 56 Mod 2. The design-release date would be July 1963.[40]

(b)(1), (b)(3)

The Mk 56 Mod 2 would not be interchangeable with Mk 56 Mod 1, and early production was scheduled for April 1964.[41]

Report SC4868(WD), Mk 56 Mod 1 Warhead Final Development Report, was issued March 1963. This noted that early production had been accomplished. The Mk 56 Mod 1 Warhead was 17.4 inches in principal diameter, 47.3 inches long, weighed 600 pounds, and was compatible with the Mk 11 re-entry vehicle.

(b)(1), (b)(3)

The electrical system had two parallel arming and firing channels. Since some of the components operated irreversibly, the signals had to be given in proper

motor. The transformer secondary was connected to storage capacitor and neutron generators through a voltage regulator.

(b)(3)

The warhead could be detonated by either air-burst or surface-burst signal. The signal was produced by the arming/fuzing system and operated a puncture switch, which discharged the storage capacitors through the warhead detonators. Output from this puncture switch also actuated the neutron generators, assuring an ample supply of neutrons at nuclear detonation time.[42]

(b)(1), (b)(3)

(b)(1), (b)(3)

Report SC4869(WD), XW-56-X3 Warhead Preliminary Development Report, was issued October 1963. This noted that the warhead would be used with the Air Force's Mk 11A re-entry vehicle system, and would provide interim hardening against blast effects. Early production was scheduled for April 1964 and the warhead would be called the Mk 56 Mod 2.

The XW-56-X3 Warhead, was 32 inches in maximum diameter, 80.5 inches long, and weighed 831 pounds.

(b)(1), (b)(3)

With minor exceptions, the warhead electrical system was unchanged. Inertial switches were redesigned, as early designs could not withstand high loads. These inertial switches were incorporated in the firing set and the firing set redesignated. The neutron generator was also redesignated, due to a change in mounting. Design release was accomplished in July 1963.[46] The report was presented to and accepted by the Design Review and Acceptance Group, and forwarded to the Division of Military Application October 31, 1963.[47]

Sandia-Livermore, in a letter dated May 20, 1966, noted that a program to harden the Mk 56 Mod 2/Mk 11A against hot (high energy) X-rays had been proposed by the Ballistic Systems Division of the Air Force Systems Command.

(b)(1), (b)(3)

The Division of Military Application, May 5, 1966, requested that the nuclear laboratories provide design support for the X-ray hardening program, and an analysis was completed and forwarded June 28, 1966.

(b)(1), (b)(3)

The forward shield that interfaced with Sandia components and the nuclear package would be designed by Sandia-Livermore. Sandia was planning design release by October 1966, with deliveries of production weapons by March 1967. The design would be called the XW-56-X4, with production nomenclature of Mk 56 Mod 3. Existing Mk 56 Mod 2 Warheads would be retrofitted with the new design.[53] Subsequently, however, delays were encountered in missile deliveries, and the design release was deferred to December 1966 and early production to February 1967.[54]

2.0 Description of the B57 Bomb

The B57 is a single stage, lightweight, multipurpose bomb designed for use as a depth bomb, or in tactical and strategic weapon applications.

[redacted]

DOE (b)(3)

The B57 is currently fielded in two basic Mods, Mod-1 and Mod-2, which are essentially identical except Mod-2 incorporates a Category B PAL. Either Mod can be configured with any one of three field-interchangeable noses. The N57-0 Ballistic Nose, N57-1 Radar Nose or N57-2. The N57-2 is an improved high friction impact nose designed to remove the low level delivery restriction on the bomb with the Mod-0 Nose. The B57 may be deployed in either depth bomb or Laydown with any of the three noses; however, it must have the N57-1 Radar Nose for the Airburst options.

B. Reservoirs.

[redacted]

DOE (b)(3)

The following definitions apply:

Cycle Life - The interval from fill time to the time that the gas no longer meets the weapon yield certification because of tritium decay.

[redacted]

DOE (b)(3)

Extended Cycle Life - The interval from fill time to the time that "unacceptable" yield degradation results from tritium decay and helium generation. This time is greater than the cycle life and less than or equal to the limit life.

Limit Life - The interval from fill time to the time that the structural integrity of the reservoir, including an appropriate factor of safety, may be compromised, resulting in an increased probability of a tritium leak.

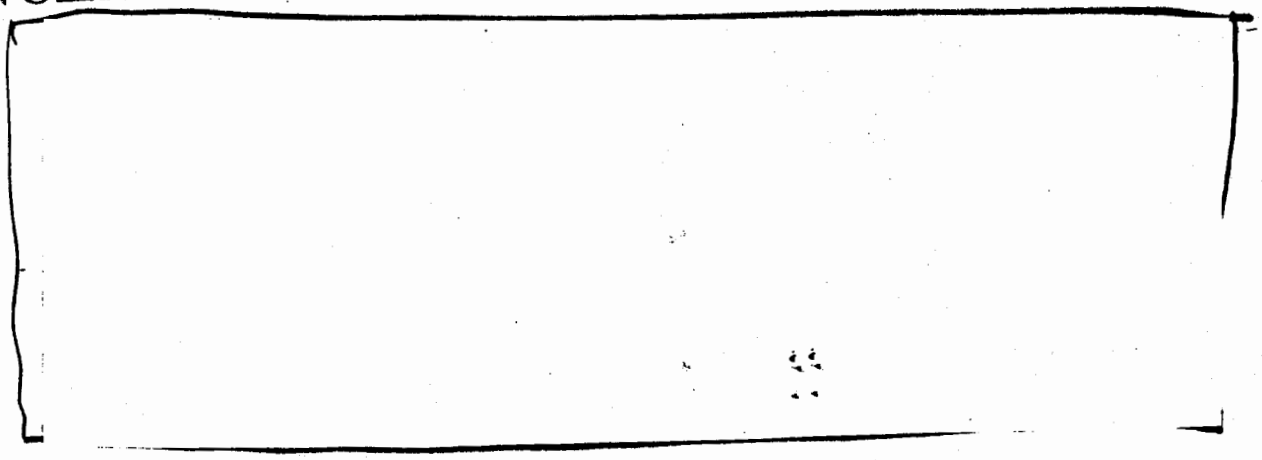
2.5.2 Current authorized STS is FC/10610257, RS 3446/1964, published 31 October 1961

Several revisions to this basic document have been proposed but none have been accepted due to the extensive test program that would have to be initiated to verify the requested changes in requirements that were proposed.



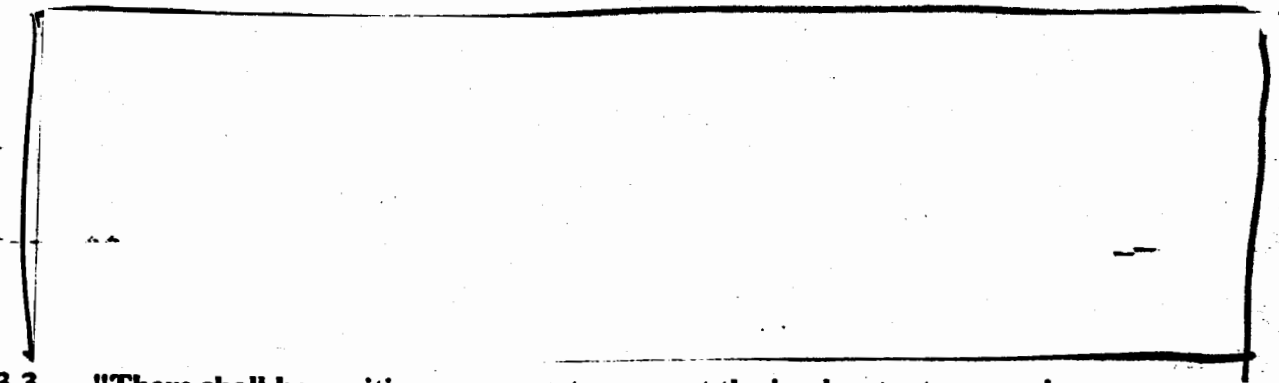
3.0 Description of Positive Measures

The B57 pre-dates Enhanced Nuclear Detonation Safety (ENDS) design methodology and components, Fire Resistant Pit (FRP) designs and the development of Insensitive High Explosive(IHE). It also pre-dates the development and definition of Nuclear Safety Rules. Following paragraphs identify design features that provide some assurance against the requirements of each of the Nuclear Safety Rules.

3.1 "There shall be positive measures to prevent nuclear explosives involved in accidents or incidents from producing a nuclear yield."

[redacted] DOE 6(3)

[redacted] DOE (6)(3)



3.1.1 During carriage on a strike aircraft (accident or jettison):

1. The Ready/Safe switch should be in the "SAFE" position.
2. There should be no power on the pull-out cable, required to start the prearm sequence.

3.1.2 During a logistic movement operation (accident or incident):

1. The Ready/Safe Switch will be in the "SAFE" position, isolating internal power.
2. The Strike Enable Plug should be absent (isolating internal battery power).
3. There are no lanyard connections to either the pulse plug or the pull-out switch, both of which must function to initiate prearming.
4. Neither of the trajectory sensing systems will normally experience the environment required to operate the trajectory switch, thereby precluding further arming of the bomb.

3.2 "There shall be positive measures to prevent deliberate prearming, arming or firing of a nuclear explosive except when directed by competent authority."

3.3 "There shall be positive measures to prevent the inadvertent prearming, arming, launching, firing or releasing of a nuclear explosive in all normal and credible abnormal environment."

The required sequence of events under normal environments would act to preclude inadvertent prearm, arm or release.

[redacted]

DOE (b)(3)

3.4 "There shall be positive measures to ensure adequate security of nuclear explosives pursuant to the DOE safeguards and security requirements."

Security is handled by systems external to the weapon system. Such factors as fences, guards, two person control and Personnel Assurance Program (PAP) are examples of DOE (and DoD) security measures.

3.5 "There shall be positive measures to prevent accidental, inadvertent, or deliberate unauthorized dispersal of plutonium to the environment."

There are *no* **positive** measures; the B57 has conventional high explosive.

4.0 Summary of Past Safety Studies and Investigations

4.1 DOE and Laboratory Internal Studies

The B57 bomb is a weapon designed prior to the incorporation of the modern safety concepts of isolation, inoperability and incompatibility. The weapon does not utilize Enhanced Nuclear Detonation Safety (ENDS) nor does it have IHE or FRP.

[redacted]

DOE (b)(3)

4.1.1 Retrograde Surety

A study was conducted for the Executive Management Team for Dismantlement to identify options for enhancing Surety during the dismantlement process. In

recognition of system deficiencies, as detailed in paragraph 3 above, we have identified options to address these shortcomings. A tabulation of these options and the relative improvements to nuclear detonation safety and plutonium scatter is shown in the following table. Additional comments on each option are provided below:

Option 1. [redacted]

Option 2. [redacted]

DOE (b)(3)

Option 3. Use of the Transportation Accident Resistant Container (TARC), in the B57 application, requires disassembly of the bomb and shipment of only the separate Center Bomb Subassembly in the container. Work is moving apace in the development, testing and fabrication of this configuration.

Option 4. Restricting shipment of B57 bombs to the SST is the recommended option.

4.2 TWG Reports. In 1975-76 there was a joint ERDA(DOE)/DoD effort to characterize "older weapons" in abnormal environments and combinations of these abnormal environments. The reports generated by these studies are referred to as "TWG Studies" (Technical, Working Group). The findings of these working groups are common across the services; only the individual accident scenarios differ..

- In mechanical abnormal environments, Impact, Crush, Immersion, Puncture, Acceleration, Blast, and Vibration, B57 response is completely predictable only in Immersion, Acceleration and Vibration environments.
- In Electrical abnormal environments, External Power Sources, Static Charge, EMR, and Lightning, the B57 response is completely predictable only in Static Charge and EMR environments.
- In Thermal environments the response of the B57 is predictable below 500°C or beyond the temperature at which the HE ignites. The possibility of Pu scatter as one result of HE ignition was not considered by the TWG.
- The B57 response to Chemical environment is predictable.

See Appendix B for additional details

MC1362 GAS GENERATOR
MC1108 DETONATORS

7.0 Findings and Recommendations

7.1 General

Although the B57 bomb meets the Military Characteristics and Stockpile-to-Target Sequence specified, it does not incorporate enhanced nuclear detonation safety design features and predates the development of insensitive high explosives(IHE) and plutonium scattering safety features. Thus, there is no assured level of safety in a broad range of abnormal environments such as could be encountered during alert, force generation exercises, and air transport.

The following issues prevail:

- The MC1362 Gas Generator propellant is approaching the limit of assured safety. The threat, the failure mechanism, is possible auto ignition, presenting a personnel / facility hazard.

DOE (b)3

DoD b(1)

7.2 Recommendations

DOE (b)(3)

- As a DOE position, the use of SSTs is the only proven safe, secure means of transporting the B57.
- Air transportation should be considered only if other factors eliminate the use of SSTs. If air transportation is necessary, both the use of TARCs (H1501 or H1501A) and the employment of Alt 914 should be required. Alt 914 improves the nuclear detonation safety, with or without the use of the TARC, two to three orders of magnitude. The use of TARC will improve Pu scatter probability by an order of magnitude.

Appendix B

ERDA(DOE)/DoD TECHNICAL WORKING GROUP (TWG) STUDIES OF 1976

During the TWG studies no attempt was made to quantify anticipated responses to abnormal environments, or combinations of environments as represented by accident scenarios studied. Rather, anticipated responses to these environments were characterized as one of three predefined conditions:

PREDICTABLE	A predictable response is one in which a critical component, subsystem or system can be depended upon with a high degree of confidence to respond in a manner that is known and safe.
UNPREDICTABLE	An unpredictable response is one in which a component, subsystem or system responds in a manner that is not always repeatable and may contribute to the weapon being unsafe.
UNDESIRABLE	An undesirable response of a critical component or subsystem in one in which it is expected to respond in a manner that contributes to a weapon being less safe. An undesirable response for a system is one in which it is expected to respond in a manner that is unsafe.

Note that the single concern was nuclear contribution to an accidental detonation. Plutonium scatter was not a concern during this era. Hence an assured HE detonation which will have no nuclear contribution was termed "Predictable".

B57 response to the various abnormal environments individually is common to both Air Force and Navy TWGs and are summarized in Table 1.

B57 responses to Air Forces Accident Scenarios is presented as Table 2. Navy responses are presented in Table 3.. The effects of performing Alt 914 on anticipated Navy accident scenarios responses is presented as Table 4.

THIS DOCUMENT CONSISTS OF 25 PAGES

~~SECRET~~ UNCLASSIFIED

Timetable of Mk 58 Events

Mid-1959	Development of concern over enemy defenses to ballistic missile attacks. Cluster warheads proposed.
8/59	Study of cluster warheads completed, and design recommended.
11/24/59	Director of Defense Research and Engineering requests Atomic Energy Commission to participate in feasibility study of a cluster warhead for the POLARIS missile.
1/22/60	Feasibility study report recommends development of thermonuclear cluster warhead for POLARIS.
7/60	Decision made that both air-burst and surface-burst fuzing be provided.
7/19/60	Director of Defense Research and Engineering requests United States Atomic Energy Commission to design POLARIS warhead. Nuclear portion of project assigned to Lawrence Radiation Laboratory.
8/16/60	Military characteristics for POLARIS warhead approved by Military Liaison Committee.
10/60	Nomenclature of XW-58 assigned to warhead.
1/25/61	Sandia and Lawrence Radiation Laboratory forward development program definition of XW-58 Warhead to Albuquerque Operations Office.
8/8/61	Report SC4830(WD), XW-58 Warhead Proposed Ordnance Characteristics, reviewed by Navy and accepted.

(b)(1), (b)(3)

11/6/62	Mk 58 Warhead program authorized for production.
5/16/63	Mk 58 Mod 0 Warhead design released.

(b)(1), (b)(3)

Preliminary design suggested that the three re-entry bodies be mounted on a support structure and an ejection system be provided to disperse the rocket-propelled re-entry bodies at an altitude of about 200,000 feet on the exit phase of the missile trajectory. An ejectable fairing would cover the three re-entry bodies during underwater launch of the POLARIS A-3 missile and throughout early flight phase.

(b)(3)

Two basic configurations were being considered for the re-entry bodies. Both had the same cylinder and flare, but differed in nose shape. A hemispherical nose shape would be made of pyrolytic graphite material, and an elliptical nose shape would be made of either pyrolytic graphite or beryllium. Either design would result in a maximum inner wall temperature of 1500°F, and insulation between the inner wall and the warhead would limit the temperature of the latter to not more than 300°F.[7] The hemispherical shape was eventually chosen.

By July 1960 a decision had been made that both air-burst and surface burst fuzing would be provided. (b)(3) The air-burst fuze would be an inertial type consisting of a range-corrected timer started by decelerometer. The air-burst fuze would be effective against about 95 percent of the targets proposed for the POLARIS weapon system. The remaining 5 percent would be located at too high an altitude, and would be attacked with the surface-burst fuze. A means would be provided for selecting surface burst for any target.

The primary safety component was the decelerometer. This would be an integrating type requiring a deceleration of 10 g's for 5 seconds before permitting arming. An integrating accelerometer would function as a complementary safety device for added safety during handling and to isolate electrical circuits entering the re-entry body. An interlock assembly and a pulse-type pullaway connector would prevent arming in the event the missile was off course or re-entry body/missile separation was not achieved. A thermal battery initiated by re-entry heat would supply power.[8]

The Director of Defense Research and Engineering, in a letter dated July 19, 1960, requested the United States Atomic Energy Commission to proceed with design of the POLARIS Warhead.[9]

(b)(1), (b)(3)

It was noted that the Lawrence work load was quite heavy, and that no new development programs should be assigned to this laboratory in fiscal 1961 without compensatory reduction in other programs. However, since the operational availability date of the POLARIS Warhead called for a 4-year development cycle, rather than the 3 years specified in the warhead feasibility study, it was felt that adjustments to other weapons programs might not have to be made.[10]

The military characteristics for a POLARIS Warhead were approved by the Military Liaison Committee August 16, 1960. Three similar warheads would be used in each missile assembly.

(b)(1), (b)(3)

The Department of Defense was responsible for the weapon, exclusive of the warhead, and had designated the Bureau of Naval Weapons as the cognizant agency for development of the POLARIS system. The Lockheed Missile and Space Division was missile system manager and was responsible for re-entry body system, missile assembly, support equipment, and testing. The Naval Ordnance Laboratory would provide an integrated fuzing and firing system.

The flight-test program would encompass 14 tests, which would start in October 1962. Pilot release was being planned for December 1962 with complete design release by March 1963. Early production had been accelerated to January 1964 and operational availability with a POLARIS submarine complement of 48 warheads by June 1964.

(b)(1), (b)(3)

The integrated fuzing and firing system would be a Military responsibility and would provide air-burst fuzing, controlled by a barometric switch, having three burst-height options and surface burst. Environmental sensing devices would prevent system operation until all environments associated with a normal launch and re-entry trajectory had been experienced.

The firing system would contain an explosive-electric transducer, and the warhead would be sealed, either as an entity or as an integral part of the warhead/nose-cone assembly. The boosting-gas reservoir would be installed in a well and would allow replacement without breaking the warhead seal. The warhead would be attached to the re-entry system structure by a flange near the aft end of the warhead.

The POLARIS A-3 missile had a maximum diameter of 54 inches, length of 31 feet, launch weight of 35,000 pounds, and a range from 500 to 2500 nautical miles. The missile

in coordination with Navy representatives. The review established that the design met all requirements of the approved military characteristics and all other known operational, logistic and safety requirements of the Department of Defense. The design was acceptable to the Military.[18]

(b)(1), (b)(3)

Measures were being taken to limit the effects of countermeasures on the warhead.

The individual re-entry bodies were being designed with a maximum flare diameter of 23.5 inches, length of 54 inches, and weight of 300 pounds. Each contained a nuclear system and an integrated fuzing and firing system, surrounded by an outer heat shield. This heat shield had been changed in September 1961 from a pyrolytic graphite design to an ablative heat shield integral with the warhead structure.[19]

(b)(1), (b)(3)

This redesign resulted in a delay in laboratory and flight tests, and caused the design-release date to slip about 3 months. The early production date of January 1964 was not expected to be affected.[21]

The Director of Defense Research and Engineering notified the United States Atomic Energy Commission February 20, 1963, that the Navy was considering a high-yield, semihardened warhead for POLARIS, and a feasibility study was requested.[28] The Division of Military Application subsequently noted that since the warhead characteristics were similar to those of the warhead being developed for the MINUTEMAN missile, the program should be assigned to Los Alamos.[29]

The Mk 58 Mod 0 Warhead was design released May 16, 1963, with the exception of re-entry body shell assembly, cover and primary. System release was completed by July 1963.[30,31]

Field Command notified Sandia-Livermore June 27, 1963 that Report SC4860(WD), Mk 58 Mod 0 Interim Development Report, had been reviewed by the Navy. The design met most requirements of the approved military characteristics. Insufficient data were available to make an evaluation of the capability of the explosive actuator to meet vulnerability requirements. Otherwise, the design met the known operational, logistic and safety requirements of the Department of Defense, but Sandia was requested to ensure that the actuator satisfied vulnerability requirements.[32,33]

(b)(1), (b)(3)

Report SCL-WD-64-18, Mk 58 Mod 1 Warhead Final Development Report, was accepted by Field Command September 2, 1964.

(b)(1), (b)(3)

Air-burst fuzing was

provided, with choice of three heights, as well as an electronic surface-burst fuze that could be used either as primary option or as backup.

The POLARIS missile had a maximum diameter of 54 inches, length of 32.32 feet, launch weight of 35,000 pounds, and a range from 500 to 2500 nautical miles. The missile was a two-stage solid-propellant rocket, with a spin-separation rocket on each re-entry body, and could be launched from either submerged or surfaced submarines. One of three height-of-burst options (timer fire) or a surface-burst option (proximity fuze) could be selected before launch and stored in the missile programmer. At launch an accelerometer enabled the warhead circuits.

Underwater launches could be made at depths up to 100 feet. The missile was ejected from the launch tube by either compressed air or a solid-propellant/steam-launch system. After the missile emerged from the water, the first stage was ignited. First-stage acceleration caused an accelerometer to operate, closing contacts which connected warhead circuitry to thermal battery and missile programmer. This accelerometer operation occurred about 55 seconds after launch, at an altitude of about 62,000 feet.

(b)(1), (b)(3)

The Bureau of Naval Weapons notified Sandia-Livermore, October 7, 1964, that POLARIS missiles were now on station, aboard the nuclear-powered submarine USS Daniel Webster. This significant milestone of a truly global deterrent was hailed as a source of pride to everyone, military and civilian, who had taken part in the nationwide POLARIS team. A heartiest "well-done" was extended to the entire POLARIS group.[38]

A report entitled "Mk 58 Mod 1 Weapon Description" was issued in December 1965. The warhead was defined as a major assembly consisting of nuclear system and electrical circuitry, hardware to hold the parts together, DOD-supplied fuzing and firing device, and DOD-supplied ablative material bonded to the warhead case.

(b)(1), (b)(3)

The entire warhead was enclosed in a magnesium case and an aluminum cover. The warhead ablative heat shield was of nylon phenolic laminate bonded to the magnesium case. The cover incorporated two antenna connectors for the target-detecting device, a baro port which provided atmospheric-pressure information to the baroswitch, and a purging port used in filling the warhead with dry air.

(b)(1), (b)(3)

A single-channel fuzing and firing device was mounted in the warhead compartment. Battery and target-detecting-device antennas were mounted in the re-entry body flare.

Development Program Definition -- A report that describes the weapon to be designed and the steps that will be taken in its development.

Director of Defense Research and Engineering -- Handles research and development activities for the Department of Defense.

Division of Military Application -- An AEC office that functions as liaison between the Military and weapons designers and producers.

Dominic -- A full-scale test operation held in the Pacific. Series of 39 tests, April 25 to November 4, 1962. Dominic was authorized after the test ban was broken by the Soviet Union in 1961.

Environmental Sensing Device -- A device that reacts to a specific environment of the weapon, such as speed, acceleration, altitude, etc.

Field Command -- The local office of the Armed Forces Special Weapons Project (Defense Atomic Support Agency), located on Sandia Base, Albuquerque, New Mexico.

Firing System -- The electrical system of the weapon that produces and applies a high-voltage current to the detonators.

Fuzing System -- The system that arms the weapon at the appropriate time and provides a firing signal to the firing system at the selected burst height.

g -- Force equal to one unit gravity.

Gas Boosting -- The technique of increasing the yield of a nuclear device by introducing deuterium-tritium gas into the implosion process to increase fission activity.

Hardtack -- A nuclear series of 72 tests. Hardtack I was held at the Pacific Proving Grounds from April 28 to August 18, 1958. The decision to declare a moratorium on testing resulted in Hardtack II, held at the Nevada Test Site between September 12 and October 30, 1958.

Kiloton -- A means of measuring the yield of an atomic device by comparing its output with the effect of an explosion of TNT. A 1-kiloton yield is equivalent to the detonation effect of 1000 tons of high explosive.

Lawrence Radiation Laboratory -- A nuclear design organization located at Livermore, California.

Military Characteristics -- The attributes of a weapon that are desired by the Military.

Secondary -- The thermonuclear portion of a two-stage weapon.

Squib -- A device containing a small explosive charge. When detonated, the resulting gas pressure closes a switch or performs a similar action. A light, quick-acting, one-shot device.

Thermal Battery -- A battery whose electrolyte is in a solid state while inactive. To activate, heat is applied to this electrolyte, melting it and putting the battery into active output condition.

Thermonuclear -- Two-stage reaction, with a fission device exploding and starting a fusion reaction in light elements.

Tritium -- The hydrogen isotope of mass number 3.

Warhead -- A weapon carried to the target by missile.

May 1967	Production of B61-0 stopped.
Mid-1967	Modifications made on B61-0.
1/12/68	FPU of improved system accomplished.

UNCLASSIFIED RESTRICTED DATA

HISTORY OF THE TX-61 BOMB

(b)(1), (b)(3)

This weapon would be carried by Air Force Century series and STOL (Short Take-Off and Landing) aircraft.

(b)(3)

Compatibility with B-47 and B-52 aircraft appeared possible, and the group would consider application to the B-70.[3]

(b)(1), (b)(3)

Six weapons per bomb bay would be considered for the B-52, 4 weapons carried externally on pylons on the B-58, and 6 weapons per bomb bay in the B-70.

(b)(1), (b)(3)

One basic weapon configuration was desired, with maximum capability for both Tactical Air Command and Strategic Air Command applications.[5]

(b)(3)

(b)(1), (b)(3)

Environmental criteria for the TX-61 were specified. Temperature extremes from -65 to ±160 degrees F might be experienced for indefinite periods of time. Shock environments would include 50 g vertical, 40 g transverse, or 30 g longitudinal while the bomb was being transported or stored aboard ship. The exterior surfaces of the bomb might experience a maximum temperature of +275 degrees F for about 40 minutes, but all temperature-critical components would be insulated. Parachute deployment would subject the bomb to a maximum load of 255 g along the longitudinal axis.[12]

(b)(1), (b)(3)

By March 1963 the weapon was being designed so that it could be released without aircraft power after arming.

(b)(1), (b)(3)

It was hoped that the weapon would be more rugged than the Mk 57. An integrated nose assembly would contain a radar, impact crystals, and shock mitigation.

(b)(1), (b)(3)

The heavy case enclosing the nuclear assembly fuzing and firing components was being designed for maximum strength and minimum weight.

(b)(1), (b)(3)

Components would be potted and packed in foam to provide shock resistance. The afterbody would be a sheet metal assembly and would contain a power-deployed parachute system similar to that of the TX-57.[14]

The TX-61 ballistic contour would consist of a Von Karman nose, a cylindrical center section, and a parabolic afterbody. Four fins would provide stability during the drop trajectory for the free-fall

options. The unit would be parachute-retarded for the laydown and retarded-airburst options. Sufficient retardation would be provided to permit delivery from 50 feet above target elevation.[15]

The bomb would be timer-armed in all options. The firing signal would be provided by radar in the airburst option, by piezoelectric crystals in the freefall ground-contact option, and by timer in the laydown option. A gap-fired transverter-capacitor firing set and electronic neutron generators had been designated for the warhead electrical system.

(b)(1), (b)(3)

The forward subassembly would contain a bomb radar nose and its associated power supply, impact fuzes, radome, and case section. Because of the requirement for a low-drag shape to permit the weapon to be carried at supersonic speeds, the nose assembly would be pointed, and would be tipped with metal to prevent damage from rain erosion.

The center bomb subassembly would contain any elements requiring protection during laydown deliveries. These included the nuclear system, boosting reservoir and valve, firing set, permissive action link, neutron generator, sequential timer system, ready/safe rotary switch, trajectory-arm inertial switch, interval timer, and thermal batteries.

All fuzing and firing components and some nuclear system components would be mounted in polyurethane foam to maximize packaging density and to protect against laydown shock. This foam also provided thermal insulation to hold component temperatures within operational limits during supersonic carriage.

(b)(1), (b)(3)

The velocity sensor for environment sensing during freefall differed from the ones in previous weapons in that it obtained ram air pressure through a port that was located not on the weapon skin but on a cylinder which, when projected into the air stream, lifted the port about 3/4 inch from the weapon surface to prevent skin interference with air flow.

Capability would be provided for selecting any fuzing option while the delivery aircraft was airborne, as well as a preflight capability for choosing retarded or freefall delivery. Two adjustable safe-separation times would be settable before flight, and selection between these times could be made in flight. Both high and low burst heights, as well as contact backup enable, or nonbackup for the airburst options, would be selectable before flight.

(b)(1), (b)(3)

There would be some constraints on F-111 external carriage of the Mk 57, but it was felt that these would not be too severe.

The first TX-11 freefall ballistic test was held at the Tonopah Test Range August 20, 1963.

(b)(1), (b)(3)

Separation from the aircraft was clean and the weapon was stable throughout its trajectory.[16]

(b)(1), (b)(3)

Until the F-111 aircraft became available, it would be difficult to simulate this environment exactly, but some preliminary tests would be made at the rocket-sled facility in Area 3. A portable radiant-heat chamber would be used to heat the bomb, which would then be mounted on a rocket sled. When the sled had been accelerated to the proper velocity, the weapon would be ejected upward. After a prescribed delay after ejection, a gas generator would be fired, the parachute deployed, and the unit would describe a normal trajectory and impact on a flat concrete target.[17]

(b)(1), (b)(3)

Although additional development time, tradeoffs, and

probably nuclear tests would be required to attain this end, the change would be worthwhile.

(b)(1), (b)(3)

Carriage of the bomb by RF-4C aircraft was specified.[18]

(b)(1), (b)(3)

This would entail some redesign, but it was felt possible to produce a satisfactory laydown weapon. Diameter and length of the weapon would not be changed, but the weight would be increased by about 10 pounds.[19]

At this time, compatibility of the TX-61 in the freefall option with internal carriage in the F-105 had not been demonstrated, and it was thought that the aircraft suspension system might have to undergo a major redesign. The military characteristics had been amended to eliminate contact backup in the freefall option, and a strike-enable plug was added to the fuze at Navy request.

(b)(1), (b)(3)

It had been decided that trajectory arming in the freefall option would be accomplished by angular acceleration produced by a spin rocket motor. This motor, ignited shortly after bomb release, would impart a spin of 5 revolutions per second to the weapon to prevent coupling and instability under high-Mach, high-altitude release conditions.

(b)(1), (b)(3)

[redacted]

(b)(1), (b)(3)

Sandia notified the Division of Military Application that this amendment could be attained with relatively minor changes to the weapon.[26, 27]

By late 1964 discussions were being held within Sandia concerning an apparent inconsistency in the TX-61 fuzing system.

(b)(1), (b)(3)

It was pointed out that the minimum safe-separation time presently achievable in the weapon when delivered in the freefall mode was 12 instead of the advertised 10 seconds. This inconsistency was a result of a 3-second delay provided in the freefall-trajectory arming circuit. This delay dircuit prevented operation of the trajectory arming unit until 3 seconds after weapon release. When a safe separation time of 10 seconds was desired, the device was programmed to start 1 second after weapon release. However, the system could allow an additional 2 second delay, and this would result in an overall safe separation time of 12 seconds.

A spin-rocket safety-hazard tower test was conducted January 21, 1964, and showed that the 3-second delay was required. Two approaches appeared feasible; to redesign the electrical system so that a minimum safe separation time of 10 seconds could be attained when using the freefall delivery mode, or to determine whether a minimum safe separation time of 12 seconds would be compatible with the freefall delivery maneuvers specified in the stockpile-to-target sequence.

(b)(1), (b)(3)

For a minimum flight time of 16 seconds, a minimum safe separation time of 15 seconds would have to be provided so as to allow 1 second for final bomb arming. Thus the 12-second minimum safe separation time currently provided in the freefall version was adequate for the approach and delivery conditions defined in the stockpile-to-target sequence, and no modification of the timing system or junction box was required to provide compatibility with the 3-second trajectory arming delay and the minimum safe separation time of 10 seconds.[28]

The Division of Military Application notified the Albuquerque Operations Office December 24, 1964, that the first production unit date for the TX-61, in view of recent changes, would be deferred to January 1967.[29]

(b)(1), (b)(3)

A review of the development test program in late 1964 showed

that about half of the ballistic freefall and laydown tests (both sled and aircraft drops) had been completed. All these had been successful, except for a failure to stop the parachute deployment tube. Only two laydown fuzing and firing tests had been completed. The first failed due to jitter in the ready-safe switch, and the second drop missed the concrete target.

(b)(1), (b)(3)

Consideration was being given to using rocket shots or delayed parachute deployment after freefall from high altitude.[30]

Sandia notified the Division of Military Application on May 6, 1965 that some essential changes to the TX-61 nuclear system would increase the diameter of the bomb from 12.75 to 13.30 inches and the weight from 600 to700 pounds. It was felt that the established first production date could still be met.[31]

The first War Reserve TX-61-0 was accepted by the AEC October 21, 1966, which was in conformance with the scheduled production date.

(b)(1), (b)(3)

Sandia Corporation and Bendix improved manufacturing and testing procedures for the Programmer and the Air Force revised the parachute packing inspection procedures and strengthened the bag loops.

FPU of the improved system was accomplished January 12, 1968.

(b)(1), (b)(3)

The diameter is 13.3 inches, the length 141.6 inches, and the weight is about 715 pounds.

The bomb is timer-armed in all options. Firing signals are provided by radar for airburst options, by piezoelectric crystals for contact (freefall ground burst) option, and by timer for the laydown option.

(b)(3)

In all options, an escapement-regulated interval timer is used with radially or longitudinally acting acceleration switches to provide trajectory arm-

DOE (b)(3)

ing. A gap-fired transverter-capacitor firing set and an electronic neutron generator are provided to initiate weapon detonation.

Los Alamos National Laboratory
Los Alamos, NM 87545

Abstract (U)

This report describes the B61-6,8 bombs in development as a part of the Stockpile Improvement Program. The bomb design, its ancillary and support equipment, and the planned test and evaluation program are presented.

Classified by D.N. Bray, Supervisor, B61-6,7,8/W61 Division 5111, March 3, 1989.

SECRET UNCLASSIFIED

Summary

The B61-6,8 is a factory retrofit of the B61-0,2,5, utilizing an IHE nuclear primary and enhanced electrical safety components. Use control, command disable, and improved operational flexibility features are also included. The B61-6,8 was designed to be compatible with all aircraft now approved for B61 carriage. Compatibility will only be demonstrated for those Navy aircraft listed in the MCs: A-4, A-6, A-7, F/A-18, and A-12 (when available). No known problems exist.

The B61-6,8 will be fielded to be compatible with aircraft employing AMACs without Intent Unique Signal (IUQS) generators through the employment of the MC3025 Signal Selector. The MC3025 will be removed from all bombs on or before 1 January, 2000. Only aircraft with IUQS-capable AMACs will be compatible after this time.

Significant design features of the B61-6,8 are as follows:

Physical:

Length	3597 mm (141.6 in.)
Diameter	338 mm (13.3 in.)
Weight	350 kg (770 lb)

Yields:

DOD/DOE b(3)

Delivery Options:

Freefall Airburst (FFA)
Freefall Groundburst (FFG)
Retarded Airburst (REA)
Retarded Groundburst, Laydown (REG)

Aircraft Delivery Constraints:

Certified to maximum aircraft capabilities

DOD/DOE b(3)

Safety:

Use of IHE for primary explosive
Primary is inherently one-point safe
Enhanced electrical safety to meet modern nuclear safety standards

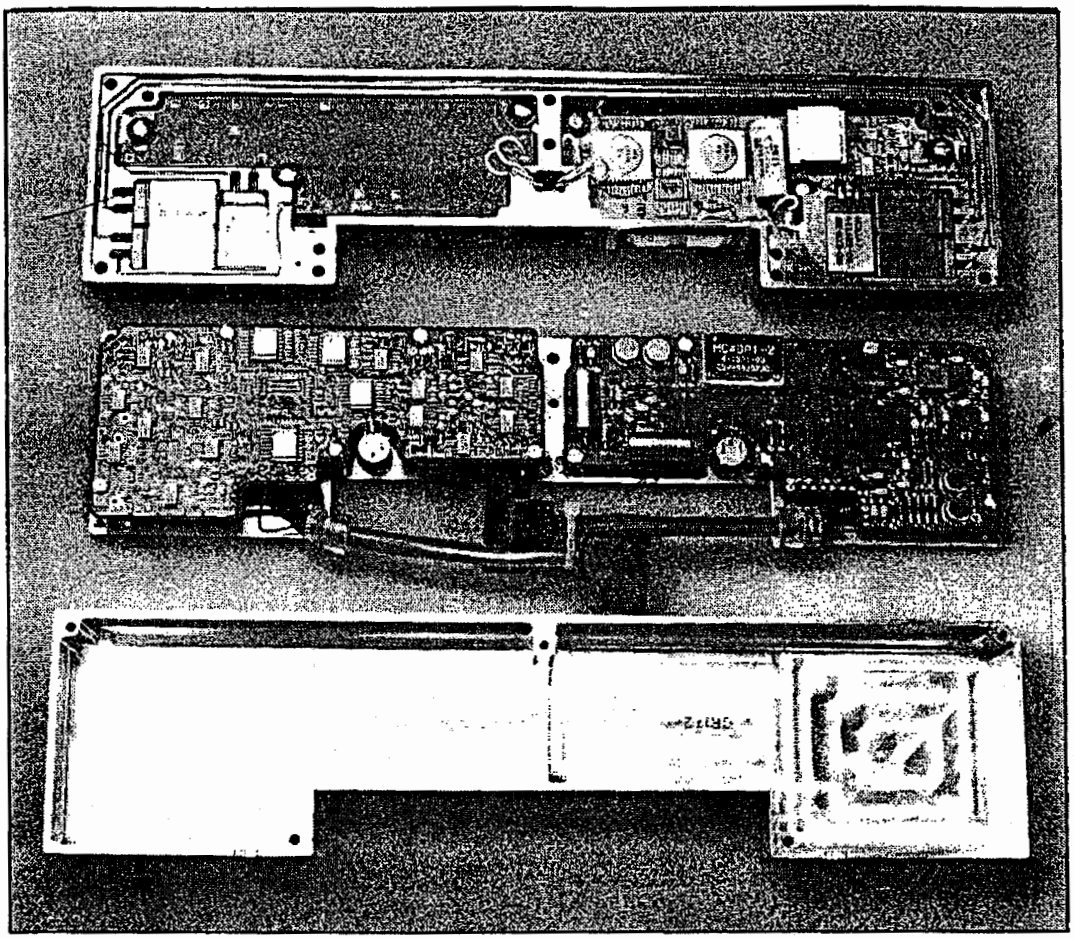
Use Control:

DOD b(3)

Limited Life Components:

DOD/DOE b(3)

Intrinsic Radiation:



DOD b(3)

MC4137 TSSG

The "intent-enabled" design of the MC4137 requires the MC4137 TSSG electronics to "store" the IUQS signal which enables (operates) the MC2969 Intent Strong Link Switch in the firing set during the prearming of the bomb before aircraft release. Until the MC2969 arming sequence is complete, the TUQS signal is not "stored" in the MC4137 electronics. Without the information content of the IUQS signal, the MC4137 cannot formulate the TUQS signal. The strong link/weak-link design and packaging of earlier B61 TSSGs is also retained. Additionally, the new MC4137 "intent-enabled" TSSG is philosophically improved over the earlier TSSGs designed for the B61. Discussion of the nuclear detonation safety of the two TSSG designs appears in Chapter 4.

Figure 18. MC4137 TSSG, Intent-enabled

During prearm of the bomb, the MC4137 TSSG will store the IUQS code in "volatile" memory; without power the code will not be retained. The design of the MC4137 will assure that the IUQS is retained for a minimum of 7 seconds of power loss. If all arming power and monitor power is lost for longer than 7 seconds, the MC4137 will interrupt the arm monitor line to the AMAC. On Navy System 1 aircraft (A-7E and F/A-18), this will result in both the "arm" light and the "safe" light being illuminated when power returns. On the FSA aircraft (A-4M, A-6E,G), the "disagreement" light will illuminate. A power dropout long enough to cause this condition will require the pilot to retransmit the IUQS to "rearm" the TSSG. Power dropouts of shorter duration will not affect the AMAC indications or cause additional pilot workload. The use of "volatile" memory for IUQS retention is a desirable nuclear safety design feature.

Although the B61-6,8 MCs only require compatibility with Navy strike aircraft, the MC4137 TSSG will be designed to be compatible with all aircraft approved for carriage of any B61. Additionally, all aircraft listed in the B90 MCs will be tested for compatibility during development. Demonstration of aircraft compatibility and subsequent incorporation in the B61 ACCD will be restricted to those listed in the MCs.

Whereas the MC4175 TSSG uses two identical, non-conductive assemblies to provide outputs to the two MC2935 Trajectory Strong Link Switches in the firing set, both channels of the MC4137 are packaged in a single conductive enclosure (Figure 18). The materials selected are 304 stainless steel for exclusion region protection and 6061 aluminum for the cover. The single housing is designed to maintain mechanical integrity of the housing, rolamites, and exclusion area electronics in abnormal environments. Isolation of all signals from the case is required.

The top assembly in Figure 18 is the exclusion region containing the rolamites, weak-link ROM, and the circuitry necessary to communicate the ROM pattern through the rolamite contacts to the microprocessor. The circuit board is ceramic. The circuit boards in the middle of figure 18 are identical, with surface mount components on one side (left) and leaded, "through-hole" components on the other. This circuitry is mounted to the steel top of the exclusion region and

SECRET
UNCLASSIFIED

d. Safe Separation Time (SST) Selection - Two independent SSTs, TA and TB are set on the preflight controller. Some AMACs can select between TA or TB. The ICU is designed to store and use this information.

After bomb release, the MC4140 is without power until the rise of the weapon system pulse batteries.

DoE/DoD b(3)

The remaining function of the ICU is to perform the timing and "gate" pulse battery power to initiate the spin rocket or gas generator. After the "deploy" function, the ICU tasks are complete and "shutdown" is commanded.

MC4136 Preflight Controller

DoE/DoD b(3)

The preflight controller also houses the DE1002 Coded Device and MC3246A Thermal Battery (identical to the MC3246[26] in the B61-7 except lithium-silicon/iron disulfide (Li(Si)/FeS_2) electrochemical system is used) for command disable, the J1 connector for PAL operations or interconnecting with the MC4142 Strike Enable Plug, and the PAL voltage regulator. The command disablement and PAL components are described in Chapter 6. The preflight controller is mounted to the preflight bomb subassembly case.

The switch markings and function associated with each switch position are as follows:

TA and TB - For non-laydown deliveries, two independent aircraft safe escape times (TA and TB) are selected. The selection of each requires the manipulation of two digital switches, one for the tens data (1-10) and one for units data (0-9). The maximum safe escape time for the B61 is 69 seconds; therefore, the 7, 8, 9, and 10 switch positions of the tens switch are shorted to the 6 switch deck. Thus, 109 becomes 69, 77 becomes 67, etc. No provision is made to prevent TB settings shorter than TA or vice versa. The selection of the appropriated safe escape time is made from the aircraft during bomb prearm.

Delivery - 2 position; RE,FF
RE - retarded
FF - freefall

Aircraft with FSA AMACs like the Navy A-6E can not override this switch. Arm position selections on the AMAC are limited to AIR and GROUND. System 1 AMACs like the Navy A-7 and A-18 can override this switch; all four delivery options are selectable from the cockpit.

Delay - 3 position; G, H, J

G — 0.3 second deployment delay
H — 0.6 second deployment delay
J — 1.6 second deployment delay

Additionally, positions G and H provide short laydown delay (30 seconds) and position J provides long laydown delay (80 seconds) for aircraft safe escape from laydown deliveries. Discussions at the B61 POM and the B61 Environmental Sugroup have recently addressed the use of "J" by Navy aircraft. Future B61 ACCDs may restrict the use of longer delay times than compatibility tests and analyses have shown to be sufficient to provide separation. No settings longer than the "minimum" times now specified in the ACCD will be approved.

3. System Operation

General

Preflight operations and arming, fuzing, and firing events for the four bomb delivery options are discussed in this chapter. A simplified functional block diagram (Figure 34) and pictorial event sequences for each bomb delivery option (Figures 35-38) are included. Those procedures and electrical system operations that are common to each delivery option are presented below.

Before takeoff, the appropriate switch settings are made on the MC4136 Preflight Controller as described in Chapter 2. At this time, the PAL could be unlocked through the J1 connector of the MC4136 with ground equipment (Chapter 6) or after takeoff if the aircraft is equipped with a PAL-capable AMAC. Complete bomb prearming cannot be accomplished until the PAL is unlocked (i.e., enabled). The MC4142 Strike Enable Plug would be installed. If the aircraft does not contain an IUQS-capable AMAC, the MC3025 Signal Selector must be rotated to the OVERRIDE position.

The bomb may now be prearmed before release by rotating the AMAC selector switch to the desired option position. On FSA/B AMACs, this selector switch provides two positions: air or ground. Retard or freefall is obtained by the delivery switch position on the preflight controller. On System I AMACs like the A-7E and F/A-18, the AMAC has four positions corresponding to the four delivery options: FFA, FFG, REA, and REG. With this capability, the RE/FF Delivery Switch on the MC4136 PFC is overridden.

The F/A-18 AMAC generates a unique train of pulses (IUQS) to drive the MC2969 Intent Stronglink Switch to the closed (enabled) position. Without the AMAC-produced IUQS, the MC2969 will be enabled by the MC3025 Signal

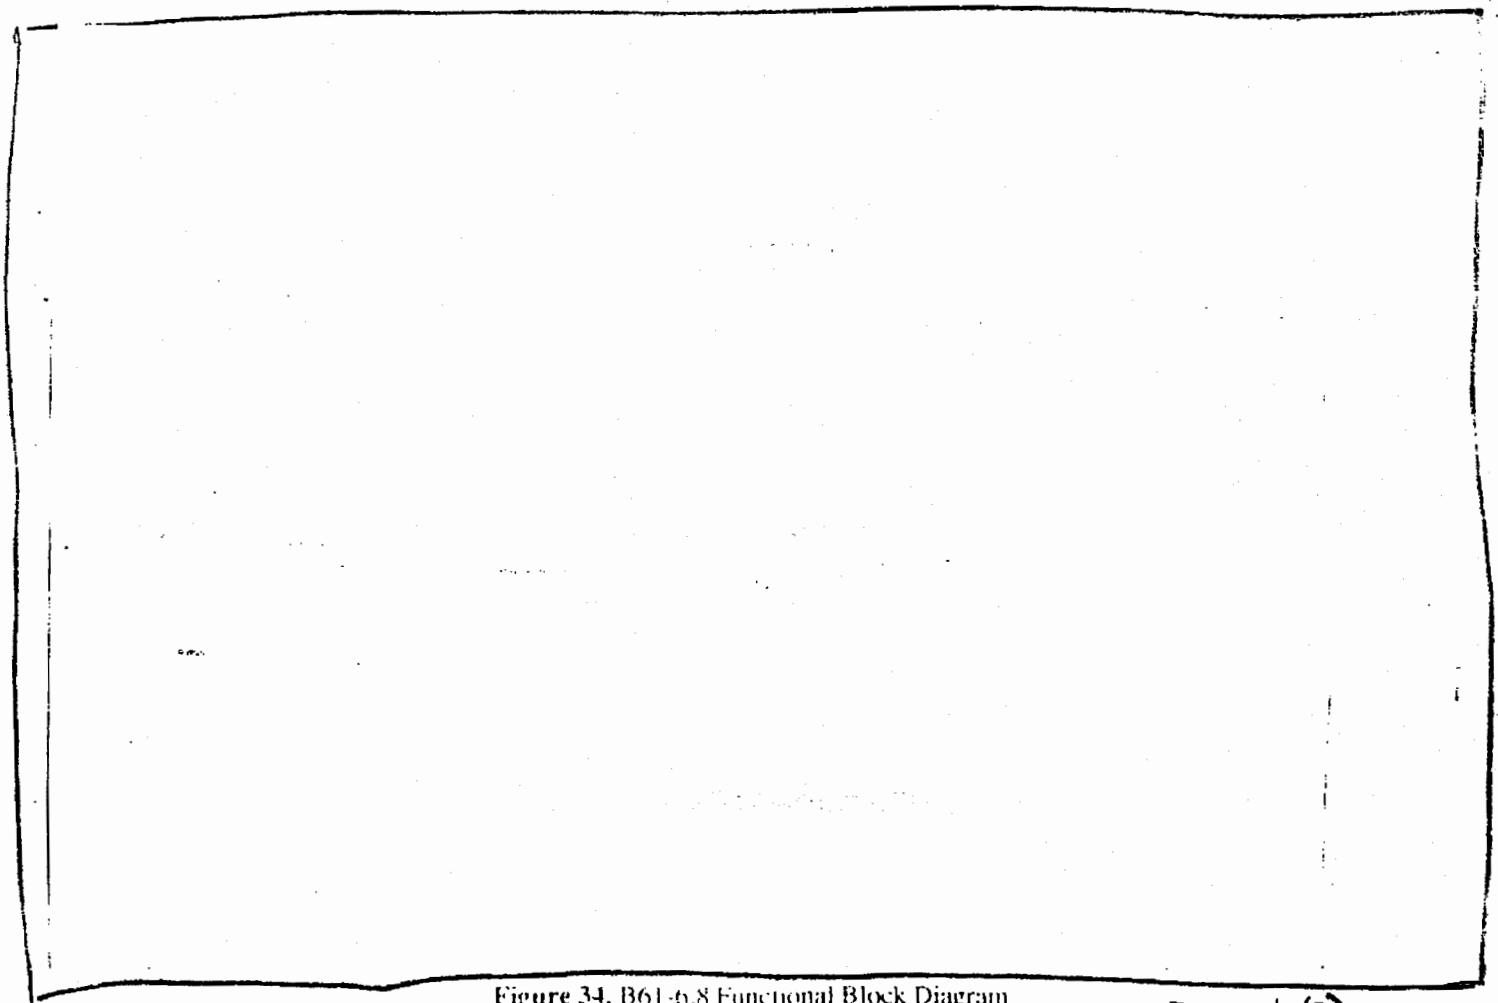

Figure 34. B61-6,8 Functional Block Diagram

DOE b(3)

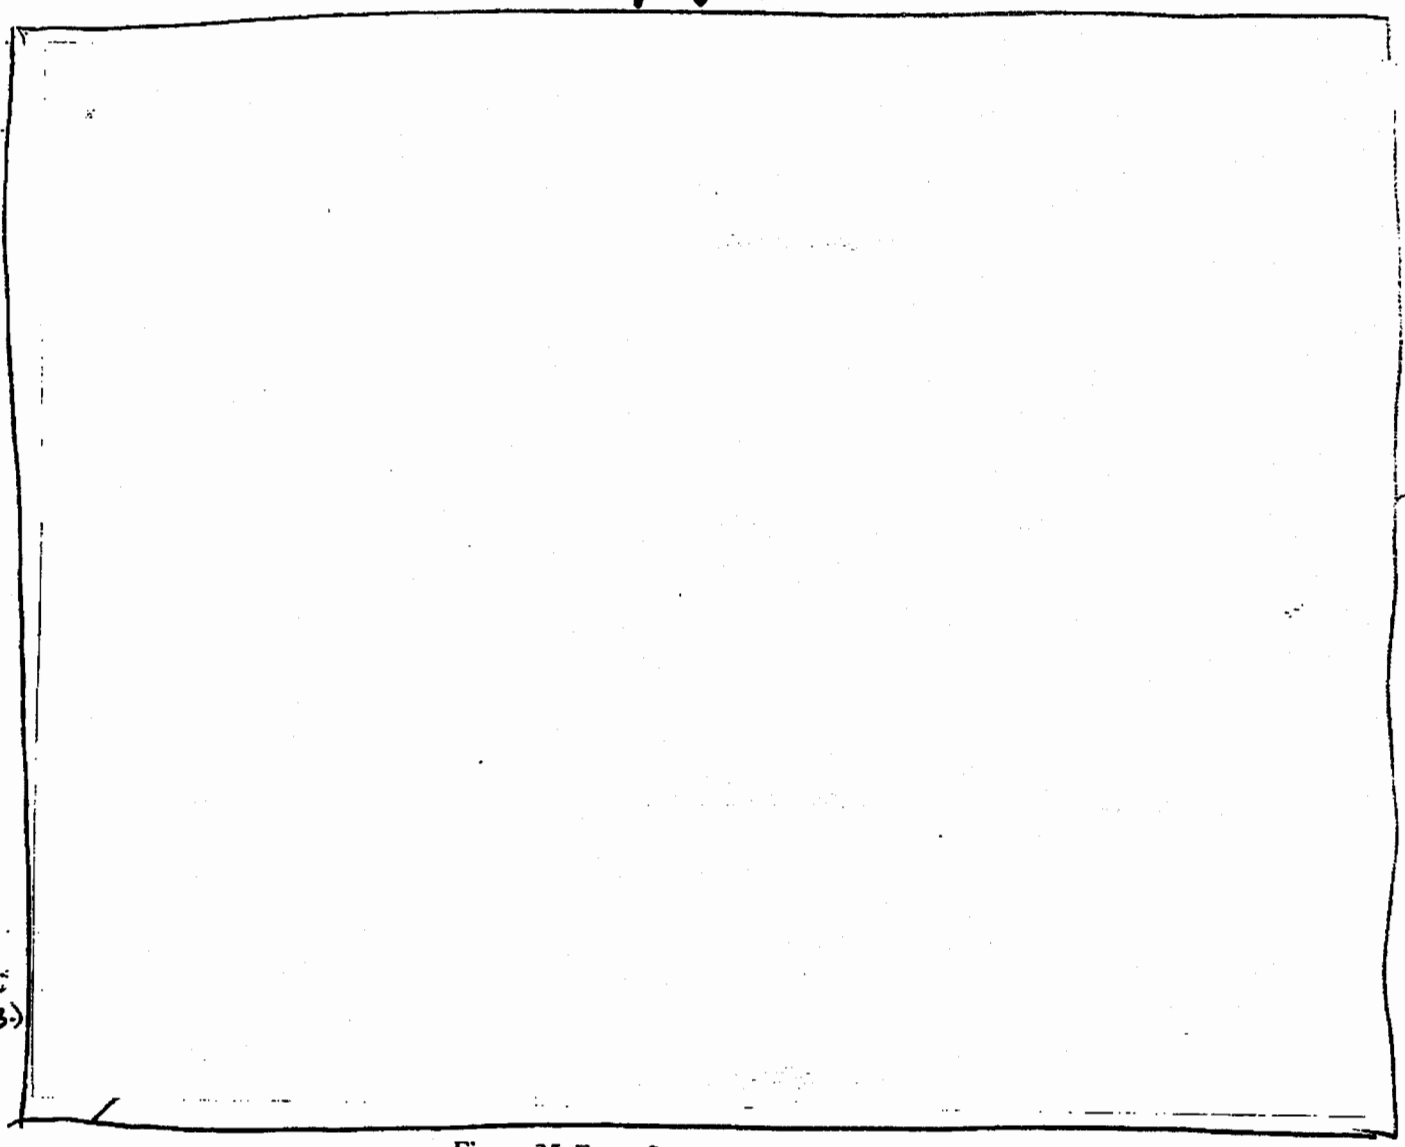

Figure 35. Event Sequence, Freefall Airburst

At safe separation time plus 1.5 seconds, programmer fire circuitry is enabled. Once this occurs, any subsequent radar fire signal will result in the programmer providing closure of the main battery to firing set (A3), causing X-unit discharge which initiates the neutron generator timing circuitry and fires the nuclear primary detonators.

If backup fuzing is selected, at SST plus 1.5 seconds the programmer will also accept impact crystal signals as valid fire signals. If neither radar nor crystal signal is received, the programmer will provide A3 at 120 seconds (design life of the main batteries). If backup fuzing is not desired, the programmer will not deliver A3 if impact crystal signal is received. Contact preclude is not guaranteed. If the bomb impacts the ground with a charged firing set, the X-unit may be triggered by the impact (bypassing the programmer), even if backup were not desired.

UNCLASSIFIED
SECRET

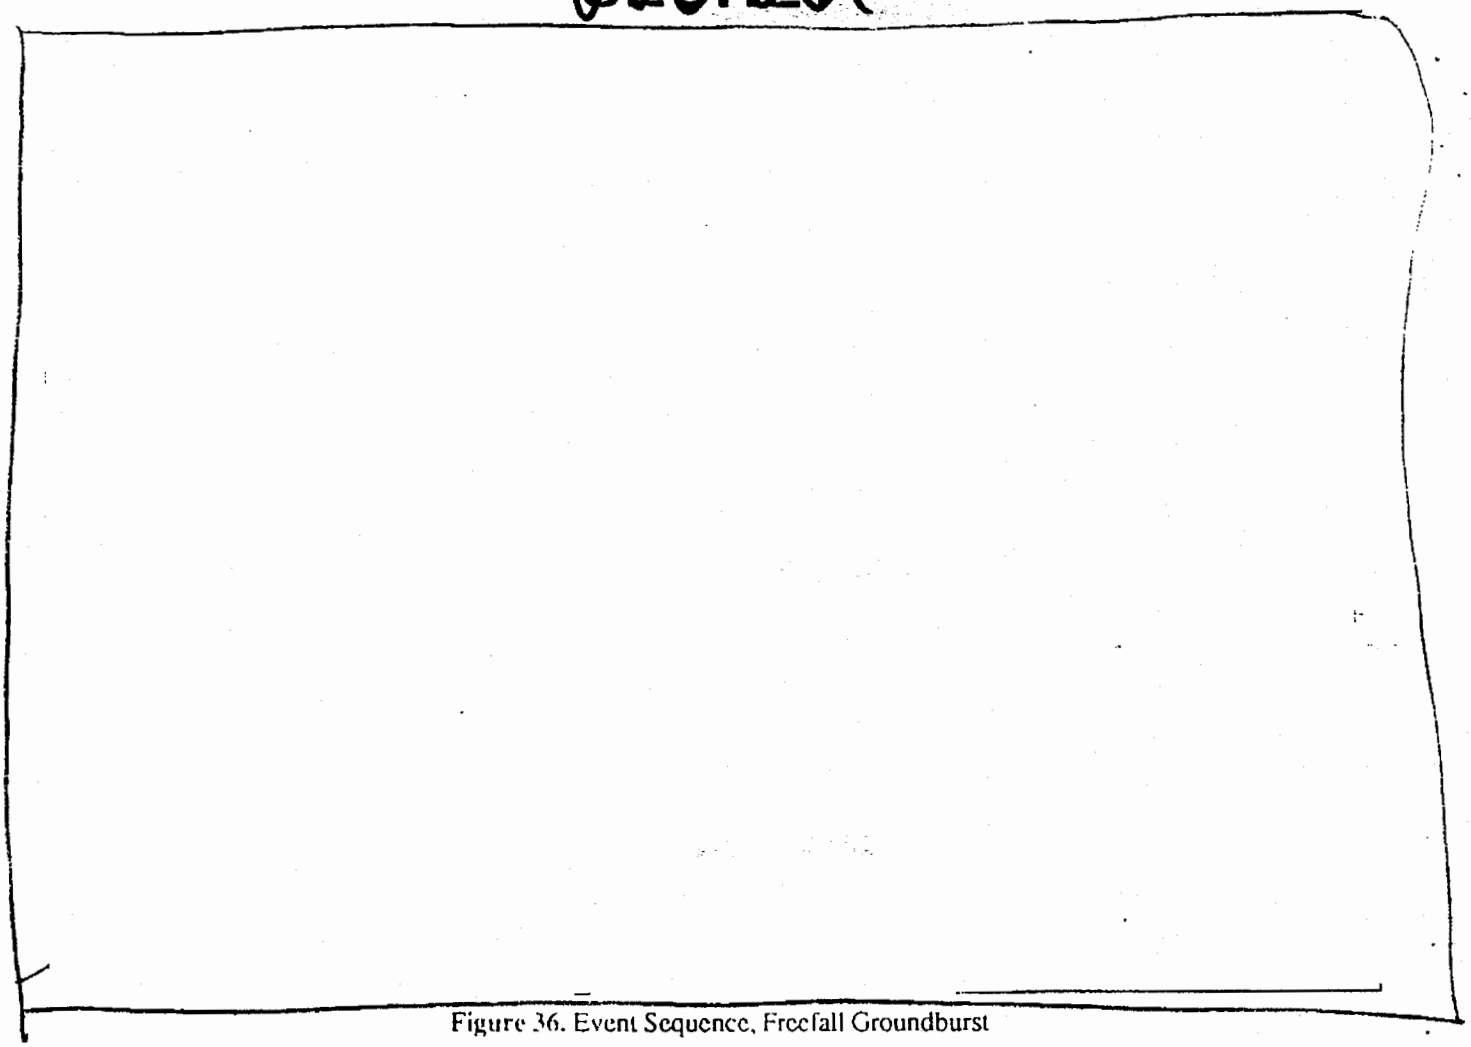

Figure 36. Event Sequence, Freefall Groundburst

Freefall Groundburst (FFG) Delivery

Upon initiation of the spin rocket, the bomb spins to a minimum roll rate of about 3 revolutions per second within about 1 second (Figure 36). The canted fins will sustain the roll rate. This roll rate closes the radial inertial switches (rolamites). At 3 seconds after release, the programmer "gates" main battery power to the MC4175 or MC4137TSSG to drive the MC2935 Trajectory Stronglink Switch in the firing set.

The aircraft-selected safe separation time (SST) has been previously communicated by the ICU to the programmer.

At safe separation time minus 3 seconds, the programmer connects main battery power to the transverter oscillator in the firing set (A1). At safe separation time, similar programmer circuitry connects main battery power to the firing set transverter (A2). With these two inputs, each electronic transverter can charge the 2.0- μF firing set X-unit capacitor and the 0.6-μF neutron generator capacitors to approximately 3300 V and 2400 V, respectively, in less than 1.2 seconds.

At safe separation time plus 1.5 seconds, programmer fire circuitry is enabled. Once this occurs, the subsequent crystal fire signal will result in the programmer providing closure of the main battery to the firing set (A3), causing X-unit discharge which initiates the neutron generator timing circuitry and fires the nuclear primary detonators.

SECRET
UNCLASSIFIED

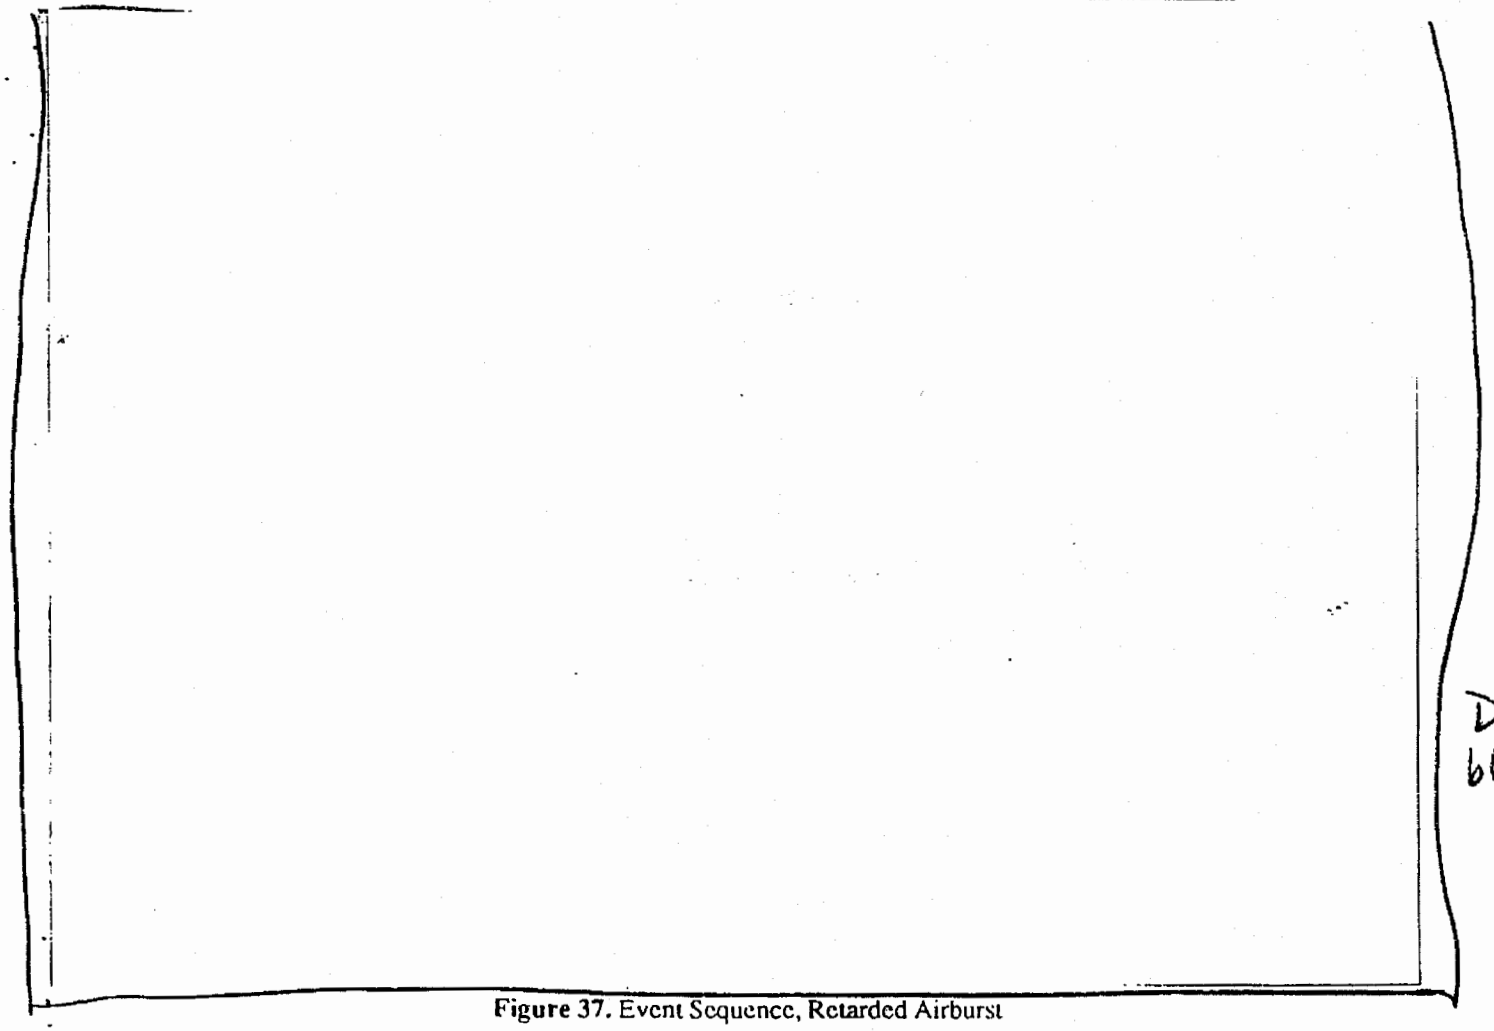

Figure 37. Event Sequence, Retarded Airburst

Retarded Airburst (REA) Delivery

Firing the gas generator into the volume enclosed by the telescoping tubes starts the parachute deployment process (Figure 37). The deceleration produced by the deployed parachute closes the longitudinal nonlatching inertial switch (rolamite). The design of the rolamite guarantees a closure time greater than the maximum required (0.734 seconds) for the MC4175 or MC4137 TSSG to enable the MC2935 Trajectory Stronglink Switch in the firing set.

The aircraft-selected safe separation time (SST) has been previously communicated by the ICU to the programmer. At 7 seconds before SST, the programmer "gates" main battery power to the radar and at 4 seconds before SST, the programmer activates circuitry to communicate height of burst selection to the radar.

[redacted]

At safe separation time minus 3 seconds, the programmer connects main battery power to the transverter oscillator in the firing set (A1). At safe separation time, similar programmer circuitry connects main battery power to the firing set transverter (A2). With these two inputs, each electronic transverter can charge the 2.0- μF firing set X-unit capacitor and the 0.6-μF neutron generator capacitors to approximately 3300 V and 2400 V, respectively, in less than 1.2 seconds.

If backup fuzing is selected, at SST plus 1.5 seconds the programmer will accept either a radar fire or impact crystal signal as a valid fire signal. Activation of the impact crystal at parachute-retarded terminal velocities (80 fps) will not be reliable in all terrain. If neither radar nor crystal signal is received, the programmer will provide A3 at 120 seconds (design life of the main battery).

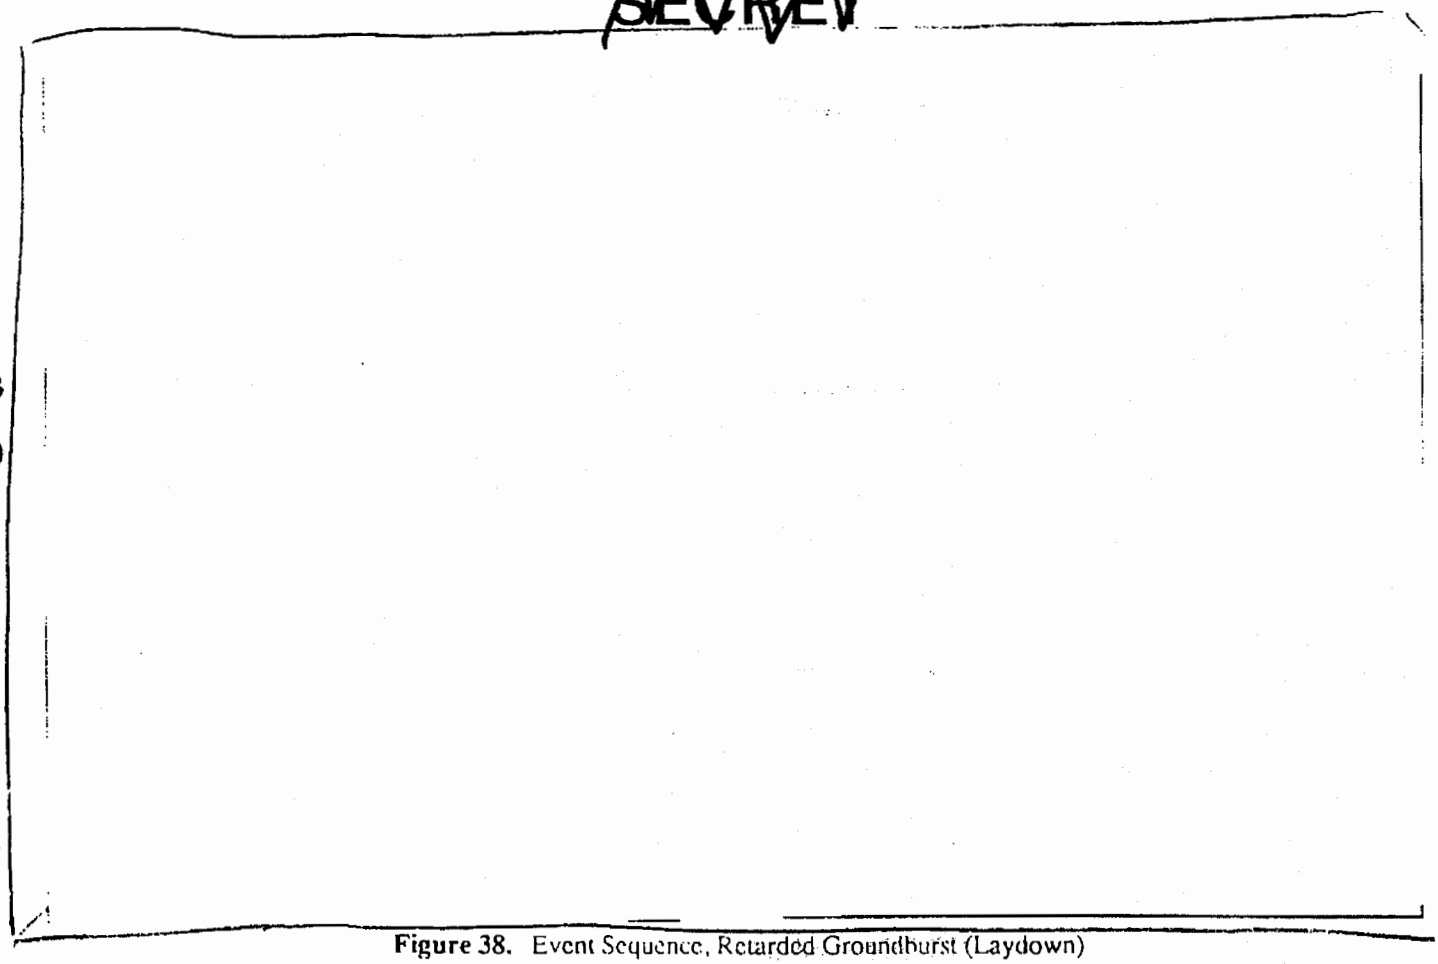

Figure 38. Event Sequence, Retarded Groundburst (Laydown)

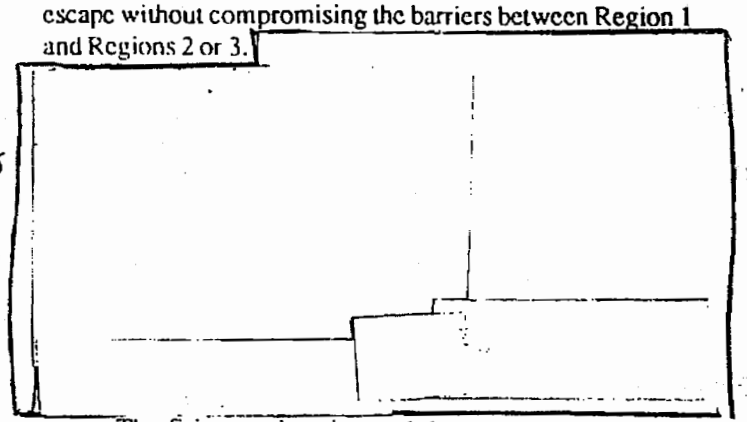
Retarded Groundburst (REG) or Laydown Delivery



Firing the gas generator into the volume enclosed by the telescoping tubes starts the parachute deployment process (Figure 38). The deceleration produced by the deployed parachute closes the longitudinal nonlatching inertial switch (rolamite). The design of the rolamite guarantees a closure time greater than the maximum required (0.734 seconds) for the MC4175 or MC4137 TSSG to enable the MC2935 Trajectory Stronglink Switch in the firing set.

For the laydown delivery mode, the safe separation times selected on the preflight controller do not apply. Aircraft safe escape maneuvers are instead constrained by the laydown delay time, which is 30 seconds or 80 seconds. Selection of G or H deploy time results in a 30-second delay, whereas J provides an 80-second delay. As discussed earlier, selection of J may be restricted in the B61 ACCD except for aircraft requiring that time to ensure safe escape.

At safe separation time minus 3 seconds, the programmer connects main battery power to the transverter oscillator in the firing set (A1). At safe separation time, similar programmer circuitry connects main battery power to the firing set transverter (A2). With these two inputs, each electronic transverter can charge the 2.0- μF firing set X-unit capacitor and the 0.6-μF neutron generator capacitors to approximately 3300 V and 2400 V, respectively, in less than 1.2 seconds.

At safe separation time plus 1.5 seconds, the programmer will provide closure of the main battery to firing set (A3), causing X-unit discharge which initiates the neutron generator timing circuitry and fires the nuclear primary detonators.

As shown in Figure 39, the sealed covers of Region 1 of the firing set are not on the same surface as the covers for Regions 2 and 3. This allows hot and possibly conductive gases generated in Region 1 by an abnormal environment to escape without compromising the barriers between Region 1 and Regions 2 or 3.

DOE
b(3)

The firing set housing and detonator cable cover is fabricated from fiberglass-reinforced, compression-molded MXB-71. MXB-71 is fire-resistant with excellent dielectric strength properties for temperatures up to 500°C. The openings in the barriers for the functional stronglink switch contacts and necessary openings into Regions 2 and 3 for test or reset of the MC2935s are sealed with high-temperature silicone. The metal mounting screws for the stronglink switches are through the container wall and are similarly closed from the exterior of the firing set by plugs of MXB-71 sealed with the same silicone.

To assure protection of the firing set exclusion regions by the stronglink switches, the contact assembly of each switch is constructed of metal and ceramic parts. The free volume is minimized to avoid bridging between input and output contacts by unintended conductive paths during abnormal thermal and crush environments. The switch housings are made of high-strength stainless steel to resist deformation in crush environments. The MC2969 and MC2935 can each withstand at least 1600 V dc at temperatures up to 400°C. Both switches contain discriminator mechanisms that, upon receiving an incorrect input signal, lock the switch in the open position. The MC2969 is resettable, requiring a pulse of correct length and amplitude to return the discriminator mechanism to its initial state. To be reset, the MC2935 requires both a manual release and a specific electrical signal input. Because physical access to the firing set is required, this procedure can only be done at a DOE manufacturing facility.

MC Requirements

Normal Environments

The B61-6,8 military characteristics state:

"The probability (per bomb lifetime) of a premature nuclear detonation for the normal environments described in the STS shall not exceed:

1. Prior to prearm (which includes application of the arming power and the unique intent enabling stimulus) and prior to release from the aircraft and in the absence of the trajectory stimulus, 1×10^{-9}.
2. After prearm and prior to release from the aircraft, and in the absence of trajectory stimulus, 1×10^{-6}.
3. After prearm and after release from the aircraft, and in the absence of the trajectory stimulus, 1×10^{-3}.

The probability (per occurrence) of a nuclear detonation in the normal release envelope after receipt of the trajectory stimulus shall not exceed:

1. Prior to expiration of the safe separation time, 1×10^{-3}.
2. After expiration of the safe separation time and prior to the intended detonation, 1×10^{-2}."

Abnormal Environments

The military characteristics for the B61-6,8 state:

"The probability (per occurrence) of a nuclear detonation of a bomb for individual or credible combinations of abnormal environments specified in the STS shall not exceed:

1. In the absence of any unique intent and trajectory stimuli, 1×10^{-6}.
2. After receipt of the unique intent and in the absence of the trajectory stimulus, 1×10^{-3}.
3. Placing the normal/override switch in the override position shall be considered intent enabling stimulus."

Safety Subsystems

Fault tree analysis techniques are useful for defining and evaluating the nuclear safety design of the bomb system. Figures 40 through 43 are abbreviated examples of fault trees. These figures illustrate the three safety subsystems incorporated in the B61-6,8 to meet nuclear detonation safety requirements in normal and abnormal environments. Both DOE (Sandia, Los Alamos, and production agencies) and DoD requirements are addressed.

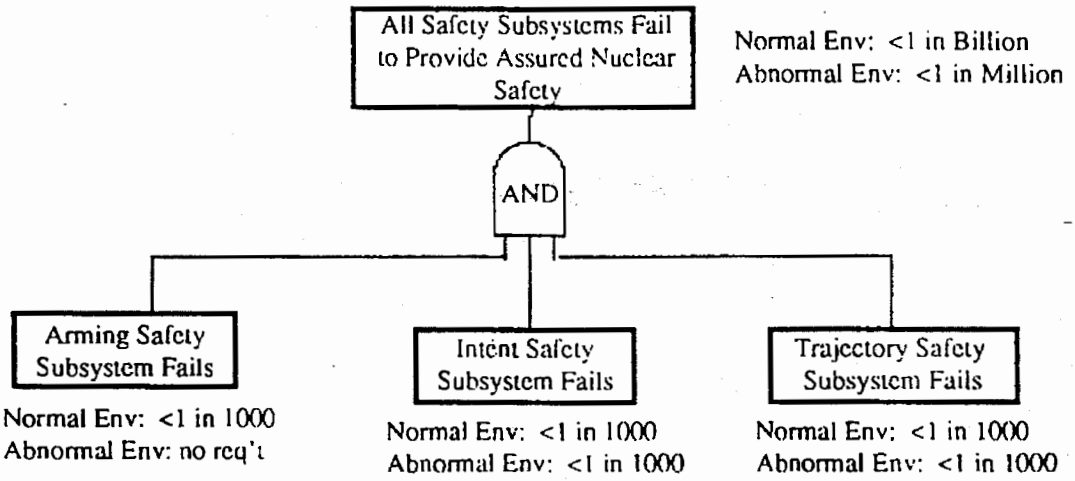


Figure 40. Fault Tree, Loss of Electrical System Safety

UNCLASSIFIED
SECRET

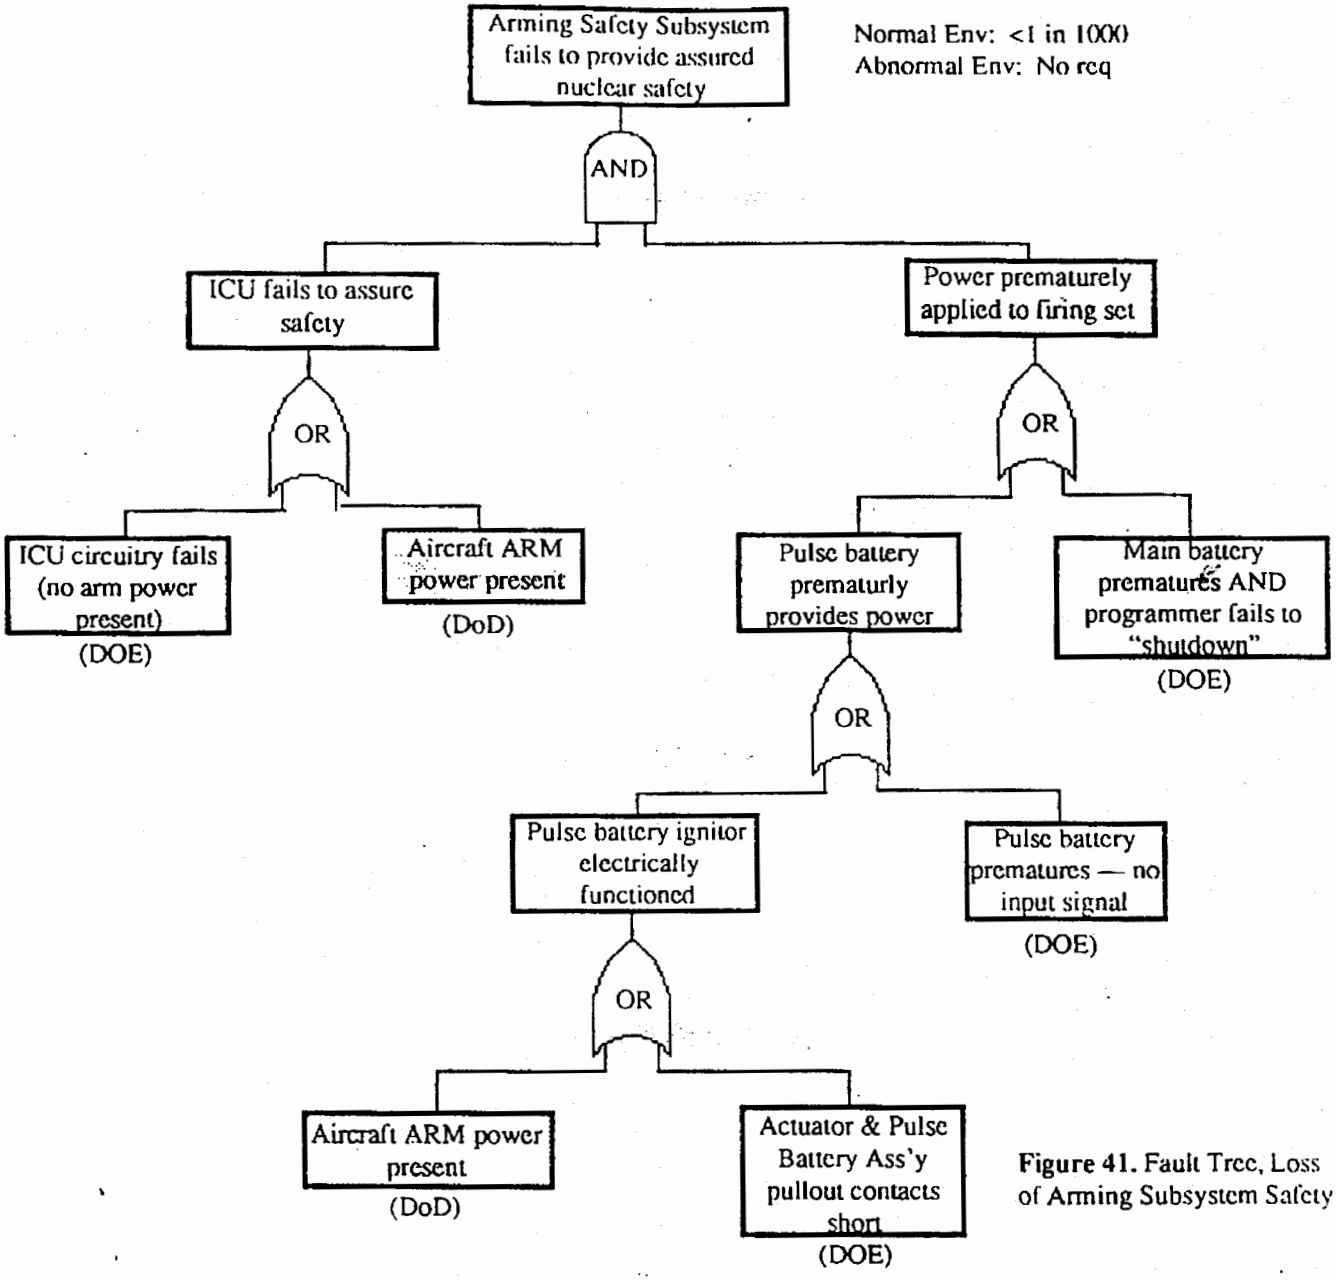

Figure 41. Fault Tree, Loss of Arming Subsystem Safety

Arming Safety Subsystem

The arming subsystem, when combined with the intent and trajectory subsystems, provides the additional 1×10^{-3} nuclear detonation safety to achieve the MC requirements in normal environments. No abnormal-environment nuclear detonation safety requirements are placed on this subsystem. This subsystem prevents the application of normal environment aircraft and bomb electrical system signals to critical circuits. Electrical signals at the bomb umbilical and preflight controller connectors are restricted to prescribed PAL or stronglink monitor signals from the aircraft or T-gear.

The component assemblies included in the arming subsystem are the MC2213(A) Actuator and Pulse Battery Assembly, the MC2238A/B Pulse Batteries, the MC3656 Main Batteries, MC4138 Programmer, and the MC4140 ICU. The delivery option selection circuitry and the ICU software provide positive control of the output of the pulse batteries. Premature actuation of a pulse battery will result in system "shutdown" without the required aircraft delivery option voltage being present. Premature of the main battery will similarly result in system "shutdown" by the programmer. Both premature actuation of the pulse battery and aircraft prearm power must occur for the ICU and programmer to function in the intended use mode. For the arming safety subsystem, the DoD must insure that prearm dc-power is not applied to the umbilical connector. The DOE will insure the components involved meet the design requirements.

SECRET
UNCLASSIFIED

Intent Safety Subsystem

As shown in figure 42, both the DoD and DOE must meet requirements for the Intent Safety Subsystem to provide assured nuclear detonation safety. The DOE must assure that the MC2969 ISLS in the firing set meets the isolation requirements and is only enabled upon the application of the IUQS. The DoD must assure that the IUQS signal is not generated prematurely due either to inadvertent or inappropriate human action or hardware malfunction of the IUQS generator in the AMAC. Both DOE and DoD must meet these requirements in the event of an abnormal environment.

If the MC3025 Signal Selector is in the OVERRIDE position, there are no requirements of the intent safety subsystem to provide protection in an abnormal environment. With the selector in OVERRIDE, the bomb will meet only a 1×10^{-3} probability of a nuclear detonation in an abnormal environment. Additionally, 1×10^{-3} probability of a nuclear detonation can only be met in the "absence of the trajectory stimulus."

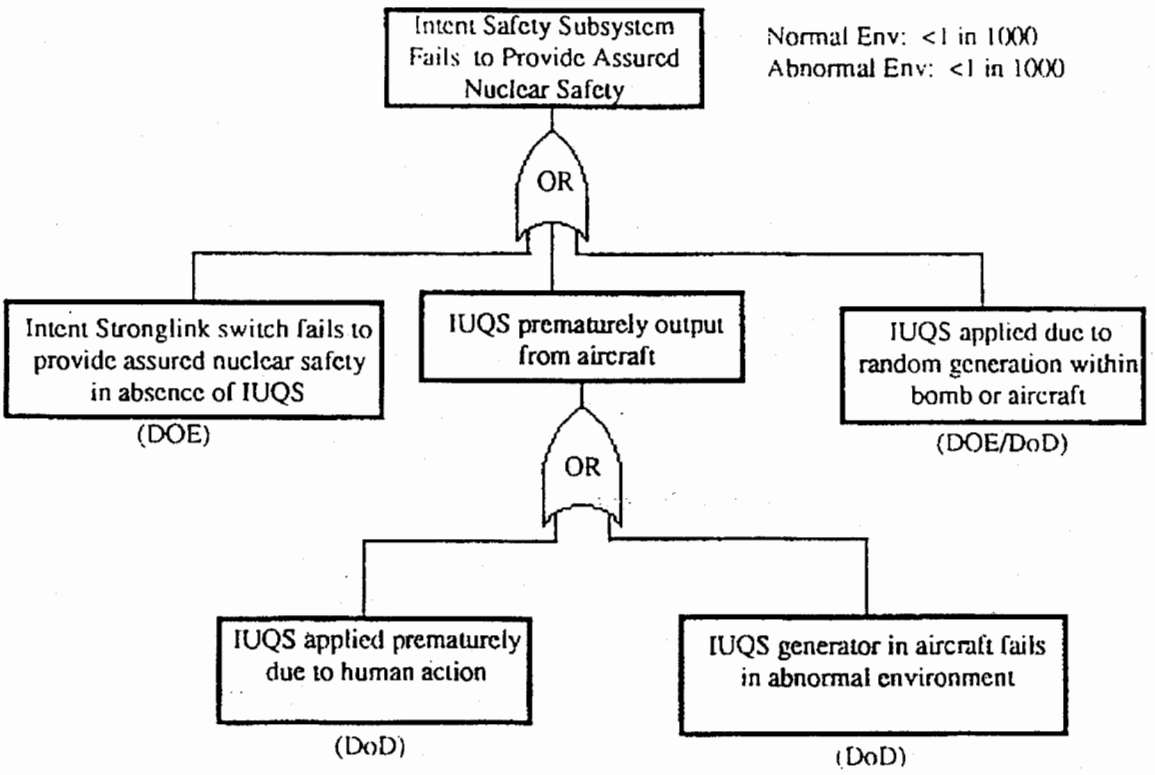

Figure 42. Fault Tree, Loss of Intent Subsystem Safety

UNCLASSIFIED
SECRET

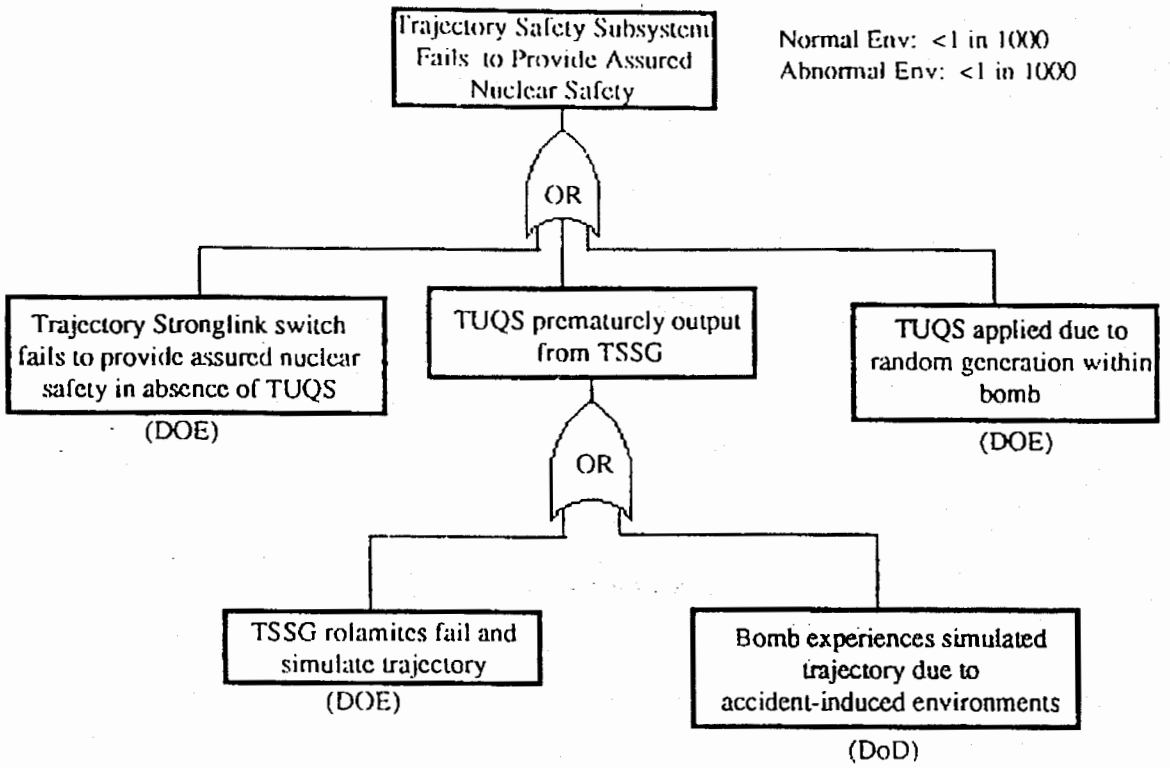

Figure 43. Fault Tree, Loss of Trajectory Subsystem Safety

Trajectory Safety Subsystem

Of the three nuclear safety subsystems, arming, intent, and trajectory, only the trajectory safety subsystem is composed entirely of DOE hardware. The DoD responsibility is to assure that no accidental simulation of the "intended use" environment (retardation or spin) occurs. Major components within this safety subsystem are the MC4175 TSSG or the MC4137 TSSG and the MC2935 Trajectory Strong-Link Switch in the firing set. The MC4175 TSSG is identical to the MC3640 TSSG (B61-7) except for a connector change and will support B61-6 production for the first six months until the MC4137 TSSG is available.

MC4175

The MC4175 TSSG is a second-generation design of trajectory sensing devices incorporated into B61 bombs to enable (close) the MC2935. In the mid-70's, the MC2948 TSSG was designed for first use in the B61-5 and was later used on the B61-3,4. Both the MC2948 TSSG and MC4175 TSSG use "stronglink/weak-link" design philosophy to achieve nuclear safety in abnormal environments. The normally open, acceleration-sensing rolamite switches (stronglinks) interrupt electrical power from the TSSG electronics that generate the trajectory unique signal (TUQS). The application of power through the inertial rolamite switches to the electronics will produce the TUQS to drive the MC2935. Thus the design theme requires that the TSSG rolamite switches (stronglinks) be capable of surviving, without shorting, higher levels of shock or temperatures produced by an accident environment than the TUQS-producing electronics/ceramic circuit board (weak-link). Failure of the stronglinks in severe environments is acceptable, but only if the weak-link also fails irreversibly.

Figure 44 is a simplified block diagram of the trajectory safety subsystem with the MC4175 TSSG which illustrates the electrical connection for both the parachute retarded and spin-stabilized freefall delivery modes of the bomb. Functional contacts of the MC2969 Intent Strong-Link Switch are required to be closed before the TUQS can drive the MC2935. Both the intent and trajectory safety subsystems are designed to meet a goal of 10^{-3} given an abnormal environment; each is considered to be independent and no contribution to the trajectory safety subsystem because of the interruption of the MC2935 drive lines by the MC2969 is assumed. In the spin-stabilized bomb delivery mode, one radially oriented rolamite switch in each of the two TSSGs must close before the series circuit is closed between the bomb power source and the TUQS-producing electronics. The two MC4175 TSSGs are mounted opposed to each other equidistance from the

SECRET
UNCLASSIFIED

UNCLASSIFIED
SECRET

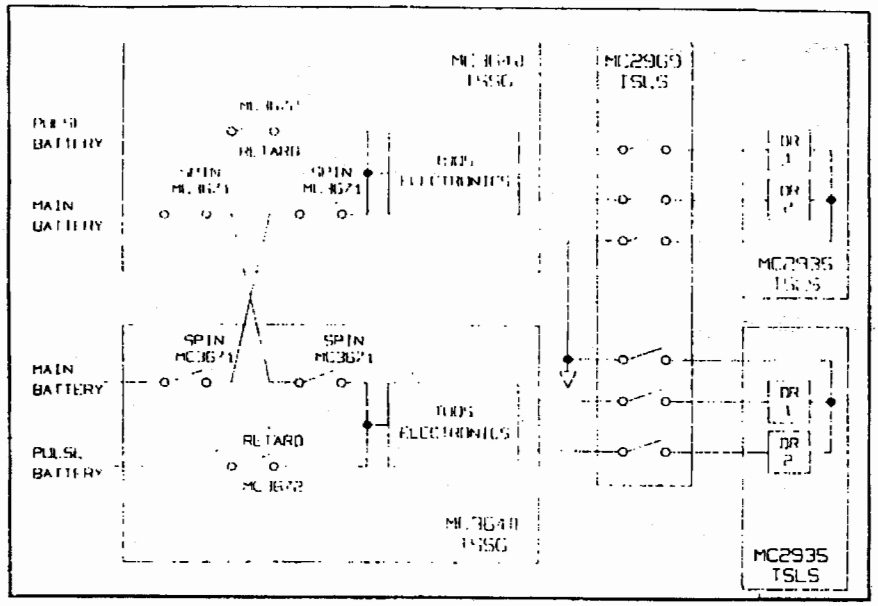

Figure 44. Block Diagram, Trajectory Safety Subsystem with MC4175 TSSG

bomb's longitudinal center line so that a radial acceleration or deceleration may cause both of the radially-mounted rolamites in one TSSG to close, but the spin rolamites in the opposite TSSG will remain reset. Spinning of the bomb is required to close all four spin rolamites.

Numerous shock tests of the MC3671 (spin) and the MC3672 (retard) rolamites have revealed the MC3671 to be most susceptible to shock: 4000g, 1ms when the direction of the shock causes the rollers to travel from the reset end (resting end) to the actuate end. The heavier rollers of the MC3671 travel to the actuate end with sufficient velocity/energy to separate the end cap from the case. In all other directions the MC3671 is 6000g's or greater, as is the MC3672 in all directions, including the actuate direction.

By design, the ceramic printed wiring board for the TUQS electronics is the weak-link for the MC4175 TSSG in the shock environment. The two-sided bonding of the DAP rolamites to the mica housing of the MC4175 TSSG insures minimum failure levels of approximately 6000g's. Whereas shocks perpendicular to the ceramic board result in breakage at as low as 330g, shocks in the plane of the board do not result in predictable failures (fracture). Abnormal environment testing of the ceramic boards have shown boards to survive ~7000g's in the plane of the board (undesirable since the stronglink rolamites can fail at lower levels). However in no system test nor component-level testing of complete MC3640 TSSGs for the B61-7 did there exist an "unsafe" condition. Some abnormal environment tests have resulted in damaged rolamites and/or lack of adhesion to the exclusion region barrier and an undamaged circuit board, but none exhibited a short circuit that could transmit power to the electronics. With the actuate contacts on one end of the rolamite, bypass requires the band or roller to remain at the actuate end. None of the damaged rolamites exhibited a potential for that condition.

Two polycarbonate capacitors, essential components for the generation of the TUQS, are used as the thermal weak-link. Both the DAP rolamite and the glass-bonded mica housing of the MC4175 TSSG retain excellent electrical insulative properties to the structural limit of the materials in high thermal environments. With a repeatable and irreversible failure temperature of 350° to 400°F, the polycarbonate capacitors will fail long before bypass of the rolamites or the housing is possible.

It is important to note that "trajectory sensing" implies the parachute was deployed and the resultant retardation forces were sufficient to close the rolamite switch or the bomb spin rate is adequate to close similar, radially oriented rolamite switches. No discrimination capability between an "intended use" and a "trajectory" resulting from an accident is possible. Any airborne accident can result in damage to the bomb tail section and resultant parachute deployment or adequate spin rates developing due to the bomb fin cant necessary to maintain roll rate for accuracy in freefall deliveries.

MC4137 TSSG

Where the MC4175 depends solely on the stronglink/weak-link design philosophy, the MC4137 also incorporates "intent-enablement" as a safety enhancement. The "intent-enabled" design of the MC4137 requires the MC4137 TSSG electronics to "store" the IUQS signal which enables the MC2969 Intent Strong Link Switch in the firing set during the prearming of the bomb before aircraft release. The TUQS signal is not "stored" in the MC4137 electronics. Without the information content of the IUQS signal, the MC4137 cannot formulate the TUQS signal. The strong link/weak-link packaging of the TSSG is also retained since the "intent-enablement" is a nuclear safety "enhancement." The trajectory safety subsystem is required to provide 1×10^{-3} protection in abnormal and normal environments requiring independence of the three safety subsystems. The strong link/weak-link packaging of the TSSG will be addressed during development as rigorously as would be required if the TUQS were "stored."

To improve the packaging for abnormal environments, both channels of the MC4137 are packaged in a single steel/aluminum enclosure (Figures 18 and 45). Conductive housing and barriers of steel are used to maintain mechanical integrity in abnormal environments. The steel housing, exclusion region barriers, and rolamites are electrically conductive and designed to divert unintended, accident-induced energy to ground. Isolation of all signals from the case is required in normal environments for reliability.

UNCLASSIFIED
SECRET

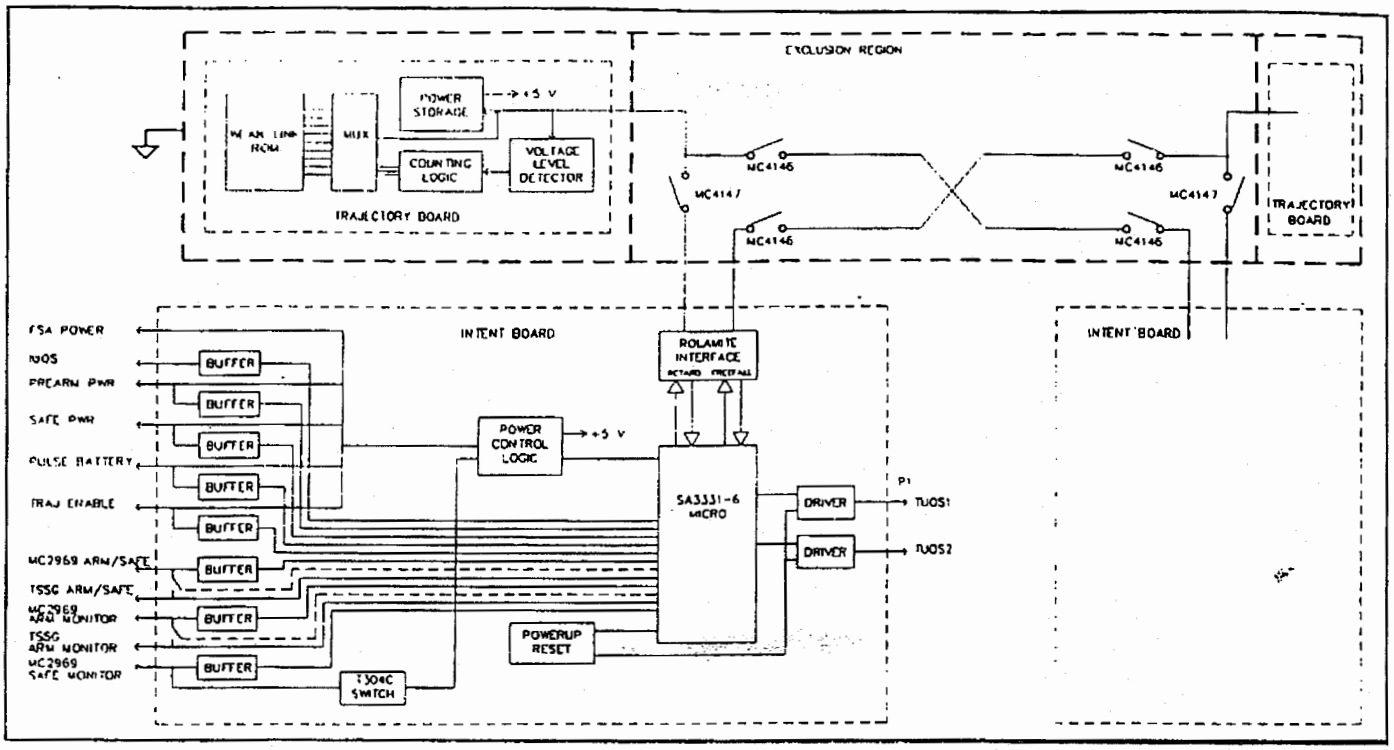

Figure 45. Block Diagram, Trajectory Safety Subsystem with MC4137 TSSG

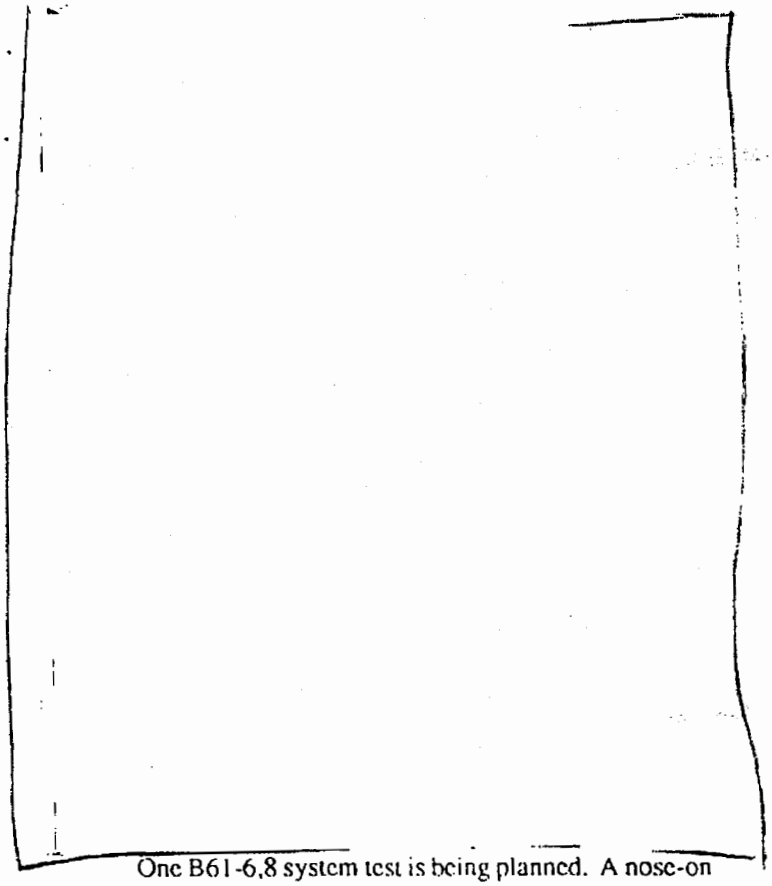

Both of the new rolamites in development (MC4146 to sense bomb spin and MC4147 for retarded drops) are steel-case, hermetically sealed assemblies. As in the MC4175, there are two spin rolamites per channel connected in series, diametrically opposed in the bomb to require true spin of the bomb. Previous rolamite designs have been constructed of insulative materials with the conductive band as the signal (power) path between the actuate contacts. The new rolamites are designed for increased ruggedness and predictability in abnormal high shock environments. The steel rolamites and TSSG housing (exclusion region barrier) will each incorporate mechanical mounting features that will insure integrity of the rolamite/barrier union through all abnormal environments. This design will result in the rolamite case electrically grounded to the housing (system ground). Therefore the contact block in the roller is required to be isolated from the roller and the band. The required electrical path is through the pins and the contact block (see Chapter 2).

In the block diagram (Figure 45) shown above, the exclusion region encompasses the rolamites, weak-link ROM, and circuitry necessary to interface with the SA3331-6 microprocessor. Each "intent board" is packaged outside the exclusion region and contains the aircraft interface circuitry, microprocessor, and TUQS drive circuits. To format the TUQS signal, each independent channel of the MC4137 TSSG (an intent board and a trajectory board plus three rolamites) will combine the information from the IUQS signal stored in the microprocessor with 24 bits stored in a thermal weak-link ROM (read only memory). Low melt alloy loops on a printed circuit board (Figure18) form the 24 bits of the weak-link ROM. Melting of the "loops" in high temperatures from abnormal environments will result in either opening or shorting to the board. Either alternative is "safe"; combining with the IUQS signal would lock up the MC2935 TSLS. Early thermal testing of the TSSG has recently led to redesign of the housing and weak-link ROM to mount the ROM to the outer wall of housing. An instrumented unit with representative rolamites and housing indicated the weak-link ROM would reach guaranteed failure temperature as the rolamite temperature was approaching its design temperature limit of 500°F, with the ROM mounted on the ceramic board. Mounting of the ROM near the outer TSSG wall resulted in considerable margin.

An additional nuclear safety enhancement achieved in the design of the MC4137 TSSG is the use of "volatile" memory (without power the IUQS code will be lost) to store the IUQS code during the prearm of the bomb. A permanent memory ("non-volatile") would require certification of the erasure of the IUQS after in-process, acceptance, and system level testing. On a "first principles" basis, the incorporation of the "volatile" memory is most attractive and defensible from a nuclear detonation safety standpoint. Capacitive "hold up" energy storage in the MC4137 will assure that the IUQS is retained for a minimum of 7 seconds in the event of an intermittent aircraft power dropout. If all arming power and monitor power is lost for longer than 7 seconds minimum

UNCLASSIFIED
SECRET

One B61-6,8 system test is being planned. A nose-on impact test at a velocity (to be determined) greater than the last B61-7 test (328 fps) and less than 492 fps will be conducted to confirm the extrapolations made on the B61-7 test. This test unit may also be used to investigate the effect of combined abnormal environments (thermal followed by impact).

Of the new components in development to support the B61-6,8, only the MC4137 TSSG has abnormal environment requirements. The weak-link ROM will be characterized in shock on both component-level testing and system tests where appropriate.

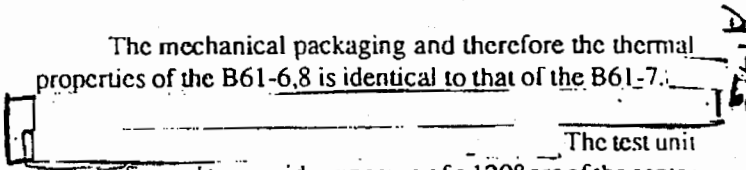
Crushing

This environment is a semi-static situation where, for example, during an accident a structural member of the aircraft comes to rest on the weapon case.

Design Theme. The MC2969 and MC2935 stronglink switches are required to hold off any energy reaching the fire set in this environment. With the structural properties of the thick aluminum center case and the steel support sleeve serving to protect the exclusion region from direct exposure to the outside world in any credible static crush abnormal environment, no weak-link needs to be identified.

Response Analysis/Tests. Tests conducted on the B61-5 and the B61-3,4, each with the identical center case (but with different support sleeve designs), showed almost linear deformation with applied load until case rupture at 305,000 lbs and 335,000 lbs, respectively. In each test, loading was applied through a rigid 2-inch bar placed perpendicular to the longitudinal axis of the bomb over the firing set. In accident possibilities for the B61-6,8, the forces necessary to rupture the center case do not exist. For example, a fully loaded B-52 weighing about 500,000 lbs could rest at most one-half or 250,000 lbs on a B61-6,8. Maintaining the integrity of the center case, with the stronglinks ensuring electrical isolation to the practical limit of the environment, assures meeting the 1 in 10^6 safety requirement.

Thermal



Complete or partial bomb engulfment by a JP-series kerosene (jet fuel) fire is possible. Fuel supplies are assumed to be sufficient to allow all processes to run to completion.

Design Theme. In abnormal thermal environments, predictable nuclear safety is accomplished by stronglink/weak-link colocation within an exclusion region whose barriers primarily consist of a high-temperature insulation material, MXB-71, and ceramic dielectric in the stronglink switches. The applicable weak-links are the X-unit capacitor and the nuclear system high explosive and detonators.

Response Analysis/Tests. Tests demonstrating safe response in abnormal thermal environments conducted during the B61-3,4 program included the following:

- High-temperature tests on switches and barriers up to 1000°F
- High-temperature tests on weak-links (capacitors and IHE) to determine failure threshold
- High-temperature tests on 12 firing sets at temperatures up to 1850°F
- High-temperature tests on four B61-3,4 test units.

The mechanical packaging and therefore the thermal properties of the B61-6,8 is identical to that of the B61-7.

The test unit was configured to provide exposure of a 120° arc of the center case directly to the fire with the remaining portion of the bomb exterior insulated and protected from direct flames. In this way, the most preferential heat path to the stronglink switches is obtained and therefore a worst-case test results. The thermocouple data (Figure 46) indicated the desired close thermal-tracking of the stronglink and weak-link temperatures. Thermocouples within the IHE indicated that in this orientation the IHE starts burning before the X-unit capacitor reaches failure temperature. The bomb IHE was totally consumed in the fire without detonating. Posttest examination of the firing set revealed total thermal destruction of the mylar X-unit capacitor while the stronglinks retained voltage

SECRET
UNCLASSIFIED

Combined Abnormal Environments

The B61-6,8 MCs require nuclear detonation safety be achieved "for individual or credible combinations of abnormal environments specified in the STS." The applicable STS for the B61-6,8 has been distributed for comments and revision. The section defining credible combined abnormal environments is being discussed and a revision has been proposed. Therefore the specific STS guidance to which the design and evaluation program for the B61-6,8 will be judged is not available.

The bombs response to combinations of abnormal environments relies on the demonstrated safe response to individual abnormal environments by virtue of the stronglink/weak-link/exclusion region design concept. For all single abnormal environments identified in the STS, it has, or will be shown that either the weak-link elements of the nuclear system or firing set become irreversibly inoperable prior to the stronglink failure, or the stronglinks maintain electrical isolation. Additionally, the relative stronglink/weak-link failure levels are sufficiently separated so that an abnormal environment not severe enough to disable the weak-link is below the level necessary to degrade the stronglink/exclusion region isolation. Thus, there are two predictably safe responses to an abnormal environment that have a direct bearing on system response to sequential exposure to abnormal environments:

1. The weak-link has become irreversibly inoperable prior to stronglink failure or bypass.
2. The stronglinks remain intact (the weak-link has not failed).

Given response #1, bomb exposure to subsequent abnormal environments would not result in a nuclear detonation since the system was rendered inoperable by the initial exposure.

Given response #2, the bomb is expected to withstand additional abnormal environments terminating in a safe condition with either the stronglinks intact or with the weak-link inoperable prior to stronglink failure or bypass.

There has never been a entire bomb system exposed to an ordered sequence of abnormal environments. There has been abnormal environment testing performed at the major component level (e.g., the firing set) to identify potential problem areas. Numerous tests have been performed on the MC2918 Firing Set to establish structural properties and dielectric properties of the stronglink/exclusion region following a high thermal abnormal environment. There are development activities in progress to improve the structural support of the stronglink switches following elevated temperatures resulting from fire and therefore address a combined abnormal environment of high thermal followed by shock. An aircraft crash (shock, static loading of the case) followed by fire is a "more credible" order of the combined environments and one for which the firing set response is predictably safe.

There are plans to test the new MC4137 TSSG to combined shock and thermal tests. The steel case (exclusion region) and rolamites were selected based on the threat of combined abnormal environments. The sequence of the thermal and shock should pose no threat to the predictability of the all-steel design.

5. Reliability

Summary

The reliability of the B61-6,8 has been predicted using the methods briefly described in this chapter.

To predict the bomb reliability, a failure analysis is performed for each component. Current assessments are used for the components of the parent weapon or those that are common to the B61-7 or B61-3,4 based upon stockpile data. Predictions for new components are based on all available data from similar components in comparable weapon systems and on data for individual piece parts and their design use.

The command disablement system is to have the following MC-specified reliability and premature probability characteristics:

Conclusions

Delimiting Conditions

The predicted reliability is conditional on the following:

1. Stockpile and use environments will be no more severe than the normal logistical and operational environments described in the STS.
2. All AMAC inputs will be present and proper.
3. There will be no human errors in bomb handling or preparation for use that will reduce its reliability.
4. The bomb and all of its components will be built to the usual DOE standard of production and process control.
5. The specified end-of-life of limited-life components will not be exceeded. Reliability assessments are considered to apply at the end of specified-life for limited-life components.
6. Failure events not treated otherwise are mutually exclusive or statistically independent.

6. Use Control

The B61-6,8 use control features include a command disable system and a Category D PAL System. Additional details about these features are discussed in the Use Control Addendum for the B61-6,8 Bomb (Reference 37).

Command Disable System

Command disablement of the B61-6,8 can be initiated from the aircraft or at the preflight controller (Figure 23) on the bomb.

The disablement system is composed of a DE1002 Coded Device and a MC3246A Thermal Battery.

Disablement results when (1) the correct three-digit disablement code is set on the DE1002 Code Switches, (2) the function select switch is set to the DI (disable) position, and (3) the T-handle is extracted, mechanically initiating the MC3246A battery. The disablement loads located within the bomb center case, each isolated by discreet resistors within the MC4139 Junction Box, are in parallel off the output of the MC3246A battery.

Category D PAL

The B61-6,8 Category D PAL subsystem consists of an MC2907A Multiple Code Coded Switch (MCCS), an MC2946 Output Switch, and a PAL Regulator. When the subsystem is locked, the bomb cannot be prearmed. The PAL subsystem is shown schematically in Figure 47.

MC2907A Multiple Code Coded Switch

APPENDIX A

Military Characteristics for the B61-6,8 (Proposed)

Military Characteristics	Comments

1. (U) *General*

1.1 (C-FRD) *Purpose*: This portion of the Military Characteristics (MCs) specifies the requirements of the Department of Defense (DOD) to the Department of Energy (DOE) for the B61 Mods 6 and 8 (B61-6,8) gravity bombs. The modifications are to incorporate modern safety, security, and operational features. The B61-6, 8 designs shall have the features delineated in paragraph 2 of these MCs.

1.1.1 (U) The B61 Mod 6 is a modification of the B61 Mod 0.

1.1.2 (U) The B61 Mod 8 is a modification of the B61 Mods 2 and 3.

1.2 (U) *Contingencies*: The design, development, test and evaluation of the bombs will be coordinated by the B61 Project Officers Group (POG). Should it appear impractical to meet any of these characteristics or that meeting them will unduly delay development or production of the bombs, incur unreasonable costs, or require excessive special nuclear materials, prompt notification shall be made by the Lead Project Officer (LPO) via service channels to the Nuclear Weapons Council Standing Committee (NWCSC).

1.3 (U) *Competing Characteristics*: In the event that compliance with these MCs results in design conflict, priorities shall be observed in the order listed below, giving consideration to tradeoffs which allow higher priority MCs to be attained while minimizing the degradation of the competing lower priority MCs. Operational effectiveness, technical feasibility, schedule, and cost will provide the basis for making tradeoffs among the desired competing characteristics. Tradeoffs may be made with the guidance and approval of the B61 POG. The NWCSC must approve all MC changes.

1.3.1 (U) Nuclear Safety
1.3.2 (U) Minimum Intrinsic Radiation
1.3.3 (U) Reliability
1.3.4 (U) Physical Characteristics
1.3.3 (U) Yield
1.3.6 (U) Radioactive Material Dispersal
1.3.7 (U) HE Safety
1.3.8 (U) Economical Use of Nuclear Material
1.3.9 (U) Operational Simplicity
1.3.10 (U) Command and Control Features
1.3.11 (U) Maintenance

2. (U) *Bomb Characteristics*

2.1 (U) *General Considerations:*

2.1.1 (U) The bombs shall not require functional testing in the stockpile.

2.1.2 (U) The bombs shall be designed so that the likelihood of plutonium dispersal in an accident environment is minimized.

[redacted]

Military Characteristics	Comments

2.1.4 (U) Provision shall be made for easy removal of some component of the electrical system vital to the function of the bombs. This provision shall not compromise Service operational requirements or storage criteria. Since this feature is a use-control function only, the bomb must meet all nuclear safety requirements in paragraph 2.8 whether the separable component is installed or removed.

2.1.3 (U) The design of the bomb shall be consistent with the environmental conditions delineated in the stockpile-to-Target Sequence (STS) and shall be deliverable in accordance with aircraft profiles in the STS.

2.2 (U) *Operational Considerations:*

[redacted]

DOE/DoD
b(3)

[redacted]

DoD
b(3)

2.3.3 (U) Groundburst (Freefall)

2.3.4 (U) Laydown: (Retarded delayed groundburst.) The firing times shall be the same as the parent bomb.

[redacted]

DOE
DoD
b(3)

2.3.6 (U) The bombs shall be capable of functioning properly in water depth to the limits of the Laydown timers.

2.4 (U) *Physical Characteristics:*

2.4.1 (U) Weight: 770 pounds (nominal)

2.4.2 (U) The length shall be 141.6 inches maximum.

2.4.3 (U) The body diameter shall be 13.3 inches maximum.

2.4.4 (U) The shape and geometry of the bombs shall be such as to minimize drag and adverse flight characteristics on the strike aircraft during all phases of the flight profile.

2.4.5 (U) War reserve bombs shall be identified with permanent and distinctive markings.

Subject: Stockpile Improvement Program (U)

In August 1978, reference 1 recommended nuclear-detonation safety and radioactive-material-scatter safety upgrades for selected stockpiled weapons with high exposure to possible abnormal environments and with potentially troublesome responses to those environments. In April, 1979, with DOD concurrence (Ref. 2), we initiated development activity on the B28FI aimed at providing field retrofit kits to enhance the nuclear-detonation safety of that weapon. Although delayed one year because of production funding problems, the design is now complete. In addition to enhanced nuclear-detonation safety, the refurbished B28FI will incorporate a Category D PAL, improved EMR/EMP resistance, and a "hot drop" feature which requires aircraft power at release. More recently, because of capacitor reliability concerns we and BKC have added a provision to screen returned firing sets at BKC. I understand that BKC expects first kit shipment to the Air Force in April 1983 on schedule.

Development start-up on the W31 was delayed at DOD's request pending the resolution of differences between the DOE proposal and the Army's recommendations (Ref. 2). A joint Army/DOE study was chartered to resolve these differences, and this group provided recommendations to the Army Staff in September 1979. The Army staff responded in October 1980. This apparent lack of interest by the Army coupled with other demands placed on our weapon development activities during the intervening 21 months prior to the receipt of reference 3 have caused us to commit fully our weapon development resources through FY 1982. Following receipt of reference 5, we initiated action to examine ways of reprogramming FY 1982 resources so that W31 development could begin early next fiscal year (FY 1982). This reallocation process has not been completed; consequently, we are unable, at this time, to commit the improved W31 design to a specific date. We expect to complete this reallocation activity within a few months and will provide our schedule assessment at that time.

The B61 improvement which was also agreed to by the DOD (Ref. 2) was started concurrent with the B28FI in April 1979.

Reference 6 provided BKC's assessment of their ability to support the production schedules. It concluded that B61 improvement schedules could be supported provided that needed engineering releases occurred in the approximate time frames identified in the production planning assessment. This assessment called for early engineering releases commencing in April 1981 and continuing through September 1981 for component parts such as semiconductors, castings, connectors, and forgings. Further, releases for subassemblies were required in August 1981 to continue through December 1981. Because of the added features noted above, design maturity and development status did not and do not support the issuance of all releases needed at this time. This factor coupled with heavy demands on Sandia weapon development resources for FY 1982 suggest that a prudent approach would be to slip the B61 Phase 6 FPU by approximately 9 months. We believe this action is necessary to allow for a more orderly and less risky B61 development and production program if the design is to retain the additional features.

SECRET

SECRET UNCLASSIFIED

COPY

COPY

Although we endorse the inclusion of these additional features and believe this design should be pursued on modified timescales, another option still exists which we believe can support the existing schedule.

[redacted]

If support of the existing schedule is considered more important than provisions for these additional features, a decision must be made now while a design alternative still exists that supports the FY84 Phase 6. If we decide to accept a delay in B61-7 Phase 6, I suggest that you consider using that released production capacity to accelerate the build of the additional B61-4's now authorized.

We support and will continue to pursue the present baseline definition with all the features previously mentioned unless you notify us that current schedules must be protected.

MINUTES OF FINAL

DESIGN REVIEW AND ACCEPTANCE GROUP (DRAAG)

MEETING ON THE

B61 MOD 7 BOMB

HELD AT SANDIA NATIONAL LABORATORIES ALBUQUERQUE

17 JULY 1985

1. (U) Pursuant to the provisions of DOD Instruction 5030.55, "Joint AEC-DOD Nuclear Weapons Development Procedures," 21 January 1974, and AF Regulation 80-9, "Nuclear Weapons Development Procedures," 17 May 1976, a final DRAAG meeting to review the design of the B61 Mod 7 Bomb was held at Sandia National Laboratories, Albuquerque, NM on 17 July 1985.

2. (U) Participants in the review were representatives of the Air Force Weapons Laboratory (representing the Air Force); Naval Weapons Evaluation Facility (representing the Navy); and the Project Manager for Nuclear Munitions, Albuquerque Field Office (representing the Army). Presentations at the meeting were made by Sandia National Laboratories, Albuquerque and Los Alamos National Laboratory. An attendance list and agenda are attached.

3. (U) The design review addressed the B61 Mod 7 design as presented in the Draft Final Development Report (FDR) for the B61 Mod 7 Bomb and the Use Control Addendum for the B61 Mod 7 Bomb, both dated Jun 1985, and compliance by the DOE with the design specifications contained in Ammendment 29, Section II of the B61 Military Characteristics (MCs), 19 November 1984, and the B61 Stockpile-to-Target Sequence (STS), Revision 6 15 April 1984. Fifteen comments from the services and corresponding responses form the DOE laboratories relative to the design were discussed.

A. (U) Items specific to the B61 Mod 7.

(U) The following aspects of the B61 Mod 7 deviate from specifications in the B61 Mod 7 MCs and STS.

b(3)

(2) (U) Safety: The probability of a premature nuclear detonation in the normal environments described in the STS shall not exceed: (MC para 2.5.1.3) "After release and prior to fuzing: 1 x 10 per occurrence." (Where "fuzing" is defined as receipt of a fire signal from the radar, timer, or contact crystal, as appropriate) The DOE assesses the probability as 1 x 10 during the period after release and prior to expiration of the safe separation time. The probability of premature nuclear detonation is estimated to be 2 x 10 during the period from safe separation time to fuzing.

(3) (U) STS Environments: The nuclear environments specified in Table 3.14 of the STS for Stage 6 (Release and Free flight) are not adequately defined for testing purposes. The sensitivity of the MC 3637 Programmer and MC 3638 ICU to gamma dose and dose rate has been explored in laboratory tests.

b(3)

B. (U) B61 Mod 7 Conclusions:

(U) The B61 Mod 7 design deviations noted in para A above are considered minor and should result in no important impact on SACs planned operational use of the B61 Mod 7.

C. (U) General Items:

(U) In response to the Service Comments on the Draft FDR for the B61 Mod 7, the DOE agreed to include the following items in the Final Development Report.

(1) (U) The operating characteristics of the MC 3640 Trajectory Sensing Signal Generator will be shown, including the no-operate and operate limits.

(2) (U) DOE will expand the description of the MC 3554 Neutron Generator to explain its noise immunity.

(3) (U) The discussion of the Lightning Arrestor Connector will be expanded to show how the MC 2969/2935 Strong Link Switches add to lightning protection. A SNLA report on (LAC/SLS) reliability will be referenced.

(4) (U) An expanded discussion and analyses of credible combined abnormal environments will be included.

(5) (U) The discussion of the T 1563 APC and T 1572 PDM will be combined and expanded.

(6) (U) The FDR will reference specific sections and/or pages relative to compliance with the MCs.

(8) (U) Functional Block Diagrams of the B61 Mod 7 Bomb will be included in the FDR.

4. (U) Recommendations:

A. (U) B61 Mod 7 DRAAG Specific Recommendations:

(1) (U) Exceptions from the design requirements mentioned above be accepted for the B61 Mod 7 Bomb.

(2) (U) Changes to the Draft FDR and FDR Addendum agreed at the DRAAG meeting and listed in C above be published in the final reports.

(3) (U) The B61 Mod 7 be accepted as a standard stockpile item.

B. (U) DRAAG General Recommendations:

(U) The DRAAG did not have approved Military Characteristics at hand, but only verbal assurances of what had been approved by the MLC. The DRAAG cannot function effectively without official written approved MC's and changes. It is recommended no DRAAGs be convened on specific nuclear weapons until approved MC's on those weapons have been made available to the DRAAG members. We also recommend the DRAAG chairman receive information copies of DRAAG related documents (MCs, DRAAG Minutes, Policy guidance, etc) which are forwarded to ATSD(AE) anQ DOE/MA by Service Staffs and ATSD(AE) respectively.

SLBM PHASE 2 STUDY
EXECUTIVE SUMMARY

(U) The SLBM Phase 2 Study was conducted to identify and quantify alternatives to the W76/MK4 and W88/MK5 reentry systems. The study was in response to increased emphasis on safety, the limited production capability of the DOE complex, and the expected extremely long service life of the enduring stockpile. The alternatives were evaluated with respect to the following attributes:

Enhanced weapon system safety
Desensitization to aging effects
Minimum need for refit
Reliability
Compatibility with existing DoD/DOE hardware
Security and use control
Reduced dependence on nuclear testing
Producibility
Effectiveness

b(3)

(CRD) A broad range of MK5A candidates has been proposed.

One candidate offers a safety capsule enveloping a W76 NEP and there are three all-Oy (Oralloy) designs, which contain no plutonium. Most MK5A alternatives incorporate ENDS (Enhanced Nuclear Detonation Safety), e.g., advanced detonator safing, and robust exclusion barriers, IHE (Insensitive High Explosive), FRP (Fire Resistant Pits), and devices for use control and denial.

b(3)

DOE

Since the TRIDENT II accuracy is better than its original objective, several MK5A candidates provide effectiveness that is greater than the W88/MK5 at its original accuracy objective.

1. (U) INTRODUCTION AND OBJECTIVES

(U) The purpose of this study was to identify and quantify alternatives to the W76/MK4 and W88/MK5 for use on the TRIDENT weapons systems. These alternatives have been designated MK4A and MK5A throughout this report. While there are no presently identified deficiencies in performance, safety or service life, current strategic force planning will keep MK4 and MK5 in the deployed inventory for an extremely long time and therefore decreased sensitivity to aging was emphasized. Also stressed were enhanced safety, system reliability, decreased need for underground tests (UGT), and flexibility in meeting future requirements. Warhead yield was de-emphasized in favor of other attributes. A goal was to maximize the use of existing DoD hardware in order to minimize system costs.

[redacted] b(3) DOE

(U) Based on the above broad guidance, the study ground rules included no changes to the D5 or C4 missile system hardware or to missile-to-RBA (Reentry Body Assembly) interfaces. External MK4 and MK5 aeroshells, including nosetip and heatshield, were to be unchanged. Changes to the MK4 AF&F (Arming Fuzing & Firing System) were allowable to enhance reliability and safety. System mass properties were kept as close as possible to MK4 and MK5 values to preserve the flight test and accuracy database, and minimal change to existing Stockpile-to-Target Sequence (STS) normal, abnormal and hostile environments was desired.

(SFRD) Draft Military Characteristics (MCs) for the WXX/MK5A and WYY/MK4A increased emphasis on modern safety features and on the potential for minimizing plutonium dispersal. b(3)

[redacted] DOE, DTRA

Intrinsic radiation levels are TBD, but as low as possible (Reference 4).

(U) The study was conducted by the SLBM Phase 2 Study Group, which was formed from the W88/MK5 Project Officers Group, with the addition of the LLNL/Sandia team as study members. Observers included DOE/Headquarters, ATSD(AE) and

CNO(N514). DoD/DOE reentry concepts were developed and evaluated by technical working groups, including Design Integration, Safety, Vulnerability, Joint Test, Quality and Reliability, Logistics and Production, Fail-Safe and Risk Reduction, and Systems Performance and Effectiveness. An additional working group developed draft Military Characteristics and preliminary Stockpile-to-Target Sequences (References 4, 5 and 6).

2. (U) BACKGROUND INFORMATION

(U) In recent years, the character of the US strategic deterrent has been changing. The total US strategic inventory has been reduced by START I and II agreements, and this has increased emphasis on the SLBM force. Nuclear weapon safety has received additional attention from policy makers, with desire for increased margins, while a stringent budget climate has reduced funding for weapons-related activities. b(3) DOE

(SFRD) The MK4 and MK5 TRIDENT reentry systems meet all goals and standards, and there are presently no identified deficiencies in performance, safety or service life. b(3) DOE

b(1) DTRA

(U) On 26 March 1992, the Director of Strategic Systems Programs (SSP) initiated a formal request to the Chairman of the Nuclear Weapons Council Standing Committee (NWCSC) for a joint DoD/DOE Phase 2 Study to identify and quantify alternatives to the W76/MK4 and W88/MK5 to increase service life and increase safety margins (Reference 1). Since the alternatives would not modify existing delivery systems, a Phase 1 study was not conducted.

(U) On 27 April 1992, the Chairman, NWCSC, requested the DOE to join with the DoD in Phase 2 activities (Reference 2). IOC for the replacements would be in the late 1990's and the quantity would be sufficient to replace the existing W76/MK4 and W88/MK5 systems.

(U) The DOE(DASMA) responded to the NWCSC request on 29 April 1992 and accepted the request for a Joint DoD/DOE Phase 2 Study (Reference 3).

UNCLASSIFIED

(U) The SLBM Phase 2 Study schedule is shown in Figure 2-1. The kickoff meeting was held in June 1992 and Study Group Meetings were held approximately every six weeks. Interface definitions and requirements were developed early in the study and the DOE identified preliminary warhead concepts. Candidate warheads and associated DOE hardware were integrated into DoD-produced MK5 and MK4 hardware by a joint DoD and DOE team. Evaluation of the MK5A and MK4A candidates was done throughout the study. A DOE Peer Review, including detailed nuclear safety and performance calculations, was conducted late in the Study and will be reported separately. The SLBM Phase 2 Study was completed in January 1994 with the issuance of the final report.

3.3 (U) REPORT OF THE HASC PANEL ON NUCLEAR WEAPONS SAFETY

The following section is an extract from the executive summary of the House Armed Services Panel Report, commonly known as the Drell Report. It is included here because of its relevance to the SLBM Phase 2 Study.

(U) Concerns that have been raised recently about the safety of several of the nuclear weapons systems in the U.S. arsenal have led the government to take immediate steps to reduce the risk of unintended, accidental detonations that could result in dispersing plutonium into the environment in potentially dangerous amounts, or even generate a nuclear yield. These steps include temporarily removing the short-range air-to-ground attack missiles, SRAM-A, from the alert bombers of the Strategic Air Command and modifying some of the artillery-fired atomic projectiles (AFAPs) deployed with U.S. Forces. In addition, the Departments of Defense and of Energy, which hold dual responsibility for the surety of the U.S. stockpile of nuclear weapons systems--i.e., for their safety, their security, and their control--have initiated studies looking more broadly into safety issues.

(U) This is a very important, as well as opportune, moment to undertake a safety review of nuclear weapons for reasons that go well beyond the immediate concerns of several specific weapons. As we enter the last decade of the 20th century, the world is in the midst of profound, and indeed revolutionary, changes in the strategic, political, and military dimensions of international security. These changes, together with a continuing rapid pace of technical advances, create an entirely new context for making choices in the development of our nuclear forces for the future. It is likely that, in the future, the U.S. nuclear weapons complex will evolve into a new configuration--perhaps smaller and less diverse and at lower operating expense but with enhanced requirements for safety and control.

(U) In this report we propose organizational initiatives to strengthen and make more fully accountable the safety assurance process, and we identify priority goals for enhancing safety in a timely fashion. We

UNCLASSIFIED

emphasize the importance of developing the data bases and performing credible safety analyses to support weapons design choices. We also affirm the importance of vigorous R&D efforts in the DOE weapons laboratories in search of new technologies leading to significant advances in safety-optimized designs.

(U) The starting point of our study is provided by two recent analyses which included inquiries into the nuclear weapons safety process: The 1985 President's Blue Ribbon Task Group on Nuclear Weapons Program Management, chaired by Judge William T. Clark, and the 1988 DOE Nuclear Weapons Safety Review Group, chaired by Gordon Moe. Both of these panels addressed long-standing concerns with stockpile safety and made important recommendations, a number of which were implemented, including in particular creation of a Nuclear Weapons Council (NWC) and an NWC Weapon Safety Committee. It is our present finding that although many problems have been, or are being, fixed, still more remain to be addressed. We are concerned, as were these earlier panels, that serious issues that had been known for at least a decade remained unattended for so many years.

(U) We make seven major recommendations for strengthening the safety assurance process. They should be implemented promptly and effectively.

(U) 1. Create joint DoD/DOE dedicated "Red Teams" with the important responsibility to scrutinize and challenge the weapons designs and operational procedures for each nuclear weapons system remaining in the stockpile or under development. The Red Teams would normally interact directly with the Weapons Design Teams. However, in case of unresolvable differences of views on safety issues, the Red Teams would have direct channels up the line of authority to the Nuclear Weapons Council and to the Secretaries of Defense and Energy if necessary.

(U) 2. Create a Joint Advisory Committee for Nuclear Weapons Surety which would report directly to the two Secretaries of Defense and

Energy. This committee would be responsible for examining ongoing practices in both DoD and DOE with respect to nuclear weapon surety, would have oversight of the surety reviews conducted on specific systems, and would identify and inform the Secretaries of any serious surety issue and provide advice as to the appropriate response.

(U) Together with the Red Teams, the Joint Advisory Committee will provide confidence that all surety issues and requirements for the U.S. stockpile are identified, given a thorough technical analysis, and addressed in a timely fashion.

(U) 3. Strengthen and more tightly focus the responsibilities of the two offices charged with managing nuclear weapons issues within the Departments of Defense and Energy. Within Defense this is the Office of the Assistant to the Secretary of Defense for Atomic Energy [ATSD(AE)]; and, in Energy it is the Office of the Assistant Secretary for Defense Programs (ASDP). To be effective the charters of both of these offices must clearly delineate their responsibilities and assure their direct access to their respective Secretaries on critical and dangerous issues of nuclear weapons system surety. In particular, the ATSD(AE) should be given a more senior status as a member of the Nuclear Weapons Council (NWC) and upgraded to the same status as an Assistant Secretary of Defense, with a direct line of reporting to the Secretary.

(U) 4. The Deputy Assistant Secretary for Military Applications (DASMA), who plays a crucial role within the DOE Office of the ASDP and also chairs the Nuclear Weapons Council Weapons Safety Committee (NWCWSC), currently is required to be a flag-rank officer on active military duty. We recommend that the occupant of this position be chosen as the most qualified individual--civilian or military.

(U) 5. Designate the Assistant Secretary for Defense Programs (ASDP) in DOE as chairman of the Nuclear Weapons Council, whose other two members are from Defense (the DDRE and the Vice Chairman of the

(U) The primary goal of these seven recommendations is to establish a process for safety assurance that is pro-active, effective, and vigilant in search of the desired balance between maximum safety and reasonable military requirements.

(U) Our four major recommendations for enhancing the safety of nuclear weapons systems by reducing the risks of an unintended, accidental, or unauthorized nuclear detonation or dispersal of plutonium apply both to the warheads themselves and to the entire weapon system. For the warheads they imply design choices for the nuclear components, the high explosives, and the electrical arming system. For the weapons system--i.e., the rocket motors to which the warhead is mated in a missile and the aircraft or transporter that serves as the launcher--safety implies choices of propellants and operational procedures as well as system designs.

(U) 1. Adopt and implement as national policy the following priority goals for improving the safety of the nuclear weapons systems in the stockpile, using available technology:

(U) • equip *all weapons* in the stockpile with modern enhanced nuclear detonation safety (ENDS) systems.

(U) • build *all nuclear bombs loaded onto aircraft*---both bombs and cruise missiles--with insensitive high explosives (IHE) and fire-resistant pits. These are the two most critical safety features currently available for avoiding plutonium dispersal in the event of aircraft fires or crashes.

(U) There are no technical reasons for the DoD and DOE to delay accomplishing these safety goals for existing stockpile weapons; they should be given higher priority than they currently receive.

(U) 2. Undertake an immediate national policy review of the acceptability of retaining *missile systems* in the arsenal without IHE or fire-resistant pits in their nuclear warheads and without using a safer

safety levels before proceeding with new weapons developments. Provide the resources necessary to support this work.

(U) 4. Affirm enhanced safety as the top priority goal of the U.S. nuclear weapons program and direct and appropriately fund DOE weapons laboratories, in fulfilling their national responsibilities, to vigorously pursue R&D in search of new technologies that could create new possibilities for significant advances in safety-optimized designs.

(U) In a classified section of this report we discuss individual weapons systems and the safety concerns arising from the technology they incorporate and the handling and deployment procedures they experience. Finally we discuss improvements or changes that would enhance their safety.

(U) To accomplish the goals we have set out in this study the U.S. nuclear weapons program will have to give higher priority and devote more of its resources to efforts to enhance safety--taking a long-range view in search of big advances in technology beyond just evolutionary, incremental improvements. Such a call for reorienting the emphasis of the current program should not be viewed as requiring an enlargement of the total program particularly as we look forward to maintaining a smaller nuclear force in the new strategic environment. It does however require that adequate and steady resources be made available for the RDT&E needed to underpin such a program.

3.4 (U) FARR BACKGROUND

(U) As a result of a formal request by the Senate Armed Services Committee, the Federal Advisory Committee on Nuclear Fail-safe and Risk Reduction (FARR) was chartered on December 20, 1990 by Secretary of Defense Richard Cheney. The FARR Committee assessed the current and programmed capability of the U.S. Nuclear Command and Control Systems (NCCS) to meet the dual requirements of assurance against unauthorized use and the assurance of timely authorized use, when directed by the President. They also identified opportunities for enhancement of these capabilities. The FARR Committee was tasked to explore the desirability and

feasibility of placing coded control devices in U.S. nuclear weapons at sea. The FARR Committee concluded that enhancements which would further improve the safety, security and control of U.S. nuclear weapons are both feasible and desirable. These conclusions were accepted by Secretary Cheney. Through appropriate channels, the TRIDENT Phase 2 Study Group was tasked to investigate appropriate FARR Committee recommendations for applicability and possible implementation. This is discussed in Section 10.2.

3.5 (U) DOE PRODUCTION CAPABILITY

3.5.1 (U) OBJECTIVE

(U) The Department of Energy (DOE) Production Capability section of this study was requested for the purpose of evaluating the impact on production timelines and capacity by the recently mandated DOE plant reconfiguration project.

3.5.2 (U) SUMMARY

(U) The DOE reconfiguration project consists basically of two major elements:

1. Non-nuclear Production activity; and

2. Nuclear Production activity.

(U) Hazel O'Leary, Secretary of Energy, announced May 27, 1993, that the DOE will proceed with the consolidation of its non-nuclear operations based on information from three independent consultants indicating the non-nuclear plan was cost effective and should be implemented. The nuclear reconfiguration project was basically driven by the "shutdown" of plutonium pit fabrication activity at the Rocky Flats Plant (RFP) near Golden, Colorado by the previous Secretary of Energy Admiral James D. Watkins, USN (Retired).

(U) The non-nuclear reconfiguration project was issued a Finding of No Significant Impact (FONSI) in late September 1993, one month after the scheduled date. Implementation of plans to notify facilities at the four receiver sites began October 1993. The RFP, Pinellas, and Mound donor plants will have equipment,

documentation, and people transferred to the Kansas City, Los Alamos National Laboratory (LANL), Sandia National Laboratories, and Savannah River receiver sites. The last activity transfer (neutron generators) is scheduled to be completed October 1999.

(U) The nuclear reconfiguration project has proceeded through a public comment and scoping period at the various receiver candidate sites during the July - September 1993 period. After appropriate revisions to the implementation plan and drafting a Programmatic Environmental Impact Statement (PEIS), there will be another public comment and hearing period from January - March 1994. A final PEIS is scheduled by August 1994, and a decision by the DOE Secretary whether or not to proceed with the nuclear reconfiguration plan is scheduled in the September - December 1994 time frame.

(U) First Production Unit (FPU) delivery dates for all candidates were assessed based on the DOE reconfiguration schedule and basic guidelines. Candidate FPU delivery dates were analyzed in three time frames:

1. Less than five years;

2. Five to ten years; and

3. Greater than ten years.

(U) A basic DOE guideline is that pit reuse facilities would not be operational in less than five years, and plutonium (Pu) fabrication facilities would not be available within ten years.

(U) In conclusion, the FPU for all candidates is projected to be five or more years after an assumed Phase 3 beginning fourth quarter of FY94. The planned Pantex pit reuse facility is expected to have a capacity of 10 pits per month per shift, expandable to 20 if necessary, which raises concerns for producing an Initial Operational Capability (IOC) quantity by the end of 1999 for those candidates requiring this facility.

3.5.3 (U) BASIC GUIDELINES & GROUND RULES

A. (U) Assumes Phase 3 start fourth quarter FY94.

B. (U) Years to component FPU based on Phase 3 start date.

- Phase 3 delay would shorten time to FPU for mid and far-term in Tables 3.5-1 and 3.5-2.

2. (U) The RFP production contingency mission was removed by DOE several months ago. The DOE Revised Notice of Intent and Programmatic Environmental Impact Statement for Complex-21 are very emphatic that RFP will no longer be able to fabricate Pu pits. Complex-21 will not be available to fabricate new pits until many years after FPU for SLBM. LANL and LLNL both have a capability to fabricate a small number of Pu test articles, but by no stretch of the imagination could this be considered a production capability. b(3) [redacted] DOE

3. (U) The Y-12 plant is currently at a semi-production level of capability and has a production capacity higher than the capability envisioned for the Pantex pit reuse program. If Y-12 were given the budget and programmatic requirement basis within the next few years, it could fabricate all Oy pits on a production basis within three years of notice to do so. Y-12 anticipates substantial budget reductions starting in FY95. If after the budget cuts, Y-12 is able to sustain a minimum capability, it could still begin Oy pit production within three years notice to do so. If the budget cuts reduce Y-12 to a storage-only mode, then five or more years advance notice would be required before Y-12 could start production of an all Oy pit. The year FY95 is a key decision date if the SLBM will use an all Oy pit and if its current production schedule is to be met. b(3) [redacted] DOE

For the CSAs or other Y-12 products required for a complete NEP, Y-12 would be able to meet production requirements subject to the same caveats given in the previous paragraph.

5.1.4.2 (U) W76 Warhead in Safety Capsule (LA5-2)

(CFRD) The W76 warhead inside a custom-designed protective envelope in the MK5 RB is a low cost, maximum reuse proposal that approaches nuclear weapon safety from a different perspective. While significant advances were made in the b(3) DTRA

5.1.4.2.1 (U) *Nuclear System Performance Record*

(U) The safety capsule has been designed to minimize the impact of the safety features upon the proven nuclear performance of the W76 weapon. The material nearest the case is insulating foam which is close to the density of the foam used to mount the W76 warhead in the MK4 RB. Thus the safety capsule is expected to have minimum perturbation on the normal function of the W76 NEP. Indeed the foam fully surrounding the case may even improve radiation case integrity.

(U) In order to demonstrate the viability of the nuclear system when surrounded by different materials than were used in the nuclear tests, an extensive local test program will be pursued. Hydrodynamic tests (hydros) of the baseline W76 will be

compared to hydros of the W76 in the safety capsule. [redacted] b(3) DOE, DTRA

(CFRD) The W76 nuclear system is one of the most completely tested systems in the enduring stockpile. [redacted] b(3) CG-W-5 710 DOE, DTRA

The tests pertinent to this proposal are shown in Table 5.1-4. [redacted] TG-NAS-2 801 DOE, DTRA b(3)

5.1.4.4.8 (U) *Electrical Support System Options, LA5-9*

(U) CAT-E PAL and detonator enabling/safing systems are included in LA5-9. Electrical support systems drawings that follow (Figures 5.1-17 and 5.1-18) are identical, except for detonator and neutron generator designator locations, to those systems described for LA5-4, -6, and -7. New detonator and neutron generator cables are required because of warhead orientation within the RB.

5.1.4.5 (U) All Oy Design (LA5-5)

(U) The usual approach to reducing the hazard of Pu scatter is to reduce the hazard of detonating the HE around Pu bearing pits. Building a pit that does not use Pu is another approach. Oy is an alternative nuclear material that poses a much lower hazard than Pu. This hazard reduction is several orders of magnitude, even after considering that more material is required to achieve a nuclear yield.

(U) FIGURE 5.1-17

DOE
DTRA
b(3)

b(3)
DOE
DTRA

The required interface is accomplished by the addition of through connectors on the seal cover and aft closure with an interconnecting cable. The connectors and cable are the responsibility of the DOE. The connector on the aft closure will require RF and thermal protection. Other than the addition of the connector on the aft closure its design remains very similar to the W88/MK5. Candidate mass properties (RB weight and CG location) are shown in Figure 6.2-2.

(U) This design provides compatibility with the DoD hardware including the AF&F. The proposed CAT-E PAL use control capability is feasible and the concept is compatible with all the missile physical and functional interfaces. The concept has good aerodynamic stability margins.

6.4.3.2 (U) LL5-3a Normal Reentry Structural Assessment

(U) Analysis Approach

(U) The approach used to assess the LL5-3a concept was to compare the design attributes of the forward wedge support area and the aft warhead support to designs that have already been assessed. (See Figure 6.4.3-1). The LL5-3a concept has an aft warhead support design that is similar to the LA5-6 design but with a thicker attachment flange, and a forward warhead support wedge that is structurally the same as the LL5-1 wedge. Both the LL5-1 and LA5-6 designs were extensively analyzed by finite element models. Since the aft warhead support and wedge area were the same or similar to the above mentioned designs, an engineering judgment was made as to the feasibility of the LL5-3a design. The seal cover has a

double curved design similar to the LL5-1 and was assessed based on that design. (See Figure 6.4.3-1). The warhead attachment, the wedge, and the seal cover designs were assessed for the three critical MK5 V–γ trajectories (upper middle-UM, upper left-UL, and upper right-UR) by comparison.

(U) Assessment Results

(U) The assessment of the LL5-3a aft warhead support, the forward wedge support area and the seal cover has margins equal to or greater than the W88/MK5 design based on engineering judgment.

6.4.3.3 (U) LL5-3a Hostile Reentry Structural Assessment

(U) Material Vulnerability Assessment

(U) The candidate utilizes a foam sleeve similar to that used in the LL5-1 design and employs a bond material similar to that of LL5-1 as well. These configurations were assessed as feasible based on MK5 and LLNL UGT test experience.

b(3)
DOE
STRA

(U) Structural Vulnerability Assessment

(U) For the LL5-3a the high-frequency response effects were only investigated for the substrate stress response in the vicinity of the aft support under side-on impulse loading. This approach was taken because evaluation of a similar design (LL5-1) had indicated that the impulse loading imposed the largest stress on the candidate.

(U) A DYNA3D finite element model was developed to predict the local stress response in this vicinity. The results showed that the peak stresses developed at

critical points in the substrate and in the connecting bolts and bracket were below the corresponding material allowable (i.e., yield strengths).

(U) With regard to low-frequency responses, only blast loading was analyzed since it had been identified as imposing larger stresses than cold or hot X-ray loadings. The approach to assess blast response is illustrated by the flow diagram of Figure 6.4.3-5. The centerpiece of the analysis is the low-order full-body model dynamic analysis. The required warhead forward and aft support stiffness data were determined from separate DIAL finite element analyses. The required warhead spring and mass constants were calculated using the stiffness and mass distribution information supplied from LLNL.

(U) The low-order blast analysis provided the general stress, internal forces/ moments and deflection responses. However, the local stresses (including shell bending effects) at the new warhead support junctions were not calculated. These responses were calculated using the DIAL finite element local support models where the boundary loads were the internal forces and moments obtained from the low-order analysis.

(U) The results showed that the most critical responses occurred in the vicinity of the aft warhead support (Figure 6.4.3-4). The highest stress, 42 ksi, occurred at the substrate inside surface located at the forward edge of the aft support on the hit side. This stress was below the static material (aluminum) yield strength of 49 ksi, at 200° F and was therefore assessed as acceptable.

(U) The DOE/DoD component relative deflection responses at potential physical impact locations indicated that the relative lateral deflections between the chimney and the aeroshell substrate was most critical similar to LL5-1. The potential for impact between the chimney and the aeroshell can be eliminated by increasing the gap between the two components. This was accomplished for the LL5-1 design, and has now been accomplished for the LL5-3a design.

FIGURE 6.4.3-5

(U) BLAST ANALYSIS APPROACH

6.4.4.3 (U) LL5-3b Hostile Reentry Structural Assessment

(U) Material Vulnerability Assessment

(U) The LL5-3b design has a new foam sleeve design with a bond similar to that of candidate LL5-1 which was assessed to be feasible based on MK5 and MK21/W87 UGT experience.

6(3)
DOE
DTRA

(U) Structural Vulnerability Assessment

(U) For high-frequency responses only the substrate stress response in the vicinity of the aft warhead mount, under side-on impulse loading was examined because evaluations made on similar designs (LL5-1 and LL5-3a) have indicated that this condition produces the maximum stress.

(U) In addition, because of their design similarities the high frequency response of LL5-3b was evaluated as being bounded by the responses of LL5-3a and LL5-1 (Figure 6.4.4-2). Therefore, since the high frequency stresses for both LL5-3a and LL5-1 were below material yield limits, the LL5-3b candidate was also expected to have positive high frequency response margin.

(U) Relative to low-frequency responses only the blast loading was analyzed since it is more critical than cold and hot X-ray loadings. The approach to assess blast response is illustrated by the flow diagram of Figure 6.4.3-5.

6(3)
DOE
DTRA

(U) This design provides compatibility with the DoD hardware including the AF&F. The proposed CAT-E PAL use control capability is feasible and the concept is compatible with all the missile physical and functional interfaces. The concept has good aerodynamic stability margins.

6.4.7.2 (U) LL5-4c Normal Reentry Structural Assessment

(U) Analysis Approach

(U) The approach used to assess the LL5-4c concept was predicated on the design attributes of the forward warhead support wedge and the aft warhead support. (See Figure 6.4.7-1). This design is very similar to LL5-4a except the weight is 10% greater and the center of gravity is more forward. The LL5-4c concept had an aft warhead support design that is similar to the MK5 IH design, and a forward warhead support wedge that is somewhat larger but is located slightly further aft than the W88/MK5 wedge. Since these two pieces of structure were similar to the MK5 tactical design, the MK5 capability curves were used to determine the feasibility of the design. A parametric study of the MK5 tactical nub concept versus the MK5 IH bolted concept established a set of knock-down factors that were used on this assessment to adjust for the difference in stresses between the MK5 tactical and the MK5 IH designs. The seal cover has a double curved design similar to the LL5-1 and was assessed based on that design. (See Figure 6.4.7-1). The warhead attachment, the wedge, and the seal cover designs were assessed for the three critical MK5 V–γ trajectories (upper middle-UM, upper left-UL, and upper right-UR).

(U) Assessment Results

(U) The assessment of the LL5-4c aft warhead support design reflected margins slightly more negative for the aft warhead flange tapers than the W88/MK5 design. The wedge concept has positive margins of safety. The seal cover design has positive margins both for stress and buckling based on the LL5-1 Assessment.

6.4.7.3 (U) LL5-4c Hostile Reentry Structural Assessment

(U) Because LL5-4a and LL5-4c have identical designs except for warhead internal

mass distribution, the vulnerability responses were expected to be the same except for possible differences in their low-frequency responses. These differences are noted below.

(U) Material Vulnerability Assessment

b(3)
DOE
DTRA

(U) Structural Vulnerability Assessment

(U) High-frequency responses for the LL5-4c candidate were investigated for side-on impulse loading only. And only the substrate stress response in the vicinity of the aft support under this side-on impulse loading was examined because evaluation of a similar design (LL5-1) indicated that the impulse loading imposed the largest stress on the hardware.

(U) A DYNA3D finite element model was developed to predict the local stress response in this vicinity. The results showed that the peak stresses developed at critical points in the substrate and in the connecting bolts and bracket were below the corresponding material allowables (i.e., yield strengths).

(U) Regarding low-frequency responses, only blast loading was analyzed since it was found to be more critical than cold and hot X-ray loadings. The approach to assess blast response is illustrated by the flow diagram of Figure 6.4.3-5. The centerpiece of the analysis is the low-order full-body model dynamic analysis. The required warhead spring and mass constants were calculated using the warhead stiffness and mass distribution information supplied from LLNL.

(U) The results showed that the highest stresses occurred near the manufacturing joint area. However, these stresses were below material limits. The LL5-4c stresses were higher than those of a similar design, LL5-4a (See Section 6.4.5) which had a lighter NEP and a more aft located CG. The stresses at the aft support region were well below yielding due to the strong "wishbone" support design. The DOE/DoD component relative deflection responses pose no concern with the current designs.

6.4.7.4 (U) LL5-4c Candidate Feasibility Statement

(U) Based on the current design information and the assessments performed, the LL5-4c concept is structurally feasible with potential modifications to the aft mount. The stresses in the aft warhead flange tapers should be examined more closely if this design is pursued.

6.4.8 (U) LL5-5 STRUCTURAL ASSESSMENT SUMMARY

6.4.8.1 (U) Design Description

b(3)
DOE
DTRA

(U) The AF&F mounting ring remains basically similar to the W88/MK5. The aft warhead support design is a two-piece IH type attachment, i.e. in-line, direct attachment. (See Figure 6.4.8-4). The NEP length and axial position has resulted in the need for a double curvature seal cover (Figure 6.4.8-1).

b(3)
DOE
DTRA

6.4.13.2 (U) LA5-4 Normal Reentry Structural Assessment

(U) Analysis Approach

(U) The approach used to assess the LA5-4 concept was to compare the design attributes of the forward wedge support area and the aft warhead support to designs that have already be assessed. (See Figure 6.4.13-1). The LA5-4 concept has an aft warhead support design that is similar to the LA5-6 design. The LA5-6 design was extensively analyzed by finite element models. Since the LA5-4 design concept is similar to the above mentioned design, a comparison of the loads and mass properties was made to determine the feasibility of the LA5-4 design. The seal cover and the wedge area are similar to LA5-6 and were assessed based on that design. (See Figure 6.4.13-1). The warhead attachment, the wedge, and the seal cover designs were assessed for the three critical MK5 V–γ trajectories (upper middle-UM, upper left-UL, and upper right-UR) by comparison.

(U) Assessment Results

(U) It is recommended that the warhead interface ring base at the warhead/ring interface be increased in the axial direction to give the ring a better moment capability. If this change is incorporated into the design, then the assessment of the LA5-4 aft warhead support and the forward wedge support area will have margins equal to or greater than the W88/MK5 design. This assessment was based on a loads and mass properties comparison between LA5-4 and LA5-6. The seal cover has positive margins based on the assessment of LL5-1 configuration that had similar geometry.

6.4.13.3 (U) LA5-4 Hostile Reentry Structural Assessment

(U) Material Vulnerability Assessment

[redacted] The LA5-4 candidate employs the same forward sleeve configuration as the LA5-6 candidate.

FIGURE 6.4.14-4

(U) AFT WARHEAD SUPPORT

b(3) DOE DTRA

(U) Structural Vulnerability Assessment

b(3) DOE DTRA

Selection of an adequately stiff wedge material was viewed as an issue for this component due to the potential shift of loading from the forward to the aft warhead mount. Also, the NEP has a longer forward reach than the W88 which results in a small gap between the NEP and the AF&F support. An adequate gap between the NEP front end and the AF&F would be required to prevent physical impact. Additional design and component stiffness information would be required to provide a more complete assessment.

6.4.14.4 (U) LA5-5 Candidate Feasibility Statement

(U) Analysis of the LA5-5 candidate design was accomplished utilizing a conceptual drawing and general mass property information. This is considerably less information than has been received for many of the other candidates and as such, has much larger uncertainties associated with the assessment conclusions. With these caveats in mind the LA5-5 design was assessed to be structurally feasible with modifications to the forward warhead support and possibly to the AF&F support ring.

(U) It should be noted though, that this candidate was outside the weight and center of gravity limits imposed by LMSC (see Figure 6.2-1). The added weight (i.e., higher ballistic coefficient) caused the reentry body to have a higher terminal velocity and greater total heating during normal reentry which violates MK5 heatshield criteria.

6.4.15 (U) LA5-6 STRUCTURAL ASSESSMENT SUMMARY

6.4.15.1 (U) LA5-6 Design Description

The AF&F mounting ring remains basically similar to the W88/MK5.

b(3)
DOE
DTRA

The required interface is accomplished by the addition of through connectors on the seal cover and aft closure with an interconnecting cable. The connectors and cable are the responsibility of the DOE. The connector on the aft closure will require RF and thermal protection. Other than the addition of the connector on the aft closure its design remains very similar to the W88/MK5. Candidate mass properties (RB weight and CG location) are shown in Figure 6.2-2.

(U) This design provides compatibility with DoD hardware including the modification of the AF&F. An alternate AF&F configuration using the existing AF&F would require that additional components be packaged in the RB to accommodate one of the new safety strong links. This configuration was not

although feasibility is likely. The proposed CAT-E PAL use control capability is feasible and the concept is compatible with all the missile physical and functional interfaces. The concept is close to the aerodynamic stability limit. A slight increase in weight in the forward area would improve this condition. (See Figure 6.2-1).

6.4.16.2 (U) LA5-7 Normal Reentry Structural Assessment

(U) Analysis Approach

(U) The approach used to assess the LA5-7 concept was to compare the design attributes of the forward wedge support area and the aft warhead support to designs that have already been assessed (Figure 6.4.16-1). The LA5-7 concept has an aft warhead support design that is similar to the LA5-6 concept. The LA5-6 design was extensively analyzed by finite element models. Since the LA5-7 design concept is similar to the above mentioned design, a comparison of the loads and mass properties was made to determine the feasibility of the LA5-7 design. The wedge area is similar to the LA5-6 and was assessed based on that design. The seal cover design is a complex configuration that is basically flat as opposed to the normal concaved configuration. This seal cover is similar to one assessed on another program and was assessed based on that analysis (Figure 6.4.16-1). The warhead attachment, the wedge, and the seal cover designs were assessed for the three critical MK5 V–γ trajectories (upper middle-UM, upper left-UL, and upper right-UR) by comparison.

(U) Assessment Results

(U) The assessment of the LA5-7 aft warhead support designs and wedge area reflected margins equal to or greater than the W88/MK5 design. The seal cover has positive margins based on the assessment of a configuration that had similar geometry.

6.4.16.3 (U) LA5-7 Hostile Reentry Structural Assessment

(U) Material Vulnerability Assessment

(U) For the proposed LA5-7 concept (see Figure 6.4.16-1) a stiffening sleeve was used to provide buckling strength for the aeroshell and to provide support to the warhead during structural vulnerability encounters. One issue associated with the sleeve was the response of the sleeve material to hot X-rays. Two sleeve configurations were examined just as for the LA5-6 candidate. See section 6.4.15.3 for a description of this work.

b(3)
DOE
DTRA

(U) Structural Vulnerability Assessment

(U) LA5-7 high-frequency responses were examined for the side-on impulse loading. Other candidate designs with similar configurations have shown that the impulse environment was most severe.

b(3)
DOE

(U) A DYNA3D finite element model was developed to predict the local stress response in this vicinity. The results showed that the peak stresses developed at critical points in the substrate and in the connecting bolts and bracket were below the corresponding material allowables (i.e., yield strengths).

(U) With regard to low-frequency responses the candidate was evaluated for its performance under blast loading conditions because it was more critical than cold and hot X-ray low-frequency loadings.

(U) The approach to assess the blast response was the same as that used for LA5-4 (see Figure 6.4.3-5). The centerpiece of the analysis was the low-order full-body

model dynamic analysis. The required warhead forward and aft support stiffness data was determined from separate DIAL finite element analyses. The required warhead spring and mass constants were calculated using the stiffness and mass distribution information supplied by LANL.

b(3) DOE

(U) The DOE/DoD component relative deflection responses at known physical impact locations indicated that the relative lateral deflection along the AF&F and the aeroshell substrate gap interface was most critical. The deflection value is higher than that of W88/MK5, however, it is still below the allowable.

FIGURE 6.4.17-4

(U) AFT WARHEAD SUPPORT

6.4.17.2 (U) LA5-8 Normal Reentry Structural Assessment

(U) Analysis Approach

(U) The LA5-8 design was assessed by engineering judgment based on limited details of a 8 1/2 x 11 layout shown in the "Excerpts from the Fourth SLBM Phase 2 Study Group", dated 4 March 1993. The aft warhead attachment is similar to the MK5 IH attachment. The LA5-8 was assessed based on the MK5 IH design concept. The forward support is the same as the MK5 concept and the seal cover is the MK5 design.

(U) Assessment Results

(U) It was assumed that because of the similarity of this design to the W88/MK5 attachment designs that positive margins of safety can be obtained for the LA5-8 concept. One area in the design needing additional assessment is the aft cover of the NEP. This can be refined if this candidate is pursued.

6.4.17.3 (U) LA5-8 Hostile Reentry Structural Assessment

(U) Material Vulnerability Assessment

(U) Based on the known materials included in the design, there are no material vulnerability concerns.

(U) Structural Vulnerability Assessment

(U) The LA5-8 candidate is a straightforward design concept. With the design information available it was noted that the aft warhead mount was similar to the MK5 IH mount and appears to be feasible. The forward warhead support or wedge, being similar in shape to the W88/MK5, likewise appeared to be feasible.

b(3)
DOE

(U) Additional information concerning the sequence of events associated with the NEP including the possible orientation of the various LA5-8 NEP components, during hostile environment encounters would need further assessment.

6.4.17.4 (U) LA5-8 Candidate Feasibility Statement

(U) Analysis of the LA5-8 candidate design was accomplished utilizing a conceptual drawing and general mass property information. This is considerably less information than has been received for many of the other candidates and as such, has much larger uncertainties associated with the assessment conclusions. With these caveats in mind the LA5-8 design was assessed to be feasible with modifications to the NEP case and aft cover to the case. In addition, information describing the operation (sequence of events) of the NEP would be needed if this candidate is to be further developed.

The required interface is accomplished by the addition of through connectors on the seal cover and aft closure with an interconnecting cable. The connectors and cable are the responsibility of the DOE. The connector on the aft closure, will require RF and thermal protection. Other than the addition of the connector on the aft closure its design remains very similar to the W88/MK5. Candidate mass properties (RB weight and CG location) are shown in Figure 6.2-2.

(U) This design provides compatibility with the DoD hardware including the modification of the AF&F. An alternate AF&F configuration using the existing AF&F would require that additional components be packaged in the RB to accommodate one of the new safety strong links. The configuration was not assessed, but feasibility appears likely. The proposed CAT-E PAL use control capability is feasible and the concept is compatible with all the missile physical and functional interfaces. The concept has good aerodynamic stability margins.

6.4.18.2 (U) LA5-9 Normal Reentry Structural Assessment

(U) Analysis Approach

(U) The approach used to assess the LA5-9 concept was predicated on the design attributes of the forward warhead support wedge and the aft warhead support. (See Figure 6.4.18-1). The LA5-9 concept had an aft warhead support design that is similar to the MK5 IH design, and a forward warhead support wedge that is somewhat larger but is located slightly further aft than the W88/MK5 wedge. Since these two pieces of structure were similar to the MK5 tactical design, the MK5 capability curves were used to determine the feasibility of the design. A parametric study of the MK5 tactical nub concept versus the MK5 IH bolted concept established a set of knock-down factors that were used on this assessment to adjust for the difference between the MK5 tactical and the MK5 IH designs. The seal cover is a complex design that is basically flat as opposed to the normal concaved

configuration. This seal cover is similar to one analyzed on another program and was assessed based on that analysis. (See Figure 6.4.18-1). The warhead attachment, the wedge, and the seal cover designs were assessed for the three critical MK5 V–γ trajectories (upper middle-UM, upper left-UL, and upper right-UR).

(U) Assessment Results

(U) The assessment of the LA5-9 aft warhead support design reflected margins equal to or greater than the W88/MK5 design. The wedge concept has positive margins of safety. The seal cover has positive margins based on the assessment of a configuration that had similar geometry.

(U) Structural Vulnerability Assessment

(U) The LA5-9 candidate has a "wishbone" shape aft warhead support, and its foam wedge forward support is located further aft than that of the W88/MK5 (see Figure 6.4.18-3).

(U) Only the substrate stress response in the vicinity of the aft warhead support under side-on impulse loading was examined when high-frequency responses were evaluated. This approach was selected because evaluation of the W88/MK5, a similar design, had indicated that the impulse loading produced the most severe stress.

(U) A DYNA3D finite element model was developed to predict the local stress response in this vicinity (see Figure 6.4.18-5). The results showed that the peak

b(3)
DE
DTRA

FIGURE 6.4.18-5
(U) HIGH FREQUENCY IMPULSE RESPONSE RESULTS FOR LA5-9

stresses developed at critical points in the substrate and in the connecting bolts and bracket were below the corresponding material allowables (i.e., yield strengths).

(U) The approach to assess low frequency blast response is illustrated by the flow diagram of Figure 6.4.3-5. The centerpiece of the analysis was the low-order full-body model dynamic analysis. The required warhead spring and mass constants were calculated using the warhead stiffness and mass distribution information supplied from LANL.

(U) The results showed that the highest stresses occurred near the manufacturing joint area, however, their estimated magnitudes were still below allowable limits. The DOE/DoD component relative deflection responses at potential physical impact locations indicated that the relative lateral deflections between the warhead and the aeroshell substrate were the most critical. Additional analysis of the forward support deflection is recommended.

6.4.18.4 (U) LA5-9 Candidate Feasibility Statement

(U) Analysis of the LA5-9 candidate was accomplished with the following conclusion: the LA5-9 candidate design is feasible with possible modifications to the forward warhead support.

deployment. This Phase 2 study was undertaken with the knowledge that tradeoffs with performance would likely be necessary to achieve improvements in safety and security in this highly optimized system. Those tradeoffs are discussed elsewhere in the report.

7.1.3 (U) AF&F AND ELECTRICAL SUPPORT SYSTEMS OPTIONS

(U) The AF&F and the other electrical support systems in the New Mexico Laboratories' proposed nuclear assembly packages for the MK4A address two specific Phase 2 Study issues, Use Control(UC) and Enhanced Nuclear Detonation Safety (ENDS). Specific implementation of UC and/or ENDS is addressed in the discussions and accompanying figures in the descriptions that follow for each candidate proposed.

[redacted] Three electrical configurations are proposed for the LA4 candidates on the D5 missile and two configurations on the C4 missile.

b(3)
DOE
DTRA

There are three electrical configurations proposed for the implementation of detonator enabling/safing for the LA4 candidates on the D5 missile and two configurations on the C4 missile.

(U) The first configuration proposed (C4 and D5) requires a complete rebuild of the MK4 AF&F. Most of the AF&F subsystems and components would be recovered during disassembly, tested, recertified, and reassembled into the new AF&F. The SALAD type device electrical system would be included in the expanded exclusion region inside the AF&F. A new, higher voltage thermal battery would replace the existing 500-volt battery to increase the fire set charge potential so that the existing fire set could fire slapper detonators. No additional electrical components are required inside the reentry body.

(U) The second configuration proposed (again C4 and D5) requires only minimal MK4 AF&F modification to replace the existing thermal battery with a higher voltage output unit. Additional components and systems are required within the

reentry body and the release assembly to provide appropriate power and control of the detonator enabling/safing system. An Environment Sensing Signal generating Device (ESSD) is required to generate and process unique signals that are used inside the reentry body to enable and trigger the SALAD type device.

(U) A third configuration is proposed for use on the D5 missile system only. Unique signals available at the MK5 platform interface (MK5 Data and Data Return) replace those signals generated by the ESSD assembly described in the configuration above. DoD hardware modifications are required to provide new cabling and connectors to and through the MK4 platform and the aft and seal covers.

DTRA

As noted above, the LL4-1a candidate provides IHE and a fire resistant pit (FRP). Its estimated INRAD values are shown in Table 7.2-1. b(3) DOE DTRA

[redacted] The LL4-1a candidate offers a CAT-E PAL option.

b(3) DOE DTRA

(U) The LL4-1a NEP emphasizes traditional warhead production technology, except for pit reuse. A facility to modify reused pits for use in new warheads is being developed in a cooperative effort between LLNL and the Pantex Plant. This development was motivated by the W89 program, but because of its generic utility, it has continued unabated even after the W89 program was canceled in July 1992. This effort is far less than would be required to establish a new plutonium fabrication facility. Pit reuse avoids the need for such a new facility. There are no identified issues that limit the longevity of a LL4-1a warhead. The NEP inside the MK4A has good vulnerability and hardening (V&H) characteristics.

7.2.2.3 (U) LL4-3a

7.2.2.3.1 (U) *Warhead Description*

b(3)
DOE
DTRA

INRAD values are shown in Table 7.2-1. Except for fabrication of a new pit, its producibility is good. However, because of its requirement for new pit fabrication, there is no near term prospect of its production in the DOE complex. There are no identified issues that would limit the longevity of a LL4-3a warhead. The LL4-3a NEP in the MK4A RB has good V&H capabilities.

7.2.2.3.2 (U) *Nuclear Test Status*

[redacted]

b(3) DOE DTRA

7.2.2.3.3 (U) *Summary Of LL4-3a*

(U) The LL4-3a candidate is the most robust and best performer of the LLNL/Sandia MK4A warhead designs. It also has the lowest INRAD. If new pits could be fabricated, it would be the LLNL/Sandia baseline design. However, because there is no near term prospect for its production, LL4-3a is an excursion that illustrates the benefits that come with a custom designed pit.

7.2.2.4 (U) LL4-1b, LL4-2b, and LL4-3b (New AF&F)

(U) Each of the above MK4A candidates has a "b" version with essentially the same NEP. These candidates are labeled LL4-1b, LL4-2b, and LL4-3b. In each "b" candidate the existing AF&F is replaced. This change offers the opportunity to place a second stronglink at the detonator, in addition to DSSL. This is done by replacing the booster pellets in the primary IHE with voids that will prevent initiation of the IHE, even if the detonators function properly.

b(3) DOE DTRA

The NEPs in the "b" candidates are the same as in the corresponding "a" candidates, except for the change in the booster pellets. Their development nuclear test requirements are the same as for the corresponding "a" candidates.

b(3) DOE DTRA

7.2.2.5 (U) MK4A NEP Summary

b(3) DOE DTRA

7.2.3 (U) WARHEAD COMPONENTS

7.2.3.1 (U) Electrical Systems

(U) There are three electrical systems available for the LL4:

1. A system that uses the W76 AF&F with its stronglinks and does not add any detonator safing;

2. A system that uses the W76 AF&F and adds detonator safing (DSSL) and a separate unique signal generator or auxiliary programmer;

3. A system that includes both DSSL and PEX Booster detonator safing. This system requires a new AF&F.

(U) Variants are possible within each of these themes as to how the unique signals are generated, the type of use control, etc.

DOE

FIGURE 7.2-3
(U) ELECTRICAL SYSTEM BLOCK DIAGRAM FOR MOD-D5 USING MC2912 AF&F

(U) All MK4 signals will be used as currently defined for the W76/MK4 at the field joint connector. The MK5 Data line could provide the unique signal information (including Intent) in the modified-D5 application. The proposed changes required to the MK4 adapter to obtain the in-flight unique signals for the modified-D5 application are shown in Figure 7.2-4. If the cable in the D5 adapter cannot be changed and the D5 data is not available, an ESSG would be used on D5 that would be similar to the ESSG used on C4 but optimized for D5 environments.

(U) The IFD for the W76/MK4 does not have sufficient number of pins for passing the unique signals required by DSSL. Replacing the 11-pin MK4 IFD insert with the 14-pin MK5 insert would correct this problem. This change will also require new cables to and from the IFD (i.e., on the RA and inside the RB). The additional conductors will be used to drive the DSSL directly from either an Environmental Sensing Signal Generator (ESSG) for the C4 and D5 application, or an auxiliary (in addition to the AF&F programmer) programmer for the modified-D5 application. The ESSG and auxiliary programmer will be mounted on the RA. The auxiliary programmer will receive the unique signal information from the MK5 Data line, which is available at the field joint connector with the changes to the MK4 adapter shown in Figure 7.2-4. The auxiliary programmer will use either the D5 unique signal information or a self-contained ESSG to generate the DSSL drive signal.

(U) Environmental-Sensing Signal Generator (ESSG)

(U) Portions of the environmental unique signal will be generated during powered flight and the remainder will be generated after RB separation from the RA. (The generation of the unique signal is addressed in more detail in Section 7.2.5.) While the post-separation portion of the unique signal must be generated by an ESSG on-board the RB, the powered-flight portion of the signal can be generated by an ESSG external to the RB. Locating this ESSG external to the RB allows the RB to be disconnected from the ESSG during shipping and storage, thus reducing the chance of inadvertent generation of the unique signal. The ESSGs will be based on technology similar to the W88 programmer (MC3811). The external ESSG will be located on the Release Assembly. Because it is not in the sealed volume, it will be hermetically sealed. The ESSG within the RB will be integral with the Seal Cover.

(U) The external ESSG should be located where it could be installed at the time that the RBA is installed to the missile. Figures 7.2-5 and 7.2-6 show potential locations for the ESSGs on the C4 and D5 RAs. The shipping container would be configured such that the RBA cannot be installed with the auxiliary ESSG attached. Safety could be improved further by the use of a Read-only Memory (ROM) key. This key would contain information necessary to generate the proper unique signal. The key would be configured as a simple connector. It would be installed on an ESSG connector during RBA mating to the missile and would be removed during demating.

(U) On the modified-D5, the unique signals would be supplied by the missile and the external ESSG would not be needed. However, the ESSG/programmer internal to the RB would always be present to allow the RB to be used on C4.

(U) The battery within the AF&F is not capable of driving DSSL. New batteries are required to operate the system with DSSL. One battery would be located on the RA. This battery would operate the ESSG (on C4 and unmodified D5 missiles) and advance the DSSL as the unique signal information was delivered to the internal programmer during powered flight. Another battery would be located in the RB, aft of the Seal Cover. This battery would power the programmer and ESSG within the RB and drive DSSL for the post-separation unique signal events. The on-board battery would be actuated by a signal from the external battery.

(U) The battery on the RA would be actuated by a G-Time sensor that would have a mechanical unlock mechanism. This mechanism is used to prevent premature actuation of the battery during transportation. The mechanism would be locked during transportation and unlocked immediately prior to installing the RBA onto the missile. The battery will use cobalt disulfide technology.

(U) The low voltage cable in the MK4 will have to be redesigned. The replacement cable will be a flat-flex cable. Two additional cables for the CAT-E PAL system are required. The cable from the seal cover to the aft cover will have to be replaced to accommodate the new auxiliary ESSG or programmer and battery.

(U) These candidates could also be produced without either DSSL or CAT-E PAL.

UNCLASSIFIED

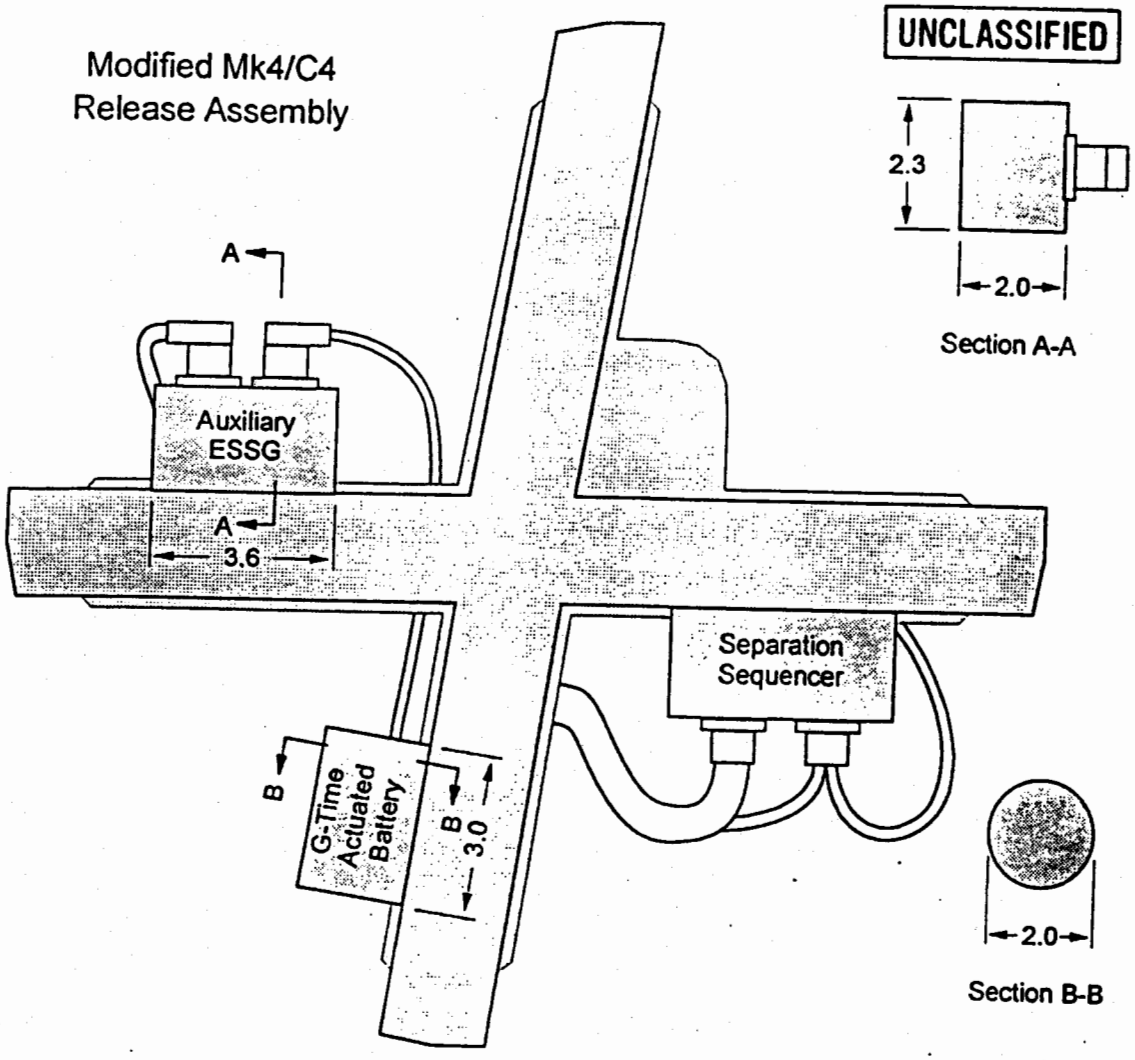

FIGURE 7.2-5
(U) ESSG MOUNTING ON C4 RA

UNCLASSIFIED

(U) The elimination of DSSL would delete the ESSG, the external programmer and the battery from the RAs and allow the use of the standard MK4 and MK5 RAs and adapter plate and cabling. The MK4A would not need the MK5 IFD insert and could use the MK4 IFD insert. The D5 MK5 Data Line would not be used.

(U) The elimination of CAT-E PAL would negate the need for the additional connector on the aft closure and seal cover and the associated cabling.

(U) The design could also be modified to incorporate Category D PAL. CAT-D PAL will require a programmer in the RB.

7.2.3.1.2 (U) *Based On New AF&F (LL4-1b, -2b, and -3b)*

(U) Block diagrams of the proposed electrical system for the MK4A using a new AF&F are shown in Figure 7.2-7 for the C4 and D5 applications and Figure 7.2-8 for the modified-D5 application. The majority of the new AF&F would be located in the same location as the old AF&F and would include a PEX system and the on-board ESSG. The only portion of the AF&F not located forward of the NEP is the fireset, which is integral with the Seal Cover. The packaging of the PEX Booster system into the new AF&F is shown in Figures 7.2-9 and 7.2-10. The PEX Booster concept and operation are described in detail in Section 5.2.5.3.

(U) The new AF&F will use technology similar to that used in the MK5 MC3719 AF&F. The ESSG/programmer in the new AF&F will use technology similar to that used in the W88 programmer (MC3811).

(U) The fireset will use capacitor discharge unit (CDU) technology similar to that used in the W87/MK21 (Peacekeeper). Because this design relies on DSSL and the PEX booster, no stronglinks are required in the fireset.

(U) The new MK4 AF&F will function much like the MK5 AF&F, and therefore require power during the entire flight of the RB. Two batteries are required; a low voltage-long life battery, and a short term negative-voltage battery. The new low voltage battery will be located in the front of the RB behind the impact fuze. The negative-voltage battery will be located in the rear of the AF&F, where the fireset was in the old AF&F.

7.2.4 (U) PACKAGING AND MOUNTING

7.2.4.1 (U) Forward Mount

(U) The three LL4 NEPs have very similar configurations and dimensions which allows their mounts to be similar to one another.

The forward mount provides both axial and lateral support. Its interface with the body section and the AF&F are identical to the W76 forward support.

b(3) DOE DTRA

(U) Like the W76, the new forward mount attaches to the NEP with a tape joint. However, because of differences between the W76 and LL4 NEPs, the tape joint is in a significantly different location (Figure 7.2-11).

(U) SECTION OF FORWARD WARHEAD SUPPORT

UNCLASSIFIED

A section of the support is shown in Figure 7.2-12.

7.2.4.3 (U) Seal Cover

(U) The sealed volume of the RB is completed by the seal cover, which is bolted to the existing substructure flange located aft of the nuclear system. Designs that do not include DSSL would use seal covers similar to the W76 seal cover. Designs that include DSSL will require a programmer; this would be mounted to the inner surface of the seal cover.

7.2.4.4 (U) Shield

b(3) DoE DTRA

7.2.5 (U) SAFETY

(U) From an IND safety perspective, all of the LL4 NEPs are the same. Therefore, they all use the same IND safety themes. The LL4 candidates provide all the modern warhead safety features of enhanced nuclear detonation safety (ENDS), IHE, and FRP. The designs can also include the additional protection provided by a detonator safing stronglink (DSSL).

(U) The W76/MK4 is the benchmark from which we would make improvements in the IND safety for MK4A candidates. The W76 encloses its fireset and trigger circuit in an exclusion barrier assembled from stainless steel and aluminum components. The entry of electrical signals through the barrier is normally controlled by routing the signals through two stronglinks in series. One stronglink is the MC2854 Accelerometer; the other stronglink is the MC2897 Decelerometer. These types of stronglinks are referred to as Environmental Sensing Devices (ESDs). The detonator leads external to the NEP

b(3)
10 USC 424

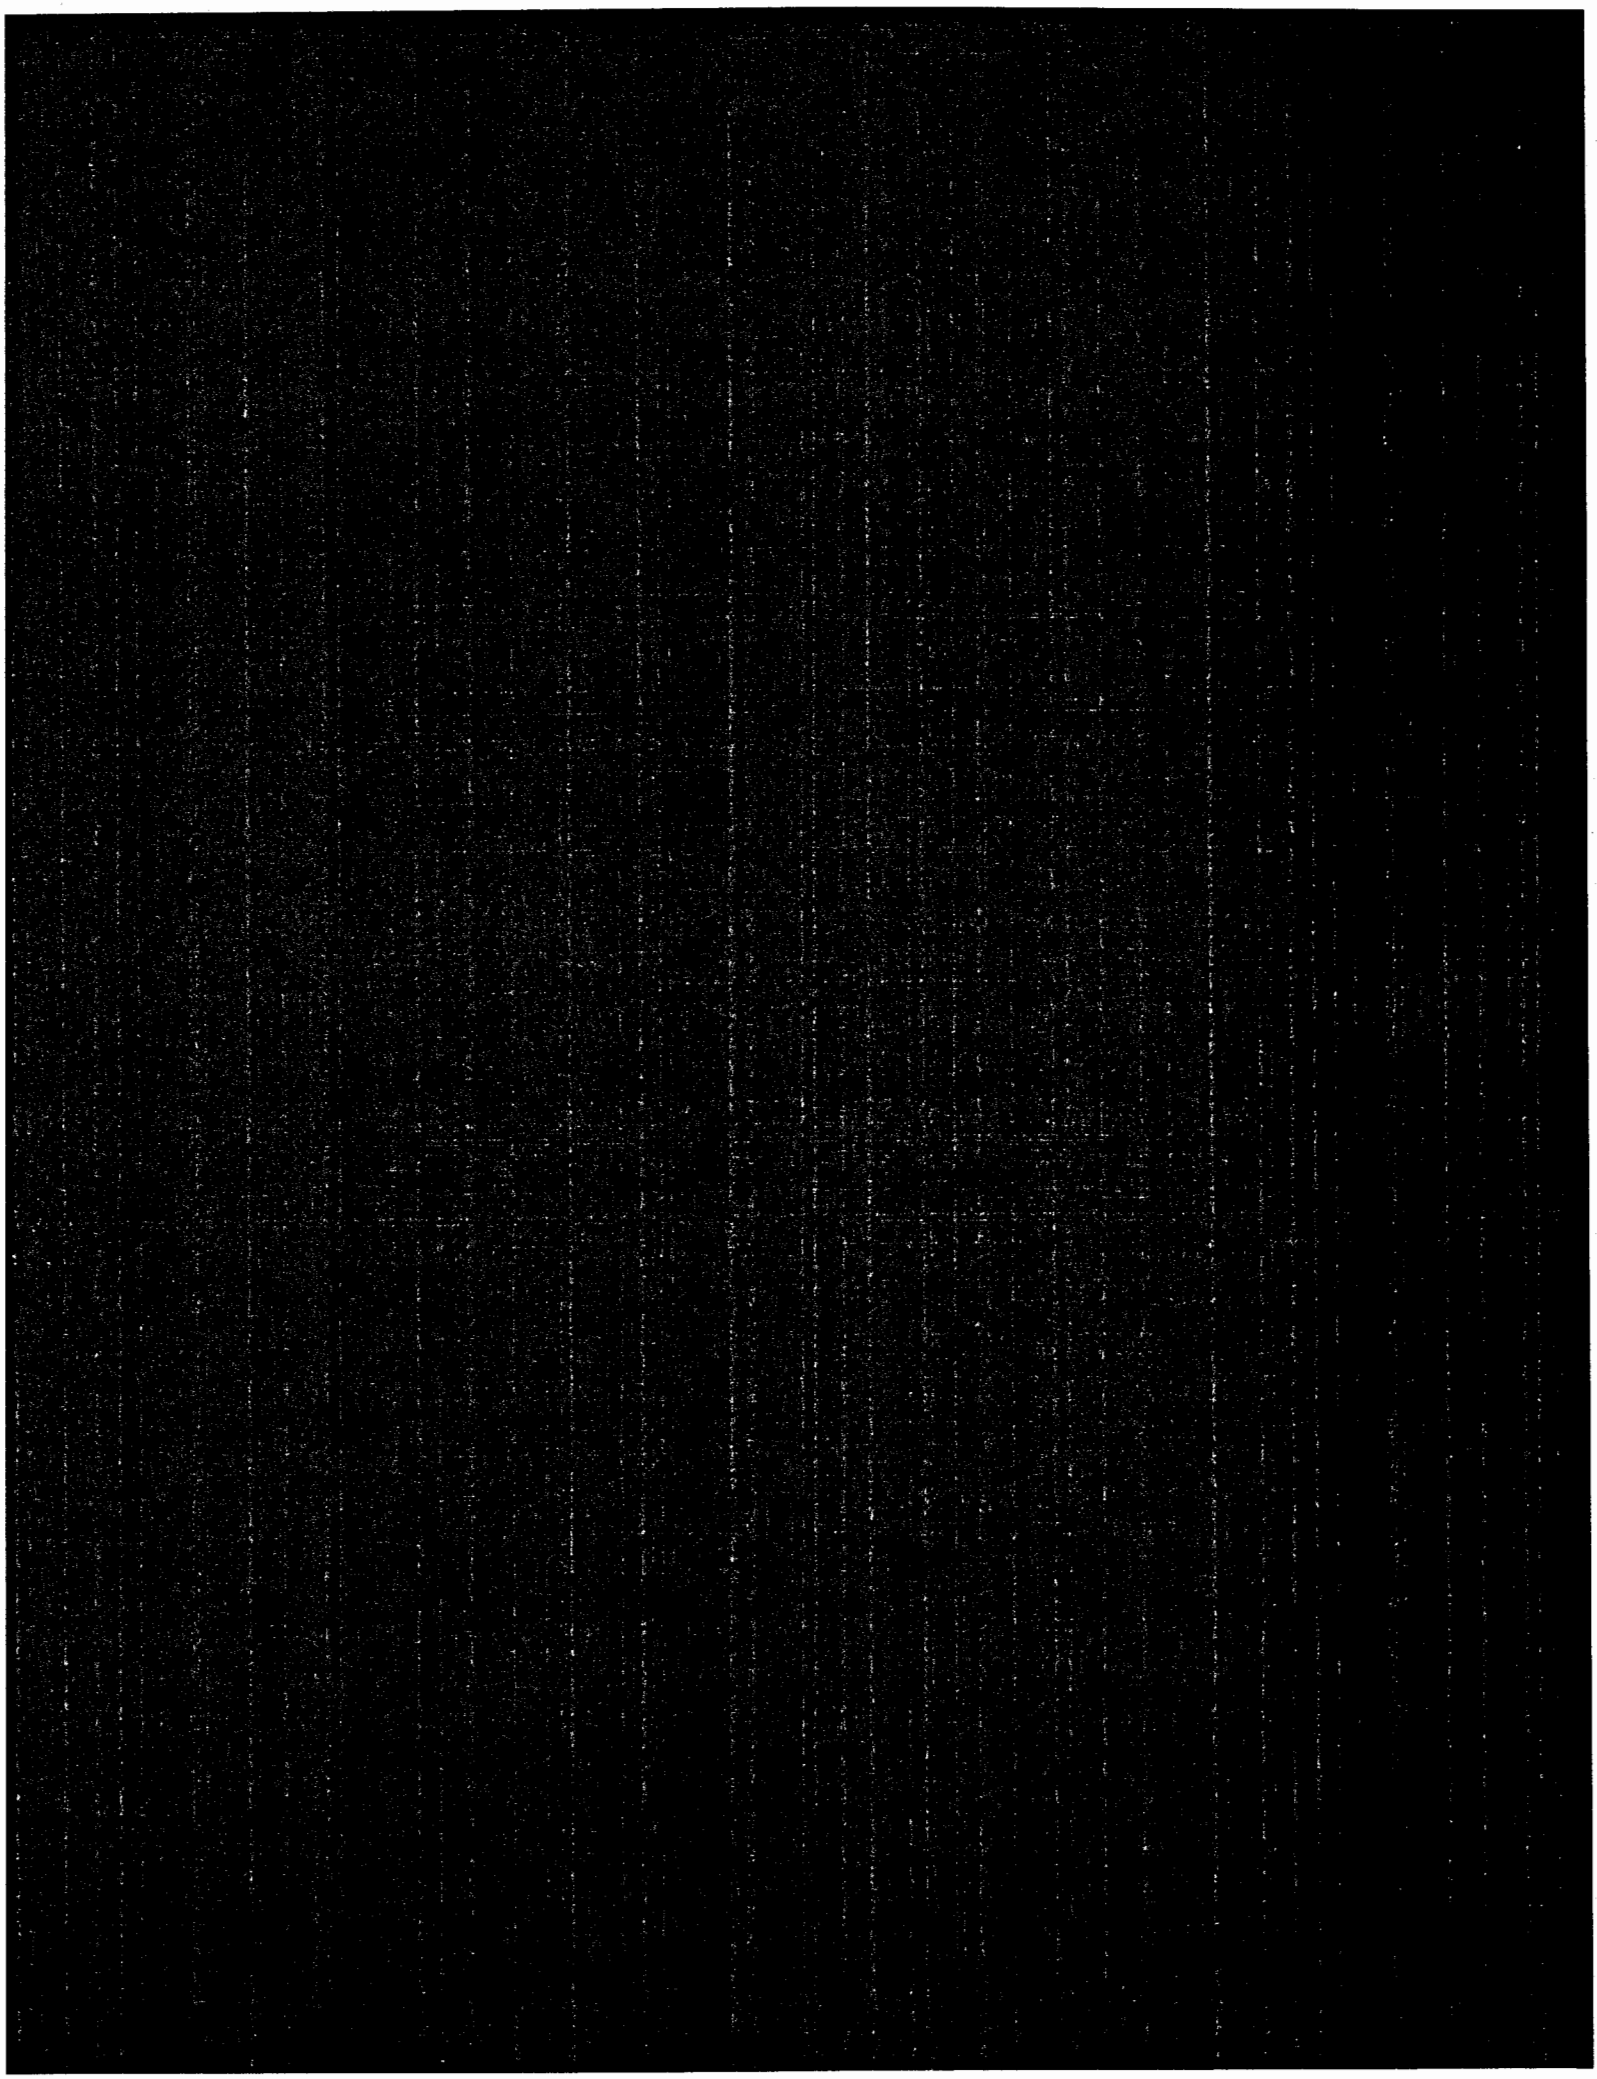
FIGURE 7.2-12
(U) SECTION OF AFT WARHEAD SUPPORT

are enclosed by the AF&F, the reentry body section (that is constructed of aluminum covered with carbon phenolic heatshield), and the aft closure and seal cover (both of which are aluminum).

(U) The LL4 designs can improve two aspects of the W76 nuclear safety theme:

b(3)
DOE
DTRA

(U) To provide positive protection even if the NEP becomes exposed in an accident, the LL4 candidates include a Detonator Safing Stronglink (DSSL) downstream of the detonator cables, within the NEP itself. As long as the DSSL has not received the correct unique signal (i.e., been prearmed), firing of the detonator bridges cannot initiate the main charge explosive.



(U) The LL4 candidates that use a new AF&F add a second nuclear safety subsystem to the NEP by incorporating PEX Booster.

DOE
DTRA
b(3)

b(3)
DTRA

These multiple event unique signals are carefully analyzed to verify that the probability of their inadvertent generation is much less than one in a million.

b(3)
DOE
DTRA

is authorized for use. This use of a human intent signal to prearm DSSL provides the optimal safety for this design. However, the C4 missile system does not have any unique signal capability and therefore is currently incompatible with this implementation. Therefore for LL4 warheads on C4, an Environmental Sensing Signal Generator would construct a unique signal by sensing a series of combinations of go/no-go environmental inputs, including acceleration and electrical signals from the missile.

b(3)
DTRA

7.2.6 (U) USE CONTROL

(U) Each of the LL4 designs is compatible with Category E PAL, Category D PAL (which requires a programmer within the RB), and command disable. These options are discussed in detail in the Use Control section of this report (Section 10.2).

b(3)
DTRA

b(3)
DOE
DTRA

7.2.8 (U) STOCKPILE AND PRODUCTION CONSIDERATIONS

(U) The LL4-1a and LL4-2a designs use standard production technology developed in previous programs. There is nothing in these designs that presents unusual production problems to the DOE complex, except for the modification of reused pits, and the development of a pit reuse production facility is underway and progressing well.

[redacted] b(3) DOE DTRA

(U) The baseline producibility comments also apply to LL4-3a, except for the pit. The pit production technology was once standard (like the W87), but with the shutdown of the Rocky Flats Plant, the DOE complex no longer has the capability to produce such pits in quantity, and there is no near-term prospect for such a capability. Thus, while LL4-3a is the best performer and has significantly lower INRAD, it cannot be produced in the present DOE complex.

7.2.8.1 (U) Use Of And Modifications To DoD Hardware

(U) This section identifies the modifications necessary to implement our candidate designs.

7.2.8.1.1 (U) *MC2912 AF&F*

(U) LL4-1a, LL4-2a, and LL4-3a can use the existing MC2912 AF&F. Tests at Sandia have shown that the existing AF&F does not have enough energy to fire slapper detonators (such as are used in DSSL). This can be resolved by changing out one of the AF&F batteries with a new higher voltage battery, or re-designing the detonators to not use slappers. Rework of the AF&Fs to exchange the battery has been studied and is straightforward requiring machining of a weld and removal of the AF&F can.

(U) The fuze settings in the existing AF&F are not optimal and changing these settings would improve the effectiveness of any of these candidates.

(U) LL4-1b, LL4-2b, and LL4-3b do not use the existing AF&F. A new AF&F is required for these candidates.

7.2.8.1.2 (U) *Aft Body Section*

(U) All of the LL4 designs use the existing MK4 Reentry Body aft sections with no modifications.

7.2.8.1.3 (U) *Nose Tip*

(U) All of the LL4 designs use the existing carbon-carbon nose tips with no modifications.

7.2.8.1.4 (U) *Forward Body Section*

(U) All of the LL4 designs require modification to the aluminum substrate of the forward body section. Ballast must be mounted in the forward end of the reentry body to keep the overall RB center of gravity within specification.[3] The ballast could be attached to the forward body section, incorporated into a new fuze shield, or incorporated into a new or repackaged AF&F (for LL4-Xb candidates). LMSC analysis shows that substantial ballast (~10 lb) can be attached to the anvil of the forward section in the void area between the forward body section and the contact fuze on the AF&F. This is the minimal amount of modification that would be required for any of the LL4 designs.

7.2.8.1.5 (U) Aft Closure

b(3)
DOE
DTRA

7.2.8.1.6 (U) *Release Assemblies*

(U) All the LL4 designs are compatible with the existing MK4 release assemblies. The candidates that use the existing AF&F and do not include DSSL can use the existing release assemblies without any modification to the RAs. However, any of the designs with DSSL will require components mounted to the RAs, e.g., ESSG, battery, and battery actuator. These components weigh about 3.5 pounds with an ESSG and about 1.5 pounds without an ESSG. These weights have not been included in the RB weight but should be considered in calculating missile and RB range capabilities. The components that must be mounted on the RAs are described in Section 7.2.3.1.

(U) Changes to the MK4 to D5 adapter cable to provide human Intent unique signals to the MK4A are discussed in Section 7.2.3.1.

7.2.8.1.7 (U) *RB Internal Cabling And In-Flight Disconnect*

(U) All of our MK4A designs using the W76 electrical system (MC2912 AF&F, no DSSL) can use the existing MK4 (11-pin) IFD and cable.

(U) Any of the candidates with DSSL will require the use of the MK5 (14-pin) IFD connector. The connector will need a right-angle backshell inside the aft closure to provide clearance for the components in the aft compartment. These designs also will need a new cable between the IFD and the seal cover to support the electrical systems that are shown in the schematics in Section 7.2.3.1.

7.2.8.1.8 (U) *Antenna System*

(U) The existing antenna system (antennas, cables, splitters, etc.) may be used without any changes for the LL4 designs that use the existing MC2912 AF&F.

(U) We have only briefly assessed the compatibility of the existing MK4 antenna system with a new AF&F. The new AF&F is based on the radar technology from the W88. The MK5 radar operates at different frequencies than the MK4 antennas are designed for. Whether it would be better for the new radar to operate at the MK4 frequency (compatible with the MK4 RB RF system) or operate at the MK5 frequencies (compatible with the MK5 radar, but not compatible with the MK4 antenna cavities) has not been

evaluated. We believe that the existing windows would not need to be changed. The performance of the modified system would not be as precise as the MK5, but could be better than the MK4.

(U) We have attempted to avoid packaging interference of the war reserve designs with the existing W76 JTA antenna system. However, we have given priority to the war reserve design -- changes to some of the JTA RF system cable routing and component mounting may be necessary for some of these candidates.

7.2.8.2 (U) Shipping And Storage Container

(U) The LL4 designs are compatible with the existing MK4 shipping and storage container.

b(3) DOE DTRA

7.2.8.3 (U) Lifetime

(U) The comments relative to the lifetime of the LL5 candidates (Section 5.2.8.3) apply to the LL4 designs as well.

7.2.8.4 (U) Reliability

The reliability estimates for the LL4 candidates are shown in Table 7.2-2.

The estimates in the Table were calculated

b(3) DOE DTRA

using the differences in the unreliabilities of candidate components relative to the corresponding W76 components.[4]

7.3 (U) THE 10 QUESTIONS OF DoD INSTRUCTION 5030.55

1. (U) What nuclear devices in production or under development appear to meet the requirement? What are the advantages and disadvantages of each? If no qualified devices are under development or in production, what are the characteristics of conceivable warheads that would meet this requirement?

   (U) No devices are in production or under development that meet the requirements. One existing device can be adapted to the MK4 RB with space and volume available for hazard protection.

   (U) Conceivable warheads that would meet the requirement(s) must provide increased safety over existing SLBM warheads, survive specialized environments of strategic reentry systems, and package in existing RBs.

2. (U) Considering only the development of this particular warhead/bomb, and without regard to other programs that might be conducted concurrently, what is the estimated length of time required for development after DoD request commencement of a Phase 3 development engineering project?

   (U) For pit reuse candidates, 5 year Phase 3, plus 2-3 years Phase 4 and Phase 5 first production before delivery to the DoD. If plutonium fabrication is required, delivery to the DoD would begin in over 10 years.

3. (U) In the context of the overall atomic energy program, what time scales might be expected for development after Phase 3 authorization during the course of a normal program? What technical development problems would be involved if the time scales were significantly decreased?

   (U) Same as above.

   (U) Decreased time scales would increase risk of fielding a warhead with a design flaw that would prevent meeting performance, surety or reliability goals.

4. (U) What development problems can be foreseen that appear difficult to solve? Do any problems require development effort on a scale that is greater or less than normal?

b(3) DOE DTRA

[redacted] Candidates without this type of pit would not require this new facility.

5. (U) What special training operational, or logistical problems are foreseen concerning the warhead that should be considered for Phase 3 development engineering?

(U) The inclusion of use control features will impact the Navy's current logistics and operations.

6. (U) What, if any, additional experimental or theoretical investigation is required to establish feasibility?

(U) Beyond-one-point-safety analysis has not been performed for any candidate during Phase 2. Selection of a candidate would mean additional theoretical and possibly experimental investigation would be required.

7. (U) What is the technical evaluation and/or recommendation made by the DOE representatives concerning nuclear testing prior to weaponizing the device for stockpile?

(U) None of the MK4A candidates can be developed without further nuclear testing. See Section 12.3 for a summary.

8. (U) What possible technical or economic advantages or nuclear materials savings would accrue from reasonable warhead/weapon system tradeoffs and changes in the requirements stated in the authorization for the Phase 2 feasibility study such as use of "natural" versus specified yields, alternative warhead or limited life

8. COMPATABILITY OF MK4A CANDIDATES W/WS

8. (U) COMPATIBILITY OF MK4A WARHEAD CANDIDATES WITH THE WEAPON SYSTEM

8.1 (U) INTRODUCTION

(U) In June of 1992, a MK4A Phase 2 (Design Feasibility) effort was kicked off using the groundrules of Table 6.1-1. As part of this effort LMSC 1) defined allowable mass/center combinations within which the DOE laboratories could create various alternative warhead concepts and 2) assessed the feasibility and compatibility of each candidate concept with the MK4 on the C4 and D5 missile systems.

(U) Section 8.2 will summarize the analysis which produced the boundaries seen in Figure 8.1-1. Each of the boundaries represents limitations imposed by a component of the overall missile system. Section 8.2 will also describe the principal limits imposed by the MK4 on C4 or D5.

8.2 (U) MASS PROPERTIES LIMITATIONS

(U) This section summarizes the MK4A RBA and C4 or D5 missile component limitations imposed on the design RB candidates. Each of the limiting boundaries shown in Figure 8.2-1 will be identified and the limiting mechanism called out. The MK4A limits are as follows:

- Release assembly structural limit during first stage ignition
- Reentry body aerodynamic stability (during reentry)
- Maintain current MK4 Interface Control Drawing (ICD) minimum weight limit

For MK4A, all missile related limits were driven by the D5 missile.

8.2.1 (U) POWERED FLIGHT

(U) Several missile events were investigated during the early portion of Phase 2, that is, during the time the design space was defined. The impact of these events on RBA performance was assessed and limits drawn. The environments of concern include the following: 1) a stowage shock event; 2) underwater launch;

b(3)
DOE
DTRA

FIGURE 8.2-1
(U) MK4A MASS PROPERTIES LIMITATIONS

3) first stage ignition and flight; 4) second stage ignition and flight; and 5) post boost flight and RB separation. Third stage ignition and flight were not seen as potential driving environments.

[redacted] Structural Mechanics evaluated several tactical MK4/D5 payload configurations with the objective of finding the limiting conditions to be imposed on the MK4A RBA on the D5 missile.

b(3)
DOE
DTRA

8.2.2 (U) DEPLOYMENT/SEPARATION MECHANICS

(U) During the design space definition process no limiting condition was identified for separation mechanics which would further reduce the design space of Figure 8.2-1. Reentry body separation velocities and spin rates all varied as expected as weight and CG combinations were evaluated, but again no limiting condition was found.

8.2.3 (U) AERODYNAMICS

(U) Reentry Aerodynamics assessed the MK4 RB's ability to maintain basic stability as weight and CG were varied. Aerodynamically, there was no concern and

therefore no limitation for the CG in the most forward possible position (i.e., towards the nosetip). The objective was to define the most aft CG position for possible MK4A candidate designs, while still maintaining a positive static margin and hence a stable RB for the current flight environment ranges.

(U) The analysis concentrated on the UL null range and the LL zero angle of attack deployments as the trajectories that would set the CG requirements. For null range deployment minimum static margin occurs during high altitude reentry, while for zero angle of attack minimum static margin occurs at low mach numbers at impact (as the mach number decreases, the center of pressure moves forward toward the center of gravity).

(U) The aerodynamic analysis employed a Monte Carlo procedure to probabilistically determine the static margin. Nine weight/CG configurations were analyzed to define the limits shown in Figure 8.2-1. For the MK4A candidates the stability limit was initially selected to be 0.1% static margin, similar to the MK4. Given the inherent uncertainties which came with extrapolating aerodynamic performance at increased RB weights, an uncertainty area was defined which accounted for these uncertainties and which provided the Design Laboratories with a design space which encouraged them to keep the CG as far forward as possible.

8.2.4 (U) THERMODYNAMICS

(U) One of the concerns that was investigated for the MK4A RB Phase 2 candidates was the heatshield and substrate temperature performance. Increasing the total RB weight will increase the RB ballistic coefficient and accordingly the reentry velocities. The increased velocities will in turn increase the heat rates and potentially the total heating on the body (increased velocities will also reduce the down time, therefore a trade-off is made with heat rate and time in the atmosphere).

(U) Three separate regions in the aeroshell have temperature limitation criteria. First, the aluminum substrate temperature; second, the temperature of the bond material between the substrate and the heatshield; and third, the heatshield temperature 50 mils from the bondline. These criteria are not a limitation for the

MK4A candidates for principally two reasons: 1) the aeroshell cone angle is lower for the MK4A; and 2) more importantly, the MK4A RB has no weather cloud specification as a design requirement.

8.2.5 (U) ADDITIONAL LIMITATIONS ANALYSES

(U) In order to increase confidence in the calculated limitations and to assure ourselves that as many as possible of the design drivers had been investigated several other reentry body and missile body analyses were performed. None of the analyses described in this section limit the design space except the ICD minimum weight limit, although other limits exist just outside of the limits shown in Figure 8.2-1.

(U) MK4A Nosetip Erosion

(U) Performance of the MK4 CMT nosetip was evaluated relative to the variations in reentry body weight and center of gravity. Approximately 20% additional weight could be accommodated before the nosetip overhang would be used up and a limit imposed. It should be noted that the increased weight would result in an increased ballistic coefficient (higher reentry velocities) and that the stagnation pressure seen by the nosetip would be larger than current flight test experience.

(U) MK4A Nosetip Thermal Strains

(U) As part of the MK4A Phase 2 study, analysis was performed to qualify the MK4A CMT graphite nosetip over the entire velocity-gamma (V–γ) map for a 20% increase in reentry weight. In this study, the finite element structural analysis results together with failure criterion were used to evaluate the structural reliability. This failure criterion is based on statistical theory and considers multi-axiality of stress states, surface and internal flaw equivalence, grain orientation (across the grain and with grain), volume of tensile stress, and temperature effects.

(U) The analytical results indicate the structural reliability (probability of survival) exceeds 0.999 over the entire V–γ map for both the MK4A (20% increase in reentry body weight) and the MK4 tactical (nominal weight).

(U) MK4A Thruster Pad Stress

(U) With the increased weights being considered for candidate MK4A RBs, the resulting stress levels in the RB thruster pads were investigated. For the design space weight increases, thruster pad stresses remained below critical levels and therefore, was not a limiting issue.

(U) MK4A Heatshield Char Sloughing

(U) One area which has on-going analysis is char loss or char sloughing. The MK4 forward heatshield wrap direction (forward-facing) is known to experience sudden loss of the char-layer during flight on severe reentry trajectories (Upper-Middle). In the extreme, loss of the insulation performance of the char could lead to excessive temperature to the RB forward structure. There are studies underway to better understand char loss and the potential for multiple char losses. As criteria for char loss are established, they will be applied to the Phase 2 warhead designs to determine if a weight increase constraint should be adjusted.

(U) MK4A Moments of Inertia Variations

(U) In order to increase confidence in the calculated limitations and to assure ourselves that as many as possible of the design drivers had been investigated, several other reentry body and missile body analyses were performed. None of the analyses described in this section limit the design space except the ICD minimum weight limit, although other limits exist just outside of the limits shown in Figure 8.2-1.

(U) C4/D5 Nose Fairing and Third Stage Clearances

(U) An RB clearance analysis was made to see if the proposed Phase 2 weight/CG limits could cause any RB contact with the nose fairing (N/F) or third stage (T/S) motor during any stowage or boost phase events. For Phase 2, a weight/CG upper limit was defined for allowable designs (limited by the reentry body separation bolts, (see Section 8.2.1). The largest RB motions for the tactical D5 missile payloads occurred during the first stage motor ignition transient.

(SFRD) The critical MK4A D5 missile payloads (7 and 8 body configurations) were evaluated because these produced the largest RB radial loads. For these MK4A payloads and mass properties, there was no contact between the RB and N/F or T/S motor.

8.2.6 (U) MASS PROPERTIES SUMMARY

(U) The design space defined by the above mentioned limiting phenomena and shown in Figure 8.2-2 constituted the boundaries for the Design Laboratories. As noted on the figure, some areas in the weight/CG space were not assessed, but concepts would be evaluated case by case. All MK4A designs were in the appropriate design space.

8.3 (U) ELECTRICAL COMPATIBILITY

(U) This section describes the electrical compatibility assessments performed on the MK4A candidates. These assessments are divided into two sections. Section 8.3.1 describes the functional interface compatibility assessment which evaluates compatibility between the MK4A candidates and the C4 and D5 missiles. This section also includes a physical interface compatibility assessment of electrical components associated with the MK4A candidates. Section 8.3.2 addresses compatibility between the MK4A RBA and the existing W76/MK4 normal, abnormal, and hostile electrical environments, all of which were incorporated into the WXX/MK4A STS. Descriptions of MK4A use control features and their associated impacts on the C4 and D5 missile systems are provided in Section 10.

8.3.1 (U) FUNCTIONAL AND PHYSICAL INTERFACE COMPATIBILITY ASSESSMENTS

(U) The functional and physical interface compatibility assessments were top level evaluations which examined the functional and physical interface requirements of each of the MK4A candidates. Functional block diagrams of each of the candidates electrical systems and design similarity between the existing MK4 interfaces and the MK4A were used as a basis for the assessment because complete electronic system definition for any of the MK4A candidates has yet to be completed.

(U) The Phase 2 groundrules require that no changes are to be made in the physical or functional interfaces to the C4 and D5 missiles, except for software changes in fire control.

LANL/Sandia Candidates

(U) The electrical systems for LA4-1 and LA4-2 are identical, except for the addition of use control features on LA4-2. The electrical systems of candidates LA4-1 and LA4-2 are presented in the three following configurations:

A. New AF&F with Integrated Safing (C4 and D5)

(U) Electrical configuration A is based on a new AF&F design. The additional safety features are integrated into the new AF&F design resulting in no change to existing missile or MK4 RB cabling or connectors. This system is fully compatible with both the C4 and D5 missiles since it only requires existing MK4 electrical signals for operation. Therefore, this electrical system configuration is feasible based on functional and physical interface compatibility.

B. Modified AF&F: ESSG on RA (C4 and D5)

(U) Electrical configuration B is based on a modified AF&F design. It utilizes an Environmental Sensing Signal Generator (ESSG), battery, and G-switch mounted on the release assembly which provides the unique signals. This system is fully compatible with the C4 and D5 missiles since it only requires the existing MK4 electrical signals for operation. Therefore, this electrical system is feasible based on functional interface compatibility.

(U) This configuration requires a new sixteen pin IFD connector to accommodate the additional signals from the ESSG. A new connector is required since the existing connectors only have 14 pins maximum. This connector change does violate the Phase 2 groundrules.

(U) This sixteen pin system could be modified with the addition of multiplexing/ demultiplexing components in order to utilize a fourteen pin IFD connector, but there are potential weight and CG penalties associated with this modification which have not been fully assessed.

C. Modified AF&F: Utilizes MK5 Data Signals (D5 Only)

(U) Electrical configuration C like configuration B is based on a modified AF&F. It utilizes the MK5 data/data return lines in place of the release assembly mounted ESSG components to provide inflight data. To provide these signals to the MK4 requires modification to the "MK5 to MK4" adapter cable on the D5 missile. This violates program groundrules and would require further assessment.

LLNL/Sandia Candidates

(U) The electrical systems for the LLNL/Sandia candidates are provided in two configurations; one which utilizes an ESSG to provide the unique signals and one which utilizes the MK5 data signals from the D5 missile. The LL4-1a, LL4-2a, and LL4-3a utilize the existing MK4 AF&F which requires a separate DSSL driver, and the LL4-1b, LL4-2b, and LL4-3b candidates utilize a new MK4 AF&F which contains an integrated DSSL driver.

A. Existing AF&F: ESSG on RA (C4 and D5)

(U) Electrical configuration A is based on the existing MK4 AF&F. It utilizes an ESSG, G-Time actuated battery, and a mechanical lock mounted on the release assembly. These components are required to provide the unique signals. This system is fully compatible with the C4 and D5 missiles since it only requires the existing MK4 electrical signals from the missile for operation. It requires a fourteen pin connector to accommodate the three extra signals from the ESSG. No issues have been identified with this configuration; therefore, this electrical system is feasible based on functional and physical interface compatibility.

B. Existing AF&F: Utilizes MK5 Data Signals (D5 Only)

(U) Electrical configuration B like configuration A is based on the existing MK4 AF&F. It utilizes the MK5 data/data return lines in place of the release assembly mounted ESSG components to provide inflight data. A mechanical lock and G-Time actuated battery are also mounted on the release assembly. It requires a fourteen pin IFD connector to accommodate both the MK5 signals and the additional signal from the G-Time switch. To provide these signals requires modification to the "MK5 to MK4" adapter cable on the D5 missile.

8.3.2 (U) ENVIRONMENT COMPATIBILITY ASSESSMENT

(U) The environment compatibility/feasibility assessment was conducted to evaluate the compatibility between the STS normal, abnormal and hostile environments of an electrical nature and the MK4A candidates.

8.3.2.1 (U) Normal and Abnormal Environment Assessment

(U) The only normal environment of an electrical nature in the MK4A (and MK4) STS is the electromagnetic radiation environment (EMR). This environment also becomes an abnormal environment in the event the RB protective RF shield becomes damaged. The EMR environment includes an average power specification which is an adaptation of the Hazards of Electromagnetic Radiation to Ordnance (HERO) specification (Mil-Std-1385B), a peak power specification, an environment for an RB connected to test equipment or disassembled, and a deperming/degaussing environment. The two concerns associated with EMR are (1) the inadvertent initiation of ordnance devices, and (2) damage to electronic circuitry.

(U) Generally, EMR protection involves the shielding integrity of the RB which consists of the aluminum substrate and aft closure in addition to all the grounding, bonding, and shielding practices implemented in the original W76/MK4 design. Since these components and practices remain unchanged for the MK4A, and the MK4 margins for the environments are quite large, all of the MK4A candidates are feasible with respect to EMR. Design feasibility for any safing components located outside the aeroshell is not an issue as long as the same level of hardness is

incorporated into package design, especially if these packages contain sensitive electronic components or ordnance devices. Consequently, achieving feasibility with regard to EMR for all the MK4A candidates is not a concern.

(U) Protection against the lightning environment is mainly influenced by the same design attributes mentioned in regard to EMR. In addition to the aforementioned design attributes, the lightning arrestor connector (LAC) provides electrical protection by its voltage breakdown characteristics as demonstrated during MK4 development. Consequently, if this connector is used and similar grounding, bonding and shielding design attributes are implemented during the incorporation of additional electrical components as part of the MK4A program, feasibility with regard to the lightning environment should not be a concern for any MK4A candidate.

8.3.2.2 (U) Hostile Environment Assessment

(U) Electromagnetic effects such as electromagnetic pulse (EMP) are substantially mitigated by the shielding integrity of the RB. Since there are large margins associated with these environments and the grounding, bonding and shielding attributes associated with the MK4 aeroshell are unchanged, there are no issues associated with achieving feasibility for any candidate.

8.4 (U) INDIVIDUAL CANDIDATE STRUCTURAL ASSESSMENTS

(U) The approach taken to assess the structural feasibility of the individual Phase 2 candidate designs is illustrated in Figure 6.4-1. As shown, when the candidate designs were received an initial screening occurred which evaluated whether the candidate design fit within the weight and CG design space described in Section 8.2 (see Figure 8.2-1). Included in the screening was a check to see if an adequate set of analyses information was provided (i.e., candidate drawing, mass properties, mass distribution and stiffness). Then two sets of analysis were performed, one covering the candidate response to the normal reentry environments of the MK4A STS and one covering the candidate response to the hostile environments of the MK4A STS. The normal reentry analysis was performed first because of its more rapid

turn-around time. Feedback was then made to the Design Laboratories through the Design Integration Technical Working Group (DITWG). This feedback included both normal and hostile/vulnerability inputs.

(U) The approach taken by the normal and hostile/vulnerability reentry assessments is provided below. Both normal reentry and hostile reentry analyses produced statements of feasibility which are summarized in Table 8.4-1.

TABLE 8.4-1
(U) SUMMARY OF MK4A CANDIDATE
STRUCTURAL FEASIBILITY STATEMENTS

UNCLASSIFIED

Candidate	Feasibility	Comments
• LL4-1A	• Feasible as Proposed	
• LL4-1B	• Feasible with Potential Mod.	• AF&F Support Ring
• LL4-2A	• Feasible as Proposed	
• LL4-2B	• Feasible with Potential Mod.	• AF&F Support Ring
• LL4-3A	• Feasible as Proposed	
• LL4-3B	• Feasible with Potential Mod.	• AF&F Support Ring
• LA4-1	• Feasible with Reservations	• Insufficient Data to Adequately Assess
• LA4-2	• Feasible with Reservations	• Insufficient Data to Adequately Assess

(U) Normal Reentry

(U) The approach utilized during the normal reentry assessment consisted of the information flow illustrated in Figure 6.4-1 which culminated with the structural assessment. Existing MK4 and MK5 ground and flight test data, extensive reentry body design experience, design similarity and finite element modeling of the candidates were the tools used for analysis. Table 6.4-2 shows the analytic approach taken which was a function of the candidate design data received and the similarity of the design to past experience.

(U) Two reentry body to NEP design areas were of most importance to the normal reentry assessment. The configuration of the forward warhead support (or wedge) and the aft warhead support (or mount). The method of attachment and the type of material utilized each contributed in determining the analysis approach chosen. All of the candidate designs had common components in these two areas which aided in completing all of the analysis associated with twenty six or more candidates within the time allotted.

(U) Hostile Environments Approach

(U) To expedite the feasibility assessment, LMSC made maximum use of the available MK4 and MK5 RB analytical models developed from the prior MK4 and MK5 programs. One model used was the DYNA3D MK4 full-body model. This model was used as appropriate during the assessment considering: 1) the required degree of accuracy, and 2) the possibility of establishing concept feasibility by analogy/similarity and by inference from previous analysis and test experience.

(U) In order to accommodate the assessment of the large number of candidates that have been generated during the Phase 2 program, LMSC utilized similarity in the candidate's forward and aft mounting design features to assemble them into two groups for the MK4A candidates. This grouping was done to more efficiently analyze the many proposed candidates. As successive candidates from these groups were analyzed the performance/response of the aeroshell due to the common design feature was better understood and this understanding was then applied to subsequent candidate assessments. This increased understanding also applied to

identifying the hostile environment which most stressed the candidates and their common design feature. Figure 8.4-1 illustrates the two candidate groups associated with the MK4A.

(U) The baseline designs for all six LL4-X candidates include an Advanced Heather gas transfer system, although two other gas systems were available for use. During the LMSC vulnerability assessment the baseline system was utilized in the full-up analyses for each of the candidates. LMSC evaluated the LL4-1a design to see if variations in the gas transfer system would significantly alter component response. It was found that, for the weight variations seen between the three gas systems, component responses were similar and therefore, the feasibility statement made for each of the baseline systems apply for all of the possible gas systems.

(U) MK4A Single Forward Support Group

(U) For the MK4A Single Forward Support Group both the forward and aft support designs were significantly different from those of the W76/MK4. Therefore, a coupled full-body DYNA3D analysis was performed for two representative concepts, LL4-1a and LL4-1b. All three hostile environments, cold X-ray impulse, hot X-ray TSR and blast, were analyzed. The feasibility of the remaining concepts in this group was assessed based on similarity to these two candidates.

(U) MK4A W76/MK4-Like Support Group

(U) For the MK4A W76/MK4-Like Support Group both the forward and aft support designs are similar to the W76/MK4 design. The only concept in this group was LA4-1.

(U) The analysis approach chosen for each candidate was dependent on the design data provided. Table 6.4-2 illustrates the various types of data (levels of design definition) that were received from the DOE Laboratories and the associated aeroshell structural analysis approach(s) that could be taken. As can be seen from the table the level of design detail covers the spectrum of finite element model (FEM) to a sketch or drawing. Once an approach was identified the objective, as stated earlier, was to assess the design response to the hostile environments defined in the respective STS documents and to provide a statement of feasibility.

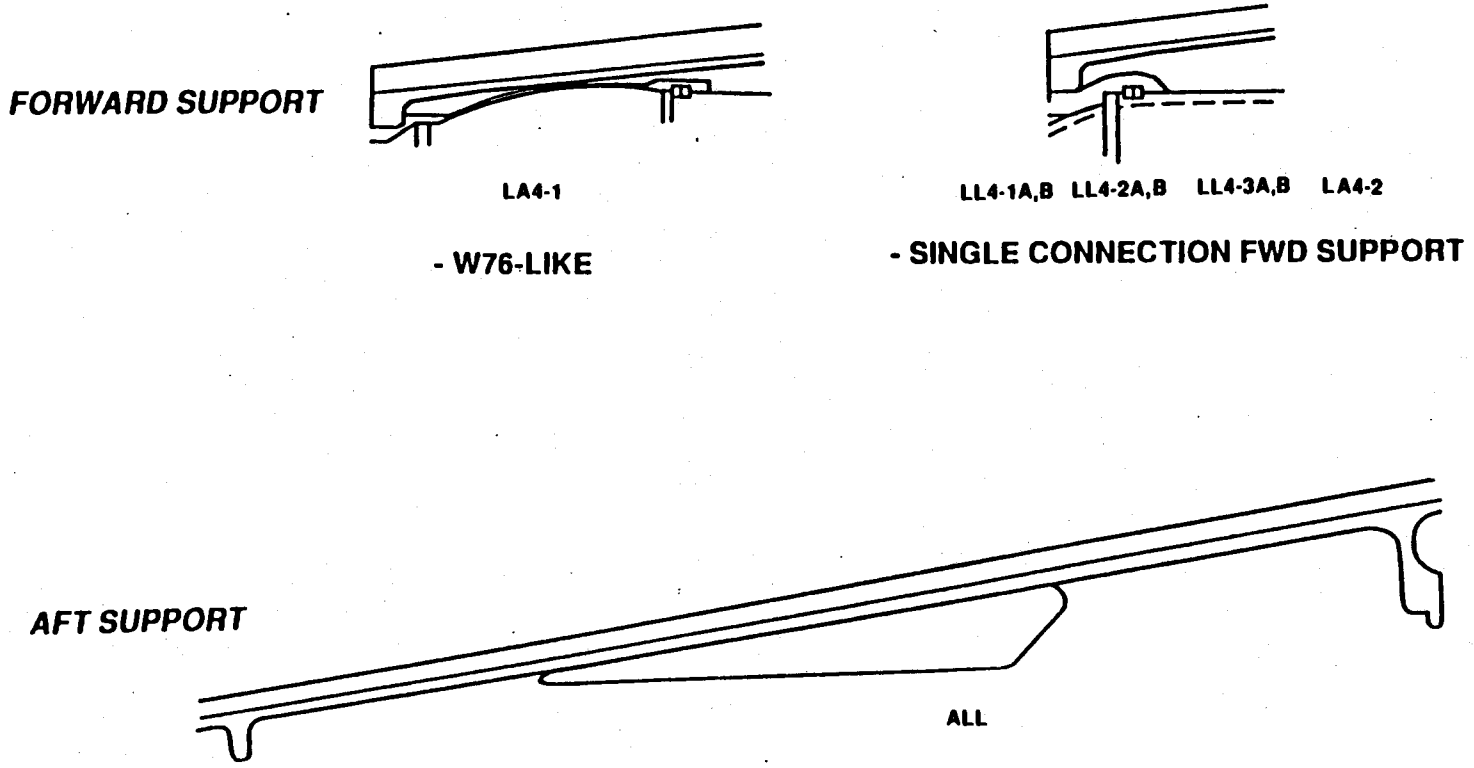

FIGURE 8.4-1
(U) MK4A GROUPS: SINGLE CONNECTION & W76-LIKE FORWARD MOUNTS

UNCLASSIFIED
UNCLASSIFIED

(U) The statements of feasibility were structured so as to cover the range of possible analytic conclusions, and are provided below:

1) the design is feasible as proposed or feasible with identified modifications,
2) the design is feasible with reservations,
3) the design is not feasible, or
4) insufficient data provided to adequately assess the candidate.

The second statement covers candidates where the identified design modification may not have a high level of confidence, or where the candidate requires a reduction in the hostile environment in order to be feasible, or where a reduction in candidate weight/center of gravity is required for candidate feasibility.

(U) Inherent in a Phase 2 study are uncertainties due to design maturity and uncertainties in modeling the performance of new design configurations. With this level of uncertainty, results which indicated yielding of component hardware were identified and design solutions recommended.

(U) Scope

b(3)
DOE
DTRA

(U) Structural vulnerability assessments of the reentry body aeroshell included the following: 1) evaluation of the relative deflection of DoD/DOE components (i.e., AF&F to aeroshell substrate, NEP to seal cover, and NEP to aeroshell substrate), 2) evaluation of forward warhead support stresses, 3) evaluation of aft warhead

support stresses, 4) evaluation of forward and aft substrate yielding and buckling at critical locations along the aeroshell, 5) evaluation of manufacturing joint region yielding and 6) evaluation of nosetip dynamic fracture. Each of the above mentioned responses can be caused by terminal air blast, side-on hot X-ray thermal structural response (TSR) and/or side-on impulse from cold X-ray encounters.

(U) Large relative deflections of the components inside the RB can cause physical impact and cable crushing during vulnerability encounters. Excessive stresses produced in the RB components can cause loss of structural integrity (i.e., yield or failure).

(U) In the following sections a summary of the vulnerability assessment made for each candidate will be presented, including a statement of feasibility regarding the candidate's material and structural responses to the MK4A hostile environments.

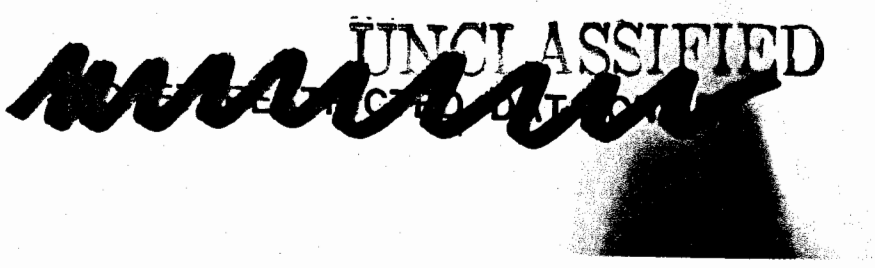
The required interface is accomplished by the addition of through connectors on the seal cover and aft closure with an interconnecting cable. The connectors and cable are the responsibility of the DOE. The connector on the aft closure will require RF and thermal protection. Other than the addition of the connector on the aft closure its design remains very similar to the W76/MK4. Candidate mass properties (RB weight and CG location) are shown in Figure 8.2-2.



(U) For either the MK4/D5 or MK4/C4 RB configuration some modification to the RBA would be required to accommodate the use of an additional nuclear safety strong link. An additional 1 to 3 components would need to be mounted on the RA to activate and power the additional strong link. The MK4 IFD needs to be replaced by a MK5-size IFD insert (to accommodate the additional pins required for the safety components). New RB and RA cable assemblies would need to be fabricated.

(U) LL4-1a requires some forward ballasting to meet the mass property design space limit. This task can be accomplished by either DoD or DOE.

DOE
DTR

FIGURE 8.4.1-5
(U) FWD SHELL MODIFICATION

8.4.1.2 (U) LL4-1a Normal Reentry Structural Assessment

(U) Analysis Approach

(U) The LL4-1a concept was assessed early in the assessment period. The approach used to assess the LL4-1a concept was predicated on the design attributes of the forward warhead support and the aft warhead wedge support. (See Figure 8.4.1-1). The LL4-1a concept had a forward warhead support design similar to the MK4 tactical design. This area was assessed using existing MK4 capability curves. The aft warhead support wedge area was originally substantially different from the MK4 tactical design and was assessed using a Finite Element analysis. The seal cover design was similar to the MK4 tactical, although a programmer has been mounted to it. Given the similarity to MK4 the seal cover was assessed to be good by inspection. (See Figure 8.4.1-1). The warhead attach, the wedge, and the seal cover designs were assessed for the critical MK4 V–γ trajectories (upper middle-UM, max axial and max transverse).

(U) Assessment Results

(U) The assessment of the LL4-1a design reflected positive margins with the exception of the aft wedge which had a negative margin. This negative margin was caused by the smaller original wedge design that was located further forward than the MK4 tactical wedge. It was suggested and subsequently implemented that a longer wedge be included in the design and this was incorporated in the latest design.

8.4.1.3 (U) LL4-1a Hostile Reentry Structural Assessment

(U) As mentioned in the beginning of this section, the baseline designs for all six LL4-x candidates include an Advanced Heather gas transfer system, although Acorn and Heather gas systems were available for use. During the LMSC vulnerability assessment the baseline system was utilized in the full-up analyses for each of the candidates. LMSC evaluated the LL4-1a design to see if variations in the gas transfer system would significantly alter component response. It was found

that, for the weight variations seen between the three gas systems component responses were similar and therefore, the feasibility statement made for each of the baseline systems apply for all of the possible gas systems.

(U) Material Vulnerability Assessment

[redacted]

b(3)
DOE
DTR

(U) Structural Vulnerability Assessment

(U) The forward and aft warhead supports and the NEP of the LL4-1a concept were quite different from those of the MK4 baseline as seen in Figures 8.4.1-3 and 8.4.1-4. Issues important to structural vulnerability were the differences in the forward support Alvis joint connection (activated when the forward support is under tension during blast, TSR and impulse encounters), the aft support and the AF&F Support ring. For the aft support, the inner foam support in the W76/MK4 was eliminated due to a larger aft warhead radius. The outer foam wedge was used and is similar to the W76/MK4.

(U) A full-body finite element (DYNA3D) analysis was performed to assess the effects of blast, TSR and impulse forcings. The model used was the existing LMSC MK4 full-body DYNA3D model in which the model for the NEP and its support was replaced with a LLNL-supplied DYNA3D model for the LL4-1a NEP. Additional concentrated masses were added to the aeroshell model to simulate the ballast of 10 lbs. attached at the nose anvil (Figure 8.4.1-1). Also, modifications were

made to simulate the AF&F support ring. The interface accounts for sliding and gap opening, elasto-plastic behavior of metal parts and dynamic structural instability.

(U) The aft-on impulse and TSR load from the aft-on cold X-ray exposures were not analyzed, because, based on past MK4 test experience, their effect is felt mostly at the aft cover and is attenuated rapidly as it moves forward through the RB structure. Since the design in this region remains the same no analyses were needed.

(U) Assessment Results

(U) LL4-1a assessment results showed that the principal structural responses of peak stress, and deflection were acceptable for the blast, TSR and impulse forcings.

(U) Both low and high frequency responses for the critical aeroshell regions, as assessed by DYNA3D blast, TSR and impulse analyses, indicated that small increases occurred in the low-frequency response levels relative to W76/MK4 responses. These response increases, though, did not exceed the design allowables.

(U) Peak relative deflections seen at hardware interfaces were found to be driven by the blast environment. The most critical response was the relative axial deflection between the AF&F tip and the aeroshell substrate. Analysis showed that this deflection was less than the existing gap width and therefore, the design was considered acceptable. Cable crushing resulting from relative lateral deflections between the NEP and the inside surface of the substrate was also found to be less than the existing gap.

(U) Additionally, the peak stresses in the aeroshell substrate, forward support, Alvis joint and the aft foam support were all below allowables for blast, hot X-ray (TSR) and cold X-ray (impulse) loadings.

(U) Finally, the possibility of shell buckling was found not to be an issue with this candidate. This was confirmed for each loading by inspecting the deformation shape of the DYNA3D model at peak response times for any indication of buckling collapse.

8.4.1.4 (U) LL4-1a Candidate Feasibility Statement

(U) Analysis of the LL4-1a candidate was accomplished early in the assessment period and concluded that the design was feasible as proposed. During the assessment period modifications were made to the LL4-1a design by the DOE laboratories to improve its performance in normal, as well as hostile environments. These modifications included the addition of foam filler around the NEP, lengthening the aft warhead support and utilizing the W76/MK4-like preloads in the aft warhead support design. These updates have been reviewed with the result being that the LL4-1a candidate was assessed as feasible as proposed.

8.4.2 (U) LL4-1b STRUCTURAL ASSESSMENT SUMMARY

8.4.2.1 (U) LL4-1b Design Description

b(3) DOE DTRA

(U) This concept is almost identical to LL4-1a with the exception of the new AF&F. In order to accommodate the new AF&F the anvil on the inside front end of the substrate must be removed. See Figure 8.4.2-2. The new AF&F radar may not be compatible with the existing W76/MK4 antenna system and would require further evaluation. This design also utilizes a PEX Booster which is incorporated in the new AF&F.

(U) The NEP is identical to LL4-1a without exception. Thus the forward and aft warhead supports are identical to LL4-1a. The seal cover is also identical to LL4-1a.

(U) Use control capability and material concerns are identical to that of LL4-1a. Safety-related component and cabling issues are also identical to that of LL4-1a. The mass properties (RB weight and CG location) of this design are shown in Figure 8.2-2.

(U) Any ballasting required will be incorporated in the new AF&F. All DoD forward ballasting capability (see the LL4-1a assessment) has been replaced by the new AF&F (Figure 8.4.2-5).

(U) As in LL4-la, MK4/D5 and MK4/C4 RAs will also need to be modified to accommodate the added safety related components. Like LL4-1a, the proposed CAT-E PAL use control capability is feasible and the concept is compatible with all the missile physical and functional interfaces. Housing the additional safety components on the RA is feasible and will require structural modification to the RAs.

8.4.2.2 (U) LL4-1b Normal Reentry Structural Assessment

(U) Analysis Approach and Results

(U) LL4-1a and b, LL4-2a and b and LL4-3a and b candidates have been grouped because of their commonality in design and have been assessed as one configuration. See Section 8.4.1.2.

8.4.2.3 (U) LL4-1b Hostile Reentry Structural Assessment

(U) Material Vulnerability Assessment

(U) The design differences of the LL4-1b and the LL4-1a do not affect this response. Therefore the conclusion for LL4-1b is the same as for LL4-1a which was acceptable. See Section 8.4.1.3..

(U) Structural Vulnerability Assessment

(U) The LL4-1b analysis used the same full-body finite element (DYNA3D) model of LL4-1a modified to reflect the additional 5.2 lbs of weight and the slightly forward CG position of the new AF&F in LL4-1b. The same critical regions and loadings were examined for LL4-1b as for LL4-1a. The results showed that the general responses were below allowables, although the most critical response, the substrate stress in the forward frustum, has small local yielding. Design feasibility should be attainable, as further studies would identify specific design solutions.

of the connector on the aft closure its design remains very similar to the W76/MK4. Candidate mass properties (RB weight and CG location) of this design are shown in Figure 8.2-2.

(U) For either the MK4/D5 or MK4/C4 RB configuration some modification to the RBA would be required to accommodate the use of an additional nuclear safety strong link. An additional 1 to 3 safety-related components would need to be mounted on the RA to activate and power the additional strong link. The MK4 IFD needs to be replaced by a MK5-size IFD insert (to accommodate the additional pins required for the safety components). New RB and RA cable assemblies would need to be fabricated.

(U) Like LL4-1a, LL4-2a requires some forward ballasting to meet the mass properties limits mentioned in Section 8.2. This task can be accomplished by either DoD or DOE.

(U) This design is not fully compatible with existing DoD hardware and will require some changes to the existing AF&F shielding for forward ballasting and both the MK4/D5 and MK4/C4 RAs for mounting added safety components. The proposed CAT-E PAL use control capability is feasible and the concept is compatible with all the missile physical and functional interfaces. Housing the additional safety components on the RA is feasible and will require structural modification to the RAs. Forward ballasting will require changes to existing DoD and DOE hardware (see LL4-1a assessment).

8.4.3.2 (U) LL4-2a Normal Reentry Structural Assessment

(U) Analysis Approach and Results

(U) LL4-1a and b, LL4-2a and b, and LL4-3a and b candidates have been grouped because of their commonality in design and have been assessed as one configuration. See Section 8.4.1.2.

8.4.3.3 (U) LL4-2a Hostile Reentry Structural Assessment

(U) Material Vulnerability Assessment

b(3)
DOE
DTRA

(U) Structural Vulnerability Assessment

(U) The structural response of the LL4-2a was expected to be similar to that of LL4-1a, as well. According to LLNL's information, the stiffness and mass distribution of LL4-1a should be used for the LL4-2a evaluations, even though the warhead contour is different at the forward end. In addition, the forward support stiffness/strength of LL4-1a can be duplicated in LL4-2a because sufficient space exists to arrive at such a design.

8.4.3.4 (U) LL4-2a Candidate Feasibility Statement

(U) The feasibility of LL4-2a (Figure 8.4.3-1) candidate design was assessed in reference to LL4-1a because of design similarity and the common stiffness and mass distribution data received. A longer forward mount was used in LL4-2a to reach the forward portion of the warhead because it was smaller than the LL4-1a design. This candidate was evaluated to be feasible as proposed.

The required interface is accomplished by the addition of through connectors on the seal cover and aft closure with an interconnecting cable. The connectors and cable are the responsibility of the DOE.

b(3) DTRA

Other than the addition of the connector on the aft closure its design remains very similar to the W76/MK4. Candidate mass properties (RB weight and CG location) of this design are shown in Figure 8.2-2.

(U) For either the MK4/D5 or MK4/C4 RB configuration some modification to the RBA would be required to accommodate the use of an additional nuclear safety strong link. An additional 1 to 3 components would need to be mounted on the RA to activate and power the additional strong link. The MK4 IFD needs to be replaced by a MK5-size IFD insert to accommodate the additional pins required for the safety components. New RB and RA cable assemblies would need to be fabricated.

(U) Like LL4-1a, LL4-3a requires some forward ballasting to meet the mass properties limit described in Section 8.2. This task can be accomplished by either DoD or DOE.

b(3) DOE DTRA

Housing the additional safety components on the RA is feasible but will require structural modification to

the RAs.

b(3) DOE STRA

8.4.5.2 (U) LL4-3a Normal Reentry Structural Assessment

(U) Analysis Approach and Results

(U) LL4-1a and b, LL4-2a and b, and LL4-3a and b candidates have been grouped because of their commonality in design and have been assessed as one configuration. See Section 8.4.1.2.

8.4.5.3 (U) LL4-3a Hostile Reentry Structural Assessment

(U) Material Vulnerability Assessment

(U) Early time material responses will not be significantly affected by the design differences between the LL4-3a and the LL4-1a. Therefore, no additional material vulnerability concerns were identified.

(U) Structural Vulnerability Assessment

(U) The late-time structural response of this candidate was assessed to be similar to LL4-1a because the stiffness and mass distribution of LL4-1a NEP were provided for use in assessing the LL4-3a candidate. Therefore, by analogy to the feasible LL4-1a design, the LL4-3a design is also feasible as proposed.

8.4.5.4 (U) LL4-3a Candidate Feasibility Statement

(U) The feasibility of the LL4-3a candidate design was assessed in reference to the LL4-1a because of design similarity and the common stiffness and mass distribution data received. These two designs are identical except for some differences in warhead or NEP internals. The results of the assessment were a feasible as proposed evaluation.

8.4.6 (U) LL4-3b STRUCTURAL ASSESSMENT SUMMARY

8.4.6.1 (U) LL4-3b Design Description

(3)
DOE
DTRA

(U) Note that this concept is almost identical to LL4-3a with the exception of the new AF&F. In order to accommodate the new AF&F the anvil on the inside front end of the substrate was removed. The new AF&F radar may not be compatible with the existing W76/MK4 antenna system and will require further assessment. This design also utilizes a PEX Booster which is incorporated in the new AF&F.

(U) The NEP is identical to LL4-3a without exception. Thus the forward and aft warhead supports are identical to LL4-3a. The seal cover is also identical to LL4-3a.

(U) Use control capability and material concerns are identical to that of LL4-3a. Safety-related component and cabling issues are also identical to that of LL4-3a. The mass properties (RB weight and CG location) of this design are shown in Figure 8.2-2.

(U) Any ballasting required will be incorporated in the new AF&F. All DoD forward ballasting capability (see the LL4-1a assessment) has been replaced by the new AF&F.

(U) This design may be not fully compatible with the existing DoD hardware depending on the radar selected. Like LL4-1b, the new AF&F radar compatibility with the existing W76/MK4 antenna system will need to be assessed when more detailed design information is available. As in LL4-3a, MK4/D5 and MK4/C4 RAs will need to be modified to accommodate the added safety related components. The forward aeroshell also needs to be modified to accommodate the new AF&F (the forward ballast would be incorporated into DOE components). Like LL4-3a, the proposed CAT-E PAL use control capability is feasible and the concept is compatible

8.4.7 (U) LA4-1 STRUCTURAL ASSESSMENT SUMMARY

8.4.7.1 (U) Design Description

b(3) DOE DTRA

The required interface is accomplished by the addition of through connectors on the seal cover and aft closure with an interconnecting cable. The connectors and cable are the responsibility of the DOE.

b(3) DTRA

b(3) DOE DTRA

8.4.7.2 (U) LA4-1 Normal Reentry Structural Assessment

(U) Analysis Approach

(U) The LA4-1 design was assessed by engineering judgment based on limited details of a 8 1/2 x 11 layout shown in the "Excerpts from the Fourth SLBM Phase 2 Study Group", dated 4 March 1993. The forward warhead attachment is that of the MK4 design and the aft wedge support and the seal cover designs are similar to the MK4 design.

b(3)

indicate that the design for the forward warhead attach, the aft wedge supp[illegible] and the seal cover would produce positive margins of safety.

8.4.7.3 (U) LA4-1 Hostile Reentry Structural Assessment

(U) Material Vulnerability Assessment

b(3)
DOE
DTRA

(U) Structural Vulnerability Assessment

(U) The LA4-1 candidate has many design features which are similar to the W76/MK4. For this reason some of the sensitivity study analysis results which were performed using the MK4 aeroshell during the early portion of Phase 2 are applicable in assessing LA4-1. In these sensitivity studies the stiffness of the warhead and warhead attach points were varied, as was the weight of the NEP allowing the analyst to evaluate the effect of each variable on system performance. Given that the LA4-1 and W76/MK4 forward and aft warhead supports are nearly identical, and that the NEP change was not large, it was felt that the structural responses of the LA4-1 design would remain within the allowable limits.

8.4.7.4 (U) LA4-1 Candidate Feasibility Statement

(U) Analysis of the LA4-1 candidate design was accomplished utilizing a conceptual drawing and general mass property information. While this may be closer to a true Phase 2 type of assessment it is still considerably less information than has been received for many of the other candidates and has much larger uncertainties associated with the assessment conclusions. With these caveats in mind the LA4-1 design was assessed to be feasible due to its similarity to the W76/MK4.

8.4.8 (U) LA4-2 STRUCTURAL ASSESSMENT SUMMARY

8.4.8.1 (U) Design Description

b(3) DOE DTRA

The required interface is accomplished by the addition of through connectors on the seal cover and aft closure with an interconnecting cable. The connectors and cable are the responsibility of the DOE.

b(3) DTRA

Other than the addition of the connector on the aft closure its design remains very similar to the W76/MK4.

b(3) DOE

This task can be accomplished by either DoD or DOE.

(U) The proposed CAT-E PAL use control capability is feasible. Forward ballasting will require changes to existing DoD and DOE hardware. This task will entail modifying the anvil for mounting the ballast and a new DOE radiation shield to fit in the remaining volume.

8.4.8.2 (U) LA4-2 Normal Reentry Structural Assessment

(U) Analysis Approach

(U) The LA4-2 design was assessed by engineering judgment based on limited details of a 8 1/2 x 11 layout shown in the "Excerpts from the Fourth SLBM Phase 2 Study Group", dated 4 March 1993. The forward warhead attach and the seal cover are similar to the W76/MK4 design configuration. The aft wedge is thinner and

(3)
DOE
DTRA

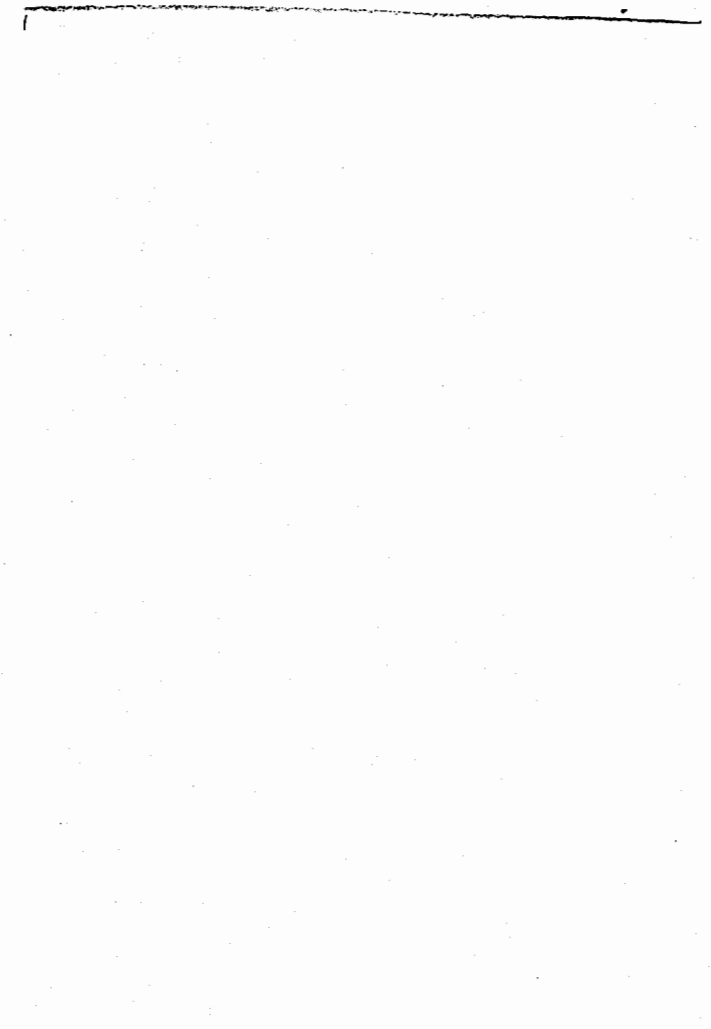

FIGURE 8.4.8-1
(U) LA4-2 FULL BODY PROFILE

[redacted]

b(3)
DOE
DTRA

FIGURE 8.4.8-4
(U) AFT WARHEAD SUPPORT

has approximately the same length as the W76/MK4, but has a forward slant at the wedge/warhead interface. This forward slant will require a gap at the wedge/warhead interface to allow for axial thermal expansion, otherwise the aeroshell will be locked at the forward warhead attach point and the wedge area, which will introduce large stresses in the aeroshell and forward wedge areas. Neither the gap nor the locked aeroshell are considered desirable conditions.

(U) Assessment Results

(U) The initial assessment of the LA4-2 based on the 8 1/2 x 11 layout would indicate that a design for the forward warhead attach area and the seal cover would produce positive margins of safety. The aft wedge design could result in high stresses in both the wedge and the aeroshell.

8.4.8.3 (U) LA4-2 Hostile Reentry Structural Assessment

(U) Material Vulnerability Assessment

b(3)
DOE
DTRA

(U) Structural Vulnerability Assessment

(U) The LA4-2 candidate has some design features which are similar to the LL4-1a, which was assessed to be feasible. Two structural design issues were noted in the assessment of the LA4-2 candidate. First, the aft warhead support was found to be thinner than the W76/MK4 support. Second, the forward warhead support appears to need strengthening in order to withstand the hostile environment encounters.

Both of these design differences involve a reduction in component size (relative to W76/MK4) which would require more analysis to determine actual structural responses.

8.4.8.4 (U) LA4-2 Candidate Feasibility Statement

(U) Analysis of the LA4-2 candidate design was accomplished utilizing a conceptual drawing and general mass property information. This is considerably less information than has been received for many of the other candidates and as such, has much larger uncertainties associated with the assessment conclusions. With these caveats in mind the LA4-2 design was assessed to be feasible with potential modifications to the forward warhead support. The slanted aft wedge design feature may need to be modified to reduce aeroshell stresses.

9. EFFECTIVENESS

presented to all working group members to review. This method added robustness to the study, by considering a greater number of analysis possibilities than if all members used the same assumptions.

9.1.3. (U) EFFECTIVENESS RESULTS SUMMARY

(U) The yields and weights of the W76/MK4, W88/MK5, and candidate warheads are shown in decreasing yield in Table 9-1 below, along with a comparative effectiveness ranking and rating.

9.2. (U) GROUND RULES AND ASSUMPTIONS

(U) The SPETWG generally followed all the ground rules and assumptions contained in the Technical Objectives and Guidelines (TOG) for this study. The SPETWG also used the additional ground rules and assumptions in Sections 9.2.1.1 through 9.2.1.5.

9.2.1. (U) MISSILE CHARACTERISTICS AND CAPABILITIES

9.2.1.1. (U) Range / Payload Performance

(U) Figures 9-1, 9-2, and 9-3 show the range/payload assumptions used for this study and are based on data provided by LMSC. Figure 9-1 shows the range/payload capabilities for the W76/MK4 on the C4 missile. Figures 9-2 and 9-3 show the capabilities for the W76/MK4 and W88/MK5 respectively on the D5 missile. Using the weights of the candidates and the weight-to-range tradeoffs shown, the SPETWG determined the range/payload capabilities for MK4A candidates on both the C4 and D5 missiles and for MK5A candidates on the D5 missile.

9.2.1.2. (U) Weapon System Accuracy

The SPETWG used weapon accuracy values for D5 and C4 missiles based upon May 1993 TRIDENT CINCEVAL accuracy projections prepared by TASC. The D5 missile weapon system accuracy is shown as a function of range in Figure 9-4.

b(3) DOE DTRA

9.2.1.3. (U) Footprinting Capability

The footprint capabilities of each of the candidates used in developing effectiveness results are based on LMSC data.

b(3) DTRA

9.2.1.4. (U) Heights of Burst Fuzing Options

The SPETWG assumed that the HOBs of a MK4A would be changed from those of the W76/MK4.

b(3) DOE DTRA

9.2.1.5 (U) Reliability

In the force level effectiveness analysis, one study assumed a weapon system reliability (WSR) of 0.89 for all missiles, regardless of the type of warhead carried. Otherwise, the SPETWG did not consider reliability issues in the rest of their effectiveness assessments.

9.2.2. (U) FORCE UTILIZATION

9.2.2.1. (U) Force Levels and Missile Configurations

b(3) DTRA

The results from the other cases did not change the conclusions drawn from the 14 TRIDENT II (D5) case and are not presented in this report.

TABLE 9-2
(U) FORCE CONFIGURATIONS

b(3) DOE DTRA

9.2.2.2. (U) Operating Areas and SSBN Deployments

b(1) DTRA

The Aleutian Island chain and the Greenland-Iceland-United Kingdom gap formed effective northern barriers to these operating areas. Some of the assessments performed in this study used large fractions of these operating areas, and other assessments focused on those parts of the operating areas closest to the target base.

9.2.3. (U) TARGET BASES

(U) Each analyst in the SPETWG developed his own target bases, according to the scenarios he was analyzing. The target bases of the different analysts had many similarities and some differences. Each analyst developed a target base in Russia and a target base in China, but the Russian target bases, being harder and more diverse, had the most influence on the analyses.

One target base used in this study representative of the START II target base is

b(1) DTRA

b(1)
DTRA

9.2.3.1. (U) Treaty and Force Configuration Scenarios

(U) The base-case scenarios assumed that the START II treaty, negotiated by Presidents Bush and Yeltsin, would become effective. However, the SPETWG also assessed cases where only the START I agreement would become effective. The SPETWG performed no specific analyses in which they assumed that both START treaties would be rejected.

9.2.3.2. (U) Damage Mechanisms

(U) For many of the effectiveness comparisons, the single-shot probability of kill (SSPK) is the primary MOE considered. The damage mechanism assumed for SSPK is air blast overpressure causing severe structural damage to the facility, as defined by the DIA's Physical Vulnerability Handbook for Nuclear Weapons (OGA-2800-23-92). For this damage mechanism, an air burst is the appropriate fuze option, and each warhead candidate was evaluated using its most effective fuze option. For MK4A candidates, the radar fuze with optimum HOBs was used. For MK5A candidates, the radar-updated path length (RUPL) fuze with optimum HOBs was used

9.3. (U) APPROACH AND METHODOLOGY

9.3.1. (U) MEASURES OF EFFECTIVENESS

(U) The SPETWG defined nine different measures of effectiveness (MOEs) for MK4A and MK5A (Table 9-3), each of which addressed a specific aspect of effectiveness.

UNCLASSIFIED

TABLE 9-3

(U) MEASURES OF EFFECTIVENESS

DTRA

9.3.1.1. (U) MK4A Measures of Effectiveness

9.3.1.1.1. (U) *SSPK Against 27P0 Target on C4*

The SPETWG calculated the SSPK of each candidate against a target with a vulnerability number (VNTK) of 27P0.

b(3) DOE DTRA

When the W76/MK4 was developed, the weapon system CEP was such that this type of target was considered difficult to successfully attack. With the improvements in CEP experienced by the C4 missile, this target is no longer the challenge it once was. Nevertheless, the SPETWG considered it to be an important MOE for this system, and used it in their analyses.

DTRA

b(3)
DOE
DTRA

FIGURE 9-7
(U) MK4A SSPK FOR A 27P0 TARGET ON C4

9.3.1.1.2. (U) *SSPK Against 46L8 Target on D5*

The SPETWG also calculated the SSPK of the MK4A candidates on a D5 missile against a hard target.

b(3)
DOE
DTRA

Figure 9-8 shows the values of this MOE for each of the candidates.

b(3)
DOE
DTRA

FIGURE 9-8
(U) MK4A SSPK FOR 46L8 TARGET ON D5

9.3.1.1.3. (U) *Average SSPK for Potential MK4A Target Set*

[redacted] The SPETWG calculated the average SSPK across the total set of potential MK4 targets softer than VNTK 46L8. This represents a set of targets likely to be eligible for the MK4A. Figure 9-9 shows the values of this MOE for each of the candidates.

b(3)
DOE
DTRA

FIGURE 9-9
(U) MK4A AVERAGE SSPK

UNCLASSIFIED

[redacted]

b(3) DTRA

9.3.1.1.4. (U) *Fraction SSPK*

[redacted] The SPETWG calculated the fraction of potential MK4 targets that are softer than 46L8[redacted] This MOE provides a concise measurement of how much of the target base is held at risk. Figure 9-10 shows the values of this MOE for each of the candidates.

b(3) DTRA

b(3) DOE DTRA

9.3.1.1.7. (U) *Number of DGZs Required to Cover Target Base*

[redacted] The SPETWG compared the numbers of DGZs (Designated Ground Zeros, or aimpoints) that would be required for each MK4A candidate to cover, or attack, a START II target base in Russia. Weapons requiring fewer DGZs to cover the target base would be more effective than those requiring more DGZs.

b3 DTRA

b(3) DOE DTRA

The SPETWG methodology associates with a given DGZ those target installations that are close enough to the DGZ that the minimum SSPK for installations offset from the actual aimpoint, PKmin(offset), would be not less than [redacted] DGZ development is insensitive to CEP and PKmin(offset), but it is sensitive to yield. Thus these resulting MOEs decreased monotonically as yield decreased, with a [redacted] swing in numbers of DGZs required from the highest to the lowest candidate yield. Figure 9-13 shows the values of this MOE for each of the candidates.

b(3) DTRA

b(3) DOE DTRA

FIGURE 9-13
(U) MK4A NUMBER OF DGZS REQUIRED

9.3.1.1.8. (U) *Weighted Worth Damaged in Strike*

(U) The SPETWG calculated the effectiveness of various strike plans developed by SPETWG analysts using MK4A RBs against Russian target bases. Different kinds of target installations were assigned different relative values by the various analysts, and the overall effectiveness of the strikes were assessed as a percentage of the weighted worth of the total target base damaged in those strikes. In these assessments, strike effectiveness was calculated using CEPs that depended on the range of the target installations from the assumed launch points. Choices of target bases, target-worth weightings, and missile launch points all varied from analyst to analyst. Even so, the results were close enough that the SPETWG was able to arrive at a single set of values representing this measure of effectiveness. This measure of effectiveness proved insensitive for MK4A comparisons, varying by only 5 per cent. Figure 9-14 shows this MOE for each of the candidates.

b(3)
DOE
DTRA

FIGURE 9-14
(U) MK4A WEIGHTED WORTH DAMAGED IN STRIKE

9.3.1.1.9. (U) *Damage to Other Military Targets*

(U) Finally, the SPETWG calculated the effectiveness of various strike plans developed by SPETWG analysts against Russian target bases. The effectiveness of these overall strike plans in attacking that subset of the target base identified as Other Military installations was calculated. The SPETWG believes that Other

9.3.1.1.10. (U) *Summary of MK4A MOE Values*

(U) A summary of the MOE values and relative scores for the MK4A is given in Table 9-4.

TABLE 9-4
(U) MEASURE OF EFFECTIVENESS VALUES FOR MK4A

b(3)
DOE
DTRA

9.3.1.2. (U) MK5A Measures of Effectiveness

(U) In addition, the SPETWG defined nine MOEs for the MK5A candidates (see Table 9-3).

9.3.1.2.1. (S) *SSPK Against 52L7*

(S) The SPETWG calculated the SSPK of each candidate against a target with a VNTK of 52L7.

b(3)
DOE
DTRA

When the W88/MK5 was developed, this was the assessed VNTK of the hardest Soviet silos. Although those SS-18 silos have since been assessed to be much harder than 7000 psi, the SPETWG considers 52L7 to be a significant figure of effectiveness for this system because of the history of its use. The was used, and the results varied monotonically with yield, with a

FIGURE 9-21
(U) MK5A FOOTPRINTING EFFICIENCY

9.3.1.2.7. (U) *Number of DGZs to Cover Target Base*

The SPETWG compared the numbers of DGZs (Designated Ground Zeros, or aimpoints) that would be required for each MK5A candidate to cover, or attack, a START II target base in Russia. Weapons requiring fewer DGZs to cover the target base would be more effective than those requiring more DGZs. The target base used in this particular calculation included [redacted] classified as Strategic Military, [redacted] categorized as Other Military, [redacted] categorized as National Leadership, and [redacted] categorized as War-Supporting Industry. The Strategic Military installations included only the numbers and types of ICBM silos permitted by the START II treaty.

b(1)
DTRA

b(3)
DOE
DTRA

[redacted] The SPETWG methodology associates with a given DGZ all target installations that are close enough to the DGZ that the minimum SSPK for all installations offset from the actual aimpoint, PKmin(offset), would be not less than [redacted] DGZ development is insensitive to CEP and PKmin(offset), but it is sensitive to yield. Thus these resulting measures of effectiveness decreased monotonically as yield decreased. Candidate yields for the MK5A in this study ranged from [redacted] Because of the dispersed nature of the target bases used in this study, this figure of merit varied by only about 10 per cent. Figure 9-22 shows the values of this MOE for each of the candidates.

FIGURE 9-22
(U) MK5A NUMBER OF DGZS REQUIRED

9.3.1.2.8. (U) *Weighted Worth Damaged in Strike*

(U) The SPETWG calculated the effectiveness of various strike plans developed by SPETWG analysts using MK5A RBs against Russian target bases. Different kinds of target installations were assigned different relative values by the various analysts, and the overall effectiveness of the strikes were assessed as a percentage of the weighted worth of the total target base damaged in those strikes. In these assessments, strike effectiveness was calculated using CEPs that depended on the range of the target installations from the assumed launch points. Choices of target bases, target-worth weightings, and missile launch points all varied from analyst to analyst. Even so, the results were close enough that the SPETWG was able to arrive at a single set of values representing this MOE. This MOE was monotonic with yield, and there was a 25 per cent swing in the values that are shown in Figure 9-23.

b(3)
DOE
DTRA

FIGURE 9-23
(U) MK5A WEIGHTED WORTH DAMAGED IN STRIKE

9.3.1.2.9. (U) *Damage to Strategic Military Targets*

(U) Finally, the SPETWG calculated the effectiveness of various strike plans developed by SPETWG analysts against Russian target bases. The effectiveness of these overall strike plans in attacking that subset of the target base identified as Strategic Military installations was calculated. The SPETWG thought that Strategic Military would be an important target set for MK5A weapons. In these assessments, strike effectiveness was calculated using CEPs that depended on the range of the target installations from the assumed launch points. Choices of target bases, designations of particular installations as falling into the Strategic Military category, and missile launch points all varied from analyst to analyst. Even so, the results were close enough that the SPETWG was able to arrive at a single set of values representing this MOE. Due to the large variation in the yields of the various candidates, there was a 30 per cent swing in the values that are shown in figure 9-24.

b(3)
DoE
DTRA

9.3.1.3. (U) Decision Analysis Tools

9.3.1.3.1. (U) *Computational Techniques*

(U) Each analyst used his own calculational techniques and tools to study some or all the MOEs that the SPETWG used. Different analysts felt that certain MOEs were more important than others and combined them in ways resulting in different overall scores. In addition, combinations of MOEs and different relative weighting schemes were studied considering possible arms control treaty scenarios.

(U) Since each analyst used his own data bases, there were small differences between values calculated by different analysts for such MOEs as damage to Other Military targets and damage to Strategic Military targets. In addition, each analyst used his own relative-weighting scheme to value the various types of target installations, thus adding yet another dimension to the assessments of weighted worth damaged in a strike. Once all the calculations had been performed, the analysts compared the various calculational results and derived a set of final numbers to be used in the overall comparisons of candidates. The SPETWG believes this method of comparing diverse techniques and tools offered robustness to the assessments.

9.3.1.3.2. (U) *Analytical Spreadsheet Models*

(U) Two different spreadsheet-based tools were used to combine the many individual calculations into an overall assessment of relative effectiveness.

(U) ROMA

(U) The ROMA (Relative Overall Merit Assessment) spreadsheet calculates an overall effectiveness score by linearly adding the scores of each of the MOEs for each of the candidates in a weighted fashion. The result is then expressed in a normalized value with the W76/MK4 or W88/MK5 having a score of one. The MOE weights used in the overall score reflect the relative importance assigned by the SPETWG consensus and by individual analysts.

(U) WESVA

(U) The WESVA (Weapon Safety Value Assessment) spreadsheet model provides a method for aggregating selected MOEs into a single number called "total military value." The WESVA approach considers how performance penalties on one MOE compare in importance to penalties on the other MOEs, and whether a severe enough penalty on any particular MOE can essentially nullify any value provided by the other MOEs.

9.3.1.3.3. (U) *Force Analyses Methodology*

(U) The SPETWG performed a number of force effectiveness analyses to help assess the relative contributions of the various candidates to the overall effectiveness of an SSBN/SLBM force. Various analysts calculated the effectiveness of various strike plans that they developed using both MK4A and MK5A RBs against selected target bases. The results of all the analysis approaches described here are consistent with the overall conclusions of the study.

(U) One model developed by the SPETWG determined an allocation of warheads for a given distribution of FBM forces using a particular target database and submarine patrol areas. The correct range dependent CEP and weight-dependent maximum-range cutoff was used in determining target accessibility and damage capability for a given set of MK4 and MK5 warhead parameters (yield and weight) and force mix (numbers of C4 and D5 available for an attack). Pseudo-footprinting was used in that each target set was sorted into geographic grid cells that are the approximate size of the missile footprinting capability. Three target databases were used for this analysis. Two covered Russia, under two different arms control agreements (START I and Bush/Yeltsin[1]), and one covered China. The Chinese database was used for studying the effects of range capability on force disposition for

[1](S) The arms control negotiations for START II were underway while this study was being conducted. Independent positions on START II were established by Presidents Bush and Yeltsin early in 1992. These positions were used for the formation of the "Bush/Yeltsin" target database. The eventual agreement, reached at a later date, established levels somewhat different than the Bush/Yeltsin target database assumed and it represents a softer target database with 154 fewer SS-18 silos remaining. This is why the second target database is referred to here as Bush/Yeltsin and not START II.

a target set different from a Russian one, especially for potential use in hostile third world areas.

(U) For other force level assessments, each analyst assumed an overall SSBN force, a force at sea with specific numbers of RBs per SLBM, and a specific set of target installations, usually with more target installations than could be attacked by the assumed SSBN/SLBM force. Most of the analysts considered different sets of launch points within the assumed operating areas and used range dependent CEPs, but some used fixed CEPs. Different kinds of target installations were assigned different relative values by the various analysts, and different analysts used different rules to determine whether a MK4A or a MK5A RB would be assigned to strike a particular target. Different analysts used different metrics to assess the overall effectiveness of the various strikes. The usual practice was to change types of candidates being used in MK4A RBs while holding the MK5 warhead constant, then to change the types of candidates being used in MK5A RBs while holding MK4 warhead constant. This approach indicated the sensitivity of the effectiveness of the total SSBN/SLBM force against a total target base to the choice of warhead candidate.

(U) Submarine Operating Areas

(U) Another SPETWG force effectiveness model assumed that the ocean operating areas are constructed for a candidate option based on the range at maximum footprint of the shortest range missile in each ocean. In the Atlantic, the backline of the operating area is defined by the range to Moscow or is constrained by the SOA and South America. In the Pacific, the backline is defined by the range to the nearest SS-18 silo field for TRIDENT II (D5) SSBNs. This constraint also provides an adequate set of targets for TRIDENT I (C4) SSBNs. Table 9-4 shows the missile ranges and operating areas used for various configurations of the D5 missile carrying W88/MK5 warheads. Backlines for the MK4A and MK5A candidates are similarly developed using their missile ranges.

U) The analysis was conducted using a model that reflects the values of nuclear warhead yield and accuracy and estimates damage recognizing target hardness. The groups of targets were "attacked" in priority order from the most important to the least important. Weapons were selected from the appropriate legs of the TRIAD and were allocated to assure complete coverage of a group before proceeding to the next group. Although targets were assigned to different priority groups, all targets were given equal value. The allocation of weapon resources to priority groups was handled by heuristics meant to simulate STRATCOM implementation of national policy directives. Within a single priority group, optimum weapon assignments were achieved by using a modified Simplex Algorithm.

(U) This approach to estimating strategic damage effectiveness indicated that in some cases, where the candidate SLBM warheads were less effective, other legs of the TRIAD could recover some of the loss in effectiveness.

9.4.2.2. (U) Force Effectiveness Analysis

9.4.2.2.1. (U) *Summary*

(U) Four force level effectiveness assessments were performed by the SPETWG. Choices of target bases, target worth weightings, missile launch points, and assessment metrics all varied from analyst to analyst. Even so, the normalized results showed consistent overall trends.

(U) Three of the studies used START II forces and target bases, one used START I forces and target base. Each target base was different. In each case there were more targets than weapons. All the studies except one used range variable CEPs from a set of assumed launch points; one used a constant CEP value. One of the studies used a weighting function to value some of the targets more than others; all others counted all targets equal.

9.4.2.2.2. (U) *MK4A*

(U) Figure 9-35 shows the normalized results of these four assessments for the MK4A candidates, along with a curve representing the average of the values. As seen, the four studies agree closely that all the MK4A candidates have essentially equivalent force effectiveness with respect to the MK4/W76.

FIGURE 9-38
(U) FORCE LEVEL EFFECTIVENESS VERSUS MK5A FORCE SIZE

UNCLASSIFIED

9.4.2.2.4. (U) *MK5A Yield*

b(3) DOE DTRA

Figure 9-39 shows an example of this tradeoff over the yield range of interest for this study. The changes in effectiveness result from an increase in the number of targets killed with higher yield versus a loss in effectiveness due to the increased weight necessary to obtain the higher yields and the resulting loss in missile range. While, increased yield gives a greater probability of damage (P_d) against a target, the increased weight and resulting decrease in range mean that fewer targets can be reached from the launch areas assumed. As a result, the number of targets killed can go down even as yield is increased. For each yield shown on the abscissa, the number of targets killed with a P_d greater than either 0.5, 0.7, or 0.9 is shown on the ordinate. The only targets considered for this assessment are ICBM silos under START I. Choosing a minimum P_d, an optimum yield can be found.

b(3) DOE DTRA

Selecting a different minimum P_d or a different target base will alter the results. A harder target base will drive the optimum yield up. A larger target base with many softer targets will drive it down. A smaller acceptable P_d will also drive the optimum yield down. Note that the baseline W88 is optimum for its yield and weight regime, and is shown in Figure 9-39 on the far right.

9.5 (U) CONCLUSIONS

(U) The SPETWG assessments led to the following overall effectiveness conclusions.

9.5.1 (U) COMPARISONS OF MK4A CANDIDATES

The DOE weapons laboratories proposed eight candidates to replace the W76/MK4.

b(3)
DOE
DTRA

The MK4 mission can also be accomplished with candidate LA5-2 on the D5 missile with approximately the same effectiveness as the baseline.

(U) The impact of missile range on the comparison of MK4 candidates should also be noted. The differences in weight of the MK4A candidates reduce full load (eight RBs) range of the C4 missile to a point where operational viability becomes a serious concern. This range is critical for the C4 missile whose deployment is on the TRIDENT submarine in the Pacific Ocean. The eight body range criterion, however, is not an effective discriminator among the candidates. Range of the C4 missile with only four RBs, a potential loading under START II rules, is large and the additional weight of the candidates is not an important discriminating factor. Range of the D5 missile, even with eight of the MK4A candidates, is not a significant issue for operations in either the Atlantic or the Pacific Ocean operating areas.

9.5.2. (U) COMPARISONS OF MK5A CANDIDATES

[redacted] Twenty-two candidates were proposed by the DOE weapons laboratories to replace the W88/MK5. While the W88/MK5 is more effective than any of the

10. SURETY

10. (U) SURETY

10.1 (U) SAFETY ATTRIBUTE IMPLEMENTATION

10.1.1 (U) INTRODUCTION

(U) The scope of this study was to review the safety attributes of the Phase 2 candidates and to identify the issues and concerns associated with implementing modern safety features. The scope did not include determining the relative need for these features in the TRIDENT weapon system.

(U) Many of the proposed warhead candidates contain a number of safety features which can enhance nuclear safety and reduce the probability of Pu dispersal with minimal impact to the weapon system. These features are grouped into two basic categories: safety systems which are common to a number of candidates; and second, unique safety systems which are specific to a single candidate or small group of candidates. The features which are common to a number of candidates include; IHE, FRPs, robust exclusion barriers, and advanced detonator safing.

DOE b(3)

(U) In Section 10.1.2, details of a number of safety features are discussed. Subsequently, candidate-specific ENDS themes, and an assessment of INRAD exposure levels are presented in Sections 10.1.3 and 10.1.3. In Section 10.1.5, Tables 10.1-2 to 10.1-5 detail the safety implementation scheme for all candidates, indicating the safety features incorporated and those which require excursions from the defined ground rules (e.g., impacts to missile system). The conclusions from this Safety Technical Working Group safety review are contained in Section 10.1.6.

(U) Recently, the possibility of plutonium scatter from nuclear weapons exposed to abnormal environments has received increasing attention. Plutonium dispersal safety features have been emphasized for all Phase 2 candidates.

UNCLASSIFIED

10.1.2 (U) SAFETY FEATURE DISCUSSION

10.1.2.1 (U) Insensitive High Explosive (IHE)

(U) The IHE formulations used by LLNL and LANL for nuclear weapon main charge high explosives are based on plastic bonded triaminotrinitrobenzene (TATB). LX-17 (92.5/7.5 wt% TATB/Kel-F 800) is used in LLNL designed weapons, while PBX 9502 (95/5 wt% TATB/Kel-F 800) is used in LANL weapons. The overall characteristics of these formulations are almost identical in safety and performance properties. The LX-17 has slightly higher physical strength properties when compared to PBX 9502.

(U) The IHEs have been demonstrated to be highly resistant to accidental initiation of a high explosive violent reaction or detonation that would result in Pu scatter in abnormal environments. Weapon systems containing IHE have been subjected to high velocity impact, fuel fires, propellant fires, bullet impacts, and sympathetic detonations from near-by warheads. Los Alamos and Sandia conducted rocket sled tests in which weapons containing PBX 9502 were impacted into rigid concrete targets at velocities ranging from 500 ft/s to 2000 ft/s. In these tests the PBX 9502 did not respond in a violent reaction or detonation. Both LANL and LLNL have subjected weapons containing IHE to fuel fires (~1 hour duration) and propellant fires (<20 minutes). In these tests the IHEs did not react violently or detonate as a result of the abnormal thermal environments. Bullet tests using 0.223 cal., 0.30 cal., 0.50 cal., 30-mm uranium and 30-mm tungsten projectiles have not resulted in violent reactions of the IHEs in full scale weapon and weapon cross-section targets. Nearby warhead sympathetic detonation tests were conducted by LANL using B61 bombs with stockpile separation distances for testing. In these configurations, the "donor" warhead, when initiated, did not produce a reaction in the near-by "acceptor" warhead. Pieces of PBX 9502 and the mock pit were recovered after the tests. Full scale tests, along with many component safety tests, conducted by LANL and LLNL have demonstrated the safety properties of IHE in these abnormal environments.

[redacted] The Warhead Sensitivity Study (Reference 8) found that IHE would detonate in response to a hypothetical third stage rocket motor detonation.

10.1.2.2 (U) Fire Resistant Pit Design

(U) Plutonium containment requirements for the Phase 2 study have not been completely specified. STS requirements have been revised to specify a fuel fire of 1100°C for one hour at a Strategic Weapons Facility and potentially a much greater time when not at a Strategic Weapons Facility.

10.1.2.2.1 (U) *LLNL FRP Design Concepts*

b(3)
DOE
DTRA

(U) The Design Laboratories have been developing fire resistant pit designs for the reduction of plutonium scatter in fire environments for well over a decade. The fire resistant pit designs have been fielded in the W84, B83 and W87, and the concepts for fire resistance have been continually improved leading to the current design standard developed into Phase 4 for the W89. The MK4A and MK5A candidates take advantage of these developments.

b(3)
DOE
DTRA

b(3)
DOE
DTRA

(U) Helium builds up in the plutonium from radioactive decay. In elevated temperature-aging studies on plutonium from old W68 pits, no change in density or other undesirable characteristics were detected. Upon melting in containment tests, a release of the helium has been noted, but there has been no detectable adverse effect on the containment capability. Helium build-up does not appear to be an issue.

b(3)
DOE
DTRA

10.1.2.2.2 (U) *LANL FRP Design Concepts*

(U) Because the duration of fires while in DOE custody is yet to be determined, LANL has adopted the requirements of 1100°C for two hours as its requirement for fire resistance. Fire resistance reduces the chance and/or magnitude of Pu dispersal in accidental fires.

10.1.2.3 (U) Detonator Safing

10.1.2.3.1 (U) *LLNL/Sandia Detonator Safing Stronglink (DSSL)*

(U) The Detonator Safing Stronglink employed by LLNL/Sandia is a nuclear safety subsystem which embeds one of the two safety-critical stronglinks deeply within the NEP. It is designed to provide a safe and predictable response in all credible environments until receipt of the correct unique prearm signal. The DSSL reduces the risk of inadvertent nuclear detonation over conventional detonators with fireset-based stronglinks by interrupting the detonation train within the NEP. This is particularly valuable in the case of severe combined accident environments in which the fireset may become separated from the NEP resulting in exposed detonator cables.

(U) The DSSL safety subsystem was developed for the W89 (SRAM-II and SRAM A). It is a mature technology (low technical risk) which has been developed well into Phase 4. It was derived from the MSAD (Mechanical Safe and Arm Detonator) which is in the stockpile in the MK21/W87 on the Peacekeeper ICBM and on the W84 ground launched cruise missile (GLCM) now in inactive reserve (IR).

(U) The DSSL consists of two basic subsystems: the actuator and warhead detonators (which each contain a unique-signal discriminator/safing mechanism). The actuator is mounted external to the NEP and receives a unique electrical signal from either the missile or a unique signal generator. The actuator uses the unique signal to enable the discriminator/safing mechanism associated with each detonator inside the NEP.

(U) The detonators each contain an electrical bridge which can be exploded by high current. The exploding bridge drives a flyer plate, which, in normal operation, impacts and detonates a small PETN explosive pellet. The PETN detonation, in-turn, drives an aluminum flyer which initiates a large booster pellet leading to the detonation of the main explosive charge. In typical (non-DSSL) flyer plate detonator designs, these components of the detonation chain are in the aligned position. For these aligned detonators, initiation of the bridge will light the main charge. Similarly, abnormal environment initiation of the PETN pellet will also initiate the main charge.

(U) In DSSL the PETN pellet is mounted in a cogged wheel, known as the discriminator wheel. Prior to prearming the DSSL, the discriminator wheel is positioned such that the PETN pellet is not aligned with either the detonator bridge or the detonator output barrel. In this position, firing the detonator bridge cannot initiate the PETN, nor could initiation of the PETN initiate the booster. Thus, the PETN pellet is isolated from the electrical source which can initiate it (the exploding bridge and flyer) and the main explosive charge is isolated from the PETN. Even if the PETN were initiated directly by some shock wave from other than the exploding bridge, it would not be able to initiate the IHE from its safed position. The detonator is inoperable until it receives the correct unique signal.

(U) To prearm the DSSL, the discriminator wheel is rotated by a series of pushes and pulls which are sent down a mechanical cable from the DSSL Actuator. If an incorrect sequence of signals is applied, the discriminator wheel will be driven to an irreversible, mechanically-locked, and safe state. The explosive pellet would remain out of line and incapable of detonating the IHE main charge. The DSSL mechanism and unique signal have been designed such that the device is highly unlikely to be enabled by energy sources found in normal or abnormal environments.

(U) The PETN pellet acts as a thermal weaklink. The pellet completely decomposes (does not detonate or ignite) at around 450°F, rendering the detonator predictably and irreversibly inoperable well before the discriminator mechanism and the stainless steel DSSL barrier lose their integrity. The DSSL does not have a defined mechanical weaklink. Therefore, Sandia cannot categorically state that it is impossible for mechanical environments to drive the code wheels into their prearmed positions. However, as the cables are not directly connected to the discriminator wheel, it would be extremely unlikely for this to occur. An abnormal mechanical environment is much more likely to detach or damage the cables than to apply the required unique series of pushes and pulls. This is particularly true relative to detonators, which do not require any unique signals for prearming.

(U) The DSSL is much less vulnerable to mechanical abnormal environments than many other safety subsystems. A single g-time pulse is insufficient to prearm the device regardless of duration or amplitude. Performance can be contrasted to an ESD, which can be set by a single linear g-time pulse.

[redacted]

(U) The DSSL is also insensitive to electrical environments including direct lightning strikes. Each DSSL detonator has two cable assemblies: the detonators use flat detonator cables to their bridges; and the DSSL mechanisms have mechanical drive cables. During development of the W89, special attention was given to preventing detonation through the propagation of lightning along these lines resulting in an improved and tested design.

10.1.2.3.2 (U) *LLNL/Sandia Paste Extrudable Explosive (PEX) Booster*

(U) The Paste Extrudable Explosive (PEX) booster found in some LLNL/Sandia designs is a recently-developed nuclear safety subsystem. Its function is to provide a second stronglink buried within the NEP - thus complementing the DSSL system described earlier. It eliminates the potential for even an armed DSSL to initiate the main charge by removing a essential component of the HE initiation chain.

(U) The output from a warhead detonator (including a prearmed DSSL or the detonators in the W76 or W88) is not sufficient to directly initiate the IHE main charge. Initiation of IHE by firing one of these detonators requires that the detonator first initiate a small explosive charge (booster) which is more easily initiated than the IHE, and which has higher output than the detonator. The output from the booster is sufficient to initiate the IHE. In the PEX booster design, the booster explosive is a paste, which is stored outside the NEP and injected into the NEP only after prearming (receipt of a unique signal). The paste explosive is a thick, viscous gel of HMX explosive, thickener, and solvents.

(U) The PEX for each booster is stored in its own separate reservoir which is connected by tubing to a booster cavity in the NEP. The plumbing for each booster is entirely separate from any other booster, so that an initiation of one booster, anywhere along the transfer tube, at the cavity, at the reservoir, etc., cannot propagate through the plumbing to another booster. This precludes the possibility of multi-point initiation of the IHE caused by single-point initiation of the PEX. The tubing between the reservoirs and the NEP is interrupted by a unique signal-operated stronglink valve. The PEX cannot be transferred into the NEP unless the stronglink valve receives its unique signal to operate.

b(3) DOE

10.1.2.4 (U) Exclusion Regions and Barriers

10.1.2.4.1 (U) *LLNL Robust Exclusion Barrier*

(U) The purpose of the robust exclusion barrier is to provide a stronger exclusion barrier between the stronglinks in the AF&F and the NEP. The barrier will fully contain the detonator leads and will provide improved thermal protection up to and including fuel fires.

b(3) DOE

10.1.2.4.2 (U) *LLNL Tough Case*

(U) Due to the characteristics of IHE, its very slow burn rate, and its insulating thermal properties, it provides a very good thermal blanket which may be capable of protecting the pit in abnormal fire environments. The difficulty, however, is that as the IHE burns, it generates massive amounts of gas which can "overpressure" the NEP leading to disassembly of the mechanical joints. The tough case design addresses a number of issues associated with maintaining NEP case integrity during a fire environment.

UNCLASSIFIED

b(3)
DOE
DTRA

b(3) DOE DTRA

10.1.2.4.4 (U) *LANL Exclusion Barriers*

(U) To improve nuclear detonation safety in abnormal environments, detonator cables require improved shielding from possible abnormal electrical environments. The exclusion barriers should have the capability to withstand temperatures exceeding 1000°C, should provide for no line-of-sight to detonator cables, should maintain good electrical continuity between the AF&F and the warhead case, and should provide a strong mechanical mounting scheme between the AF&F and the NEP.

b(3) DOE DTRA

(U) Los Alamos made a serious effort to design an exclusion region that would satisfy all requirements for ENDS. However, in the judgment of LANL and Sandia, only incremental improvements can be made toward ENDS, unless considerable modifications to the AF&F, RB, and warhead are made. See Section 5.1.4.3.3.

DOE
STRA

10.1.3 (U) ENHANCED NUCLEAR DETONATION SAFETY (ENDS)

10.1.3.1 (U) Electrical Nuclear Safety Theme

10.1.3.1.1 (U) *LANL/Sandia MK5A Electrical Nuclear Safety Theme*

(U) The electrical nuclear safety theme for almost all Phase 2 MK5A replacement warheads is similar to that of the W88/MK5 with the additional positive isolation feature of detonator safing to preclude initiation of detonators until specific functions occur enabling them. A summary of the W88/MK5 electrical nuclear safety theme is provided and is applicable to essentially all MK5A candidates.

(U) The electrical nuclear safety theme for the W88/MK5 is based on the principles of isolation, incompatibility, and inoperability and has two major parts, (1) to preclude unintended charging of the fire set Capacitor Discharge Unit (CDU) capacitors, and (2) to preclude shorts to the weapon detonator cables that could bypass the CDU.

(U) The following design objectives were formulated for the W88/MK5 to achieve the nuclear safety requirements specified in the MCs.

1. The system shall remain safe until an unambiguous indication of intended use is received.
2. The warhead shall respond to abnormal environments in a predictably safe manner.
3. The design shall meet nuclear safety requirements without the need for a detailed description of the abnormal environments that might be encountered in credible accident scenarios.

UNCLASSIFIED

(U) The design effort to implement the electrical nuclear safety theme resulted in the following system features:

1. Three independent safety subsystems, Intent, Trajectory, and Arming.
2. Exclusion region barriers to isolate the safety-critical components from available electrical energy sources.
3. Stronglink devices requiring unique enabling signals to control the transfer of electrical energy into the exclusion region.
4. Dual exclusion regions, each containing a CDU for detonator firing, without a common interconnection.
5. Collocation of stronglink and weaklink devices to ensure that each receives similar environment exposure.
6. Weaklink (HE) that becomes irreversibly inoperable in abnormal thermal environments before stronglink or barrier failures occur.
7. Widely separated (foam isolator protected) and shielded detonator cables.

(U) The Intent and Trajectory subsystems each provide independent 24-event unique signals for driving the dual stronglink assembly to the enabled position. Intent requires human action and implies a person's intention to launch the missile. Trajectory signals are derived from information developed by the missile in flight. The Arming subsystem includes the issuance of two independent electrical signals and the resultant charging of the CDU. The two required electrical arming signals are isolated from the receptor circuits by a fuse switch and by the launch accelerometer inside the AF&F. Critical circuitry of the fire set is contained within two independent exclusion regions to exclude all energy sources until intended mode operation is initiated.

(U) The electrical nuclear safety theme features and characteristics for the Phase 2 Study replacement warhead candidates are similar to the features designed into the W88/MK5 system. A third major part is added to those candidates that are compatible with detonator safing technology "to preclude initiation of system detonators until specific action is taken to enable those detonators". The Intent and Trajectory subsystems provide the unique signals required to enable the detonator enable/safe system. Detonator safing is described in the Safety Feature Discussion

UNCLASSIFIED

section of this report. In addition, if the Phase 2 Study constraints are changed to allow modification of the MK5 AF&F, a new doped-mylar "weak-link" capacitor will be included in the fire set output.

(U) The thermal weaklink in the W88/MK5 is the conventional HE in the warhead. Tests and analyses show this to be an acceptable weaklink. A study was undertaken in FY93 to identify potential thermal failure modes within the MK5 AF&F. Testing confirmed the existence of failure modes in the Dual Stronglink Assembly (DSA) inside the AF&F prior to loss of electrical isolation. These failure modes enhance the likelihood of a safe response in thermal environments and complement the HE weaklink degraded by the change to IHE and the increased high explosive spacing in the Phase 2 candidates.

(U) The study has identified irreversible, independent, yet predictable, failure modes in the MC3831 DSA resulting from exposure to abnormal thermal environments. The abnormal temperature requirement for the DSA is 650°C due to the nuclear critical safety springs in the Module D becoming indeterminate at that temperature. . Study results identified two failure modes, one involving the Duplex Bearings used in the Module C Intent Stronglink, and the second involving transformers. Module C permanent bearing seizure occurs at a temperature between 350°C and 400°C. Permanent transformer failure, precluding transfer of energy into the exclusion regions, occurs between 280°C and 435°C. Failure mode temperatures are reached in both the bearings and the transformers, under worst-case conditions (smart fire directed at the flat side of the fireset housing closest to the springs), before the spring temperature reaches 650°C.

10.1.3.1.2 (U) *LANL/Sandia MK4A Electrical Nuclear Safety Theme*

(U) The electrical nuclear safety theme for all Phase 2 MK4 replacement warheads is similar to that of the W76/MK4 with the additional positive isolation feature of detonator safing to preclude initiation of detonators until specific functions occur enabling them. A summary of the W76/MK4 electrical nuclear safety theme is provided and is applicable to all MK4A candidates.

(U) The electrical nuclear safety theme for the W76/MK4 is based upon isolation of electrical signals, diversion of electrical energy, and a predictable response relationship between components in credible abnormal environments.

(U) Isolation consists of positive measures (accelerometer and decelerometer) to preclude application of medium-voltage thermal battery power to the fire set except under intended use conditions.

(U) Energy diversion complements isolation. It consists of positive measures (Lightning Arrestor Connector (LAC)) to divert any electrical energy sufficient to cause weapon detonation.

(U) The predictable response relationship consists of positive measures to:

1. Preclude warhead operation except under normal flight conditions.
2. Assure absence of any credible warhead detonator electrical initiation source other than the armed firing set.
3. Preclude operation of critical safety components by available energy sources other than the intended source.
4. Assure that the reaction of critical safety components to environmental stresses is such as to result in a fail-safe response.

(U) A stronglink-weaklink approach is incorporated in the implementation of the safety theme. The accelerometer and decelerometer (stronglinks) provide electrical isolation by sequentially controlling access to the arming and firing circuits. The fireset itself is the weaklink and is designed to become irreversibly inoperable at environmental stress levels below those which could cause stronglink failure. Protection from a direct lightning strike is provided by the combination of the LAC, the incorporation of two stronglink switches, and the exclusion region barrier surrounding the safety-critical components.

(U) The electrical nuclear safety theme for the Phase 2 Study replacement warhead candidate LA4-1 is similar to the W76/MK4 weapon system theme. An additional positive isolation feature, detonator safing, is added in the LA4-2 candidate which modifies the safety theme "to preclude initiation of system detonators until specific functions occur enabling the detonators."

10.1.3.1.3 (U) *LLNL/Sandia MK5A Electrical Nuclear Safety Theme*

All of the LLNL/Sandia MK5A candidates are based on using the existing W88/MK5 MC3810 AF&F and are compatible with DSSL. The larger size and weight capacity of the MK5A (as compared to the MK4A) allow freedom to explore significantly different safety themes.

b(3) DOE DTRA

[LLNL MK5A candidates can be grouped into five categories. The ENDS themes for each category are discussed below.

(U) 1) LL5-1, -2, -3. These candidates all incorporate a DSSL and a robust exclusion barrier between the AF&F and the NEP. The robust exclusion barrier between the AF&F and the NEP provides enhanced safety in abnormal mechanical environments. It may reduce the likelihood that the AF&F will become detached from the warhead, thus exposing the detonator cables and bypassing the stronglinks within the AF&F. However, in these designs, the DSSL maintains safety in this situation as detailed in the DSSL description.

(U) 2) LL5-4a, -4c. These candidates have all of the safety features of the LL5-1, -2, -3 designs. In addition, the nuclear package is surrounded by an accident-resistant case. The accident-resistant case enhances safety in abnormal thermal environments.

(U) 3) LL5-4b. This candidate has a nuclear package that is similar to the LL5-4a, -4c designs. The primary difference is that LL5-4b contains a Category F Permissive Action Link (CAT-F PAL). Because of volume constraints, the accident-resistant case is not used in this design. The CAT-F PAL requires relocation of the firing set, and also requires two stronglinks between the relocated firing set and the primary detonators. The stronglinks in the existing MC3810 AF&F do not play an IND safety role in this design. In their place the DSSL and PEX booster are substituted.

b(3) DOE DTRA

b(3)
DOE
DTRA

10.1.3.1.4 (U) *LLNL/Sandia MK4A Electrical Nuclear Safety Theme*

(U) From an ENDS perspective, all of the LL4-Xa candidates are the same. Therefore, they all use the same ENDS themes. The LLNL/Sandia candidates proposed for the MK4A are designed to enhance two aspects of nuclear safety: reducing the likelihood of structural breakup and providing detonator safing.

(U) To provide positive protection, even if the NEP becomes exposed in an accident, LLNL/Sandia candidates include a DSSL downstream of the detonator cables, within the NEP itself. As long as the DSSL has not received the correct unique signal (i.e., been prearmed), firing of the detonator bridges cannot initiate the main charge explosive.

(U) This aspect of nuclear safety can be further improved in the LL4-Xb candidates by incorporating PEX Booster. Including a PEX booster system requires a new AF&F.

(U) The DSSL in LLNL/Sandia candidates provides improved safety in abnormal environments. Prearming stronglinks by unique signals which require many separate events provides greater assurance that the stronglinks will not be prearmed inadvertently. A signal generated by many events is much less likely to be inadvertently generated than one which requires only one event.

(U) The MK4A candidates could be fielded without DSSL or PEX booster.

(U) Unique Signal Generation: On the D5 missile, the unique signal to prearm DSSL would come from the Intent word which is sent in flight from the missile to the RBs. The use of a human intent signal to prearm DSSL provides the optimal safety for this design. However, the C4 missile system does not have any unique signal capability, and, therefore, is currently incompatible with this implementation. Therefore, for LLNL MK4A warheads on C4 missiles, an ESSG will be required to construct a unique signal by sensing a series of combinations of go/no-go environmental inputs, including acceleration and electrical signals from the missile. This ESSG would be designed to prearm the DSSL if the ESSG sensed events consistent with an SLBM flight, and will lock the DSSL in a safe position if it senses events which are not consistent with SLBM flight (i.e., abnormal environment). These SLBM events would be selected to discriminate between an SLBM flight and any abnormal environment, such as an aircraft crash.

(U) Modifying the MK5 to MK4 Adapter Cable on the D5 missile, which is outside the Phase 2 study groundrules, would allow the MK5 unique signal messages to be transmitted to the MK4A when mated to the D5 missile. This would eliminate the need for an Environmental Sensing Signal Generator in that application.

10.1.4 (U) INRAD EXPOSURE LEVELS

(U) Predictions for INRAD operational exposures for all Phase 2 warhead candidates have been made. The predictions are based upon a methodology that requires knowledge of neutron and gamma INRAD dose rates for each candidate, as well as operational exposure data that can be unambiguously linked to specific existing

TABLE 10.1-5
(U) LLNL/SANDIA MK4A CANDIDATE SAFETY IMPLEMENTATION

10.1.6 (U) CONCLUSIONS

(U) The STWG developed the following conclusions from its Phase 2 study effort:

1. (U) The W76/MK4 and the W88/MK5 meet the intent of all safety requirements as specified in the MCs and STSs. The STWG has not identified any safety concerns with the as-designed weapon systems. New advanced technology developments could be incorporated into system designs that offer safety enhancements to the existing MK4 and MK5.

2. (U) The proposed candidates take advantage of new technology design features/enhancements. Safety systems that can be implemented on Phase 2 candidates which are common to a number of candidate warheads are IHE, fire resistant pits, robust exclusion barriers, and advanced detonator safing (DSSL, SALAD).

3. (U) The enhanced safety concepts and features discussed herein can be incorporated into the Phase 2 candidates without violating groundrules with the exception of the LA4-1 and 2, LA5-5, LL5-5 and LL5-6 designs, and the candidates that incorporate CAT F use control features in their designs.

4. (U) The electrical nuclear safety theme to prevent inadvertent nuclear detonation for MK5A candidates is similar to that of the W88/MK5, with the additional positive isolation feature of detonator safing.

5. (U) The electrical nuclear safety theme to prevent inadvertent nuclear detonation for MK4A candidates is similar to that of the W76/MK4 with the additional positive isolation feature of detonator safing.

6. (U) No attempt was made to quantify the merits of any proposed safety features. An extensive trade-off study would be required to evaluate safety features and their impact on system performance and reliability. Further detailed studies would also be required to quantify safety enhancements and improvements in system safety.

UNCLASSIFIED

b(3) DOE DTRA

8. (U) The STS fire and nearby explosion environments have not been completely defined. Additional details on the DOE SST operations and the nearby explosion environments are needed for continued assessments.

10.2 (U) USE CONTROL

(U) This section addressed the implications of recommendations made by the Fail-Safe and Risk Reduction Committee (FARR) affecting SLBM reentry systems. The FARR working group reviewed the 58+ FARR Committee recommendations for their applicability to the TRIDENT Phase 2 Study.

(U) The following two FARR recommendations, dealing with coded control and use denial, were found to be applicable to the TRIDENT Phase 2 Study:

b(3) DOE DTRA

(U) The issues of coded control and use denial can be addressed at the reentry system level by employing combinations of four warhead use control implementations:

b(3) DOE

UNCLASSIFIED

UNCLASSIFIED

b(3)
DOE

b(3)
DOE

(U) MK5A warhead candidates have been proposed that can incorporate each type of use control device (CAT-D, E, and F PALs). MK4A warhead candidates have been proposed that can incorporate only CAT-D and CAT-E PALs.

b(3)
DOE

Table 10.2-1 summarizes which use control features can be implemented in the various warhead candidates.

(U) The Phase 2 Study was limited to identifying alternate warhead candidates for the W76/MK4 and W88/MK5. Consequently, the study group could only address implications of coded control and use denial options in the warhead and Reentry systems.

(U) Incorporation of various combinations of coded control and use-denial devices can satisfy the FARR recommendations. However, an optimal solution that incorporates coded-control and use-denial devices in combination must consider the entire weapon systems. Determining the impacts of design changes in other

UNCLASSIFIED

subsystems of the weapon systems, such as Fire Control, Launcher, etc., were beyond the scope of this study.

(U) The impacts of CAT-D, E, and F PAL and CD warhead implementations on the weapon systems likewise were not evaluated. Areas that would be affected include the following:

- Missile/Reentry body interfaces
- Fire Control
- Launcher
- Logistics/Operations
- Safety

b(3)
DOE
DTRA

11. ENVIRONMENTAL EFFECTS ASSESSMENT

11. (U) ENVIRONMENTAL EFFECTS ASSESSMENT

(U) There will be no adverse environmental effects from the development, production, testing or stockpiling of the MK4A and MK5A reentry body assemblies and their warheads that are outside of Department of Energy and Department of Defense guidelines for nuclear weapons. Information concerning the environmental impact assessment of the TRIDENT strategic weapon system may be obtained from the Director, Strategic Systems Programs.

12. CONCLUSIONS

12. (U) CONCLUSIONS

12.1 (U) BACKGROUND

(U) The guidelines established for this Phase 2 Study included tasking to "identify and quantify a broad range of alternate reentry systems for use on the TRIDENT weapon systems that emphasize longevity, increased safety margin, system reliability, and future requirements."

(U) Although the present systems are, as President Clinton, the Navy and DOE have said, safe and reliable, all of the replacement warhead candidates considered in the Phase 2 study offer surety enhancements over the currently deployed systems. Most candidates incorporate IHE, improved ENDS, FRP, and use control features. The Phase 2 Study Group evaluated these surety enhancements, and associated performance penalties and system impacts.

(U) The viability of some of the candidates depends upon the DOE's ability to produce new plutonium pits and whether the DOE weapons laboratories are permitted to conduct UGTs.

12.2 (U) EVALUATION APPROACH

(U) To examine the tradeoffs between attributes of candidates, two different evaluation approaches were developed in the System Performance and Effectiveness Technical Working Group (SPETWG). One approach is Weapon Safety Value Assessment (WESVA) (Reference 10) and the other is Relative Overall Merit Assessment (ROMA) (Reference 11).

(U) Both evaluation approaches make use of computer spreadsheets to combine figures of merit (FOMs) for each of the candidate warheads. These FOMs include the following: surety, effectiveness, vulnerability, production/logistics, engineering evaluation, and physics evaluation. Input is taken from the Phase 2 technical working groups.

(U) WESVA uses tradeoffs that measure how much the decision maker is willing to give up of one FOM to gain on another. ROMA assigns weighting coefficients to each of the FOMs that correspond to their assessed importance in overall value. The SPETWG members were polled for their preferences to establish the weighting and tradeoff measures. The spreadsheet format lends itself to interactive use, allowing the decision maker to easily test the sensitivity of results to input assumptions.

(U) The overall value of each candidate was estimated, along with its ranking relative to the W76 or W88. In all cases, no replacement candidates, MK4A or MK5A, were ranked higher than existing systems. The results presented in Section 12.3 are candidate groups which were differentiated from other candidates given the input assumptions. The candidate groups were found to be insensitive to a wide range of variations.

12.3 (U) FINDINGS

(U) The findings are presented for three potential situations which represent fundamentally different political realities and real world constraints.

12.3.1 (U) WITH UGT AND NEW PLUTONIUM PITS

(U) In this situation, the current UGT moratorium is lifted, thereby allowing development testing to demonstrate reliability and performance of replacement candidates that use new plutonium primary pits. This situation further assumes that the DOE weapons complex can manufacture new primary pits.

(U) Both the WESVA and ROMA assessment models indicate that the best alternatives for further consideration are **(the order is not significant)**:

MK4A on C4/D5:	LL4-3
	LA4-1
MK5A on D5:	LL5-2
	LA5-1

12.3.2 (U) WITH UGT AND REUSED PLUTONIUM PITS

(U) In this situation, the current UGT moratorium is lifted, but the DOE weapons complex precludes manufacture of new plutonium pits. Development testing is permitted to demonstrate reliability and performance of replacement candidates using existing primary pits.

(U) Both the WESVA and ROMA assessment models indicate that the best alternatives for further consideration are **(the order is not significant)**:

MK4A on C4/D5:	LL4-1
	LA4-2
MK5A on D5:	LL5-1 (H, M, or L)
	LL5-3a
	LL5-3b
	LA5-4 (H, M, or L)
	LA5-6

12.3.3 (U) WITHOUT UGT

(U) In this situation, the DOE nuclear design laboratories are precluded from conducting UGTs to develop replacement candidates. Historically, nuclear testing has been a necessary part of warhead development. Reducing the need for development nuclear testing is a significant challenge to a design philosophy that has relied on nuclear testing to demonstrate reliability and performance of complex systems that cannot be simulated any other way.

12.3.3.1 (U) MK4A Without UGT

(U) This study has not identified any MK4A candidates for further consideration without UGTs.

12.3.3.2 (U) MK5A Without UGT

(U) The Los Alamos and Livermore nuclear design laboratories have not reached agreement on how MK5A development and certification would be done without UGT.

(U) Pending the results from the joint laboratory peer review process and future inter-laboratory reviews during a Phase 2A or Phase 3, two positions, one each from Livermore and Los Alamos, are presented for the preferred candidates.

12.3.3.2.1 (U) *LLNL Position Without UGT*

(U) Many, but not all, of the development issues for several MK5A warhead candidates can be addressed with existing data from past nuclear tests. The following candidates have such a nuclear test background and merit further consideration as to whether or not they could be developed without additional nuclear testing. See Sections 5.2.2.1.2 and 5.2.2.2.2.

MK5A on D5	LL5-1
	LL5-2
	LA5-1

12.3.3.2.2 (U) *LANL Position Without UGT*

(U) It is the technical position of Los Alamos that any primary considered as a candidate for this Phase 2 should have or have had two successful nuclear tests in its final design configuration. Without this minimum number of tests, the confidence level of any laboratory certification would be significantly less than that of the system it will be replacing. Thus, the leading candidates that meet minimum yield and other military characteristics do not have sufficient test basis to allow certification without a serious degradation of the accompanying confidence level; the confidence level would be unknown. It is also the Los Alamos position that relaxation of MCs would still require at least one more test for certification of candidates LL5-1, LL5-2, and LA5-1. See Section 5.1.2.2.

MK5A on D5:	No candidates meet the requirements.

SLBM Reentry System Alternatives

Objective:

Identify and quantify alternate reentry systems for use on the Trident II strategic weapons systems. Alternatives should consider maximum use of existing DOD hardware in order to minimize system cost. The alternatives should be evaluated with regard to the following attributes:

- SLBM weapon system safety
- Desensitization to aging effects
- Minimum need for refit
- Reliability
- Cost (initial and life cycle)
- Compatibility with existing DOD hardware

Maximum yields commensurate with the above attributes should be identified. Both existing physics packages and those reusing existing plutonium primaries should be emphasized to minimize the impact on limited DOE production capacity.

If the DOE agrees to participate in this study, the Study Group will convene at the earliest date convenient to all study participants. Within 90 days of the initiation of Phase 2, the Study Group will present its goals, strategy, and milestones for conducting the study to the Nuclear Weapons Council Standing Committee (NWCSC). The NWCSC will review the progress and status of the study as necessary but at least annually.

Sincerely,

Bob Barker

APP. B MILITARY CHARACTERISTICS

APPENDIX B

MILITARY CHARACTERISTICS FOR THE WARHEAD FOR THE TRIDENT II (D-5) MK5A AND MK4A REENTRY BODY (U)

(This page is UNCLASSIFIED)

MILITARY CHARACTERISTICS FOR THE WARHEAD FOR THE TRIDENT II (D-5) MK5A REENTRY BODY (U)

1. (U) GENERAL

(U) 1.1 Purpose. These Military Characteristics define the Department of Defense (DOD) requirements for a warhead compatible with the Navy MK5A Reentry Body (RB) used on the TRIDENT II (D-5) Submarine Launched Ballistic Missile Weapon System. This warhead will be a replacement for the existing W88 warhead.

(U) 1.2 Contingencies. Should it appear impractical to meet any of these characteristics or should it appear that meeting of any criterion specified herein will unduly delay development or production of this warhead, or require unreasonable amounts of critical material, or incur unreasonable costs, prompt notification shall be made to the NWC.

(U) 1.3 Competing Characteristics Criteria. As a general rule, priority of consideration shall be given to nuclear safety, reliability and other operational characteristics, in that order. It is understood that technical feasibility, schedule and cost are to provide the basis for making tradeoffs among the desired competing characteristics.

(U) 1.4 Development Schedule. The warhead development schedule shall support an Initial Operational Capability of no earlier than the late 1990's.

(U) 1.5 . Design Philosophy. Attention must be directed toward a design that offers high reliability in a device that will remain in the strategic arsenal well into the next century. Warhead design should be conservative and should not attempt to extend performance beyond well established regimes. More specifically, the warhead design which is developed for this system should:

- (U) Minimize the likelihood of deleterious changes during stockpile life.
- (U) Enhance insensitivity to any changes that may occur.
- (U) Optimize the capability to replicate the design should a warhead rebuild program be required in the future.
- (U) Incorporate new modern safety features to the extent feasible consistent with yield, range and reliability requirements.

- (U) Meet the MC requirements while minimizing the dependence on underground nuclear tests and flight tests, both for development and stockpile surveillance.

- (U) Maximize compatibility with existing DOD hardware (including the AF&F) and facilities.

- (U) Optimize the producibility of the design consistent with potential limited weapon production capabilities.

2. (U) REENTRY BODY/WARHEAD TRADEOFFS

(U) 2.1 General. During the course of development, tradeoffs among competing reentry body/warhead characteristics shall be made with the guidance of the Project Officers Group to optimize overall system performance. Tradeoffs that could significantly alter the ability to meet the Military Characteristics set forth herein shall require prompt notification to the NWC.

(U) 2.2 Yield.

b(3) DOE DTRA

b(3) DOE DTRA

(U) 3.4.4 Arming. The warhead shall be designed to allow arming as late as practical in its planned flight trajectory.

(U) 3.4.5 Automatic Disarming Provisions. The warhead shall automatically disarm within 10 minutes if arming power is interrupted.

(U) 3.4.6 In the absence of arming and firing signals, the probability of nuclear detonation for normal and hostile environments specified in the STS shall not exceed:

(U) 3.4.6.1 One in 10^9 per warhead lifetime in the absence of warhead enabling stimuli*.

(U) 3.4.6.2 One in 10^6 per occurrence after application of initial enabling stimuli and in the absence of final enabling stimuli.

(U) 3.4.7 The probability of a nuclear detonation in the abnormal environments specified in the STS shall not exceed:

(U) 3.4.7.1 One in 10^6 per exposure or accident in the absence of warhead enabling stimuli.

(U) 3.4.7.2 One in 10^3 per occurrence after application of the initial enabling stimuli but prior to final warhead enabling stimuli.

(U) 3.4.8 HE Safety. The following are design requirements:

(U) 3.4.8.1 The warhead HE shall not ignite or detonate as a result of a free fall of the RBA from a distance specified in the STS.

(U) 3.4.8.2 The warhead HE shall not detonate when the RB is subjected to the fire environments described in the STS.

(U) 3.4.9 Criticality. Warhead arrays shall remain subcritical in all planned configurations and abnormal situations stated in the STS.

(U) 3.4.10 Warhead Monitoring. A positive means of monitoring WH disablement status shall be provided.

---

* (U) The enabling stimuli are generally unique signals or environments that operate safety subsystems. They are selected during weapon system development such that they will not be duplicated or simulated by abnormal environments.

MILITARY CHARACTERISTICS FOR THE WARHEAD FOR THE TRIDENT I AND II MK4A REENTRY BODY (U)

1. (U) GENERAL

(U) 1.1 Purpose. These Military Characteristics define the Department of Defense (DOD) requirements for a warhead compatible with the Navy MK4A Reentry Body (RB) used on the C4 and D5 Fleet Ballistic Missile Weapon Systems (TRIDENT I & II). This warhead will be a replacement for the existing W76 warhead.

(U) 1.2 Contingencies. Should it appear impractical to meet any of these characteristics or should it appear that meeting of any criterion specified herein will unduly delay development or production of this warhead, or require unreasonable amounts of critical material, or incur unreasonable costs, prompt notification shall be made to the NWC.

(U) 1.3 Competing Characteristics Criteria. As a general rule, priority of consideration shall be given to nuclear safety, reliability and other operational characteristics, in that order. It is understood that technical feasibility, schedule and cost are to provide the basis for making tradeoffs among the desired competing characteristics.

(U) 1.4 Development Schedule. The warhead development schedule shall support an Initial Operational Capability of no earlier than the late 1990's.

(U) 1.5 Design Philosophy. Attention must be directed toward a design that offers high reliability in a device that will remain in the strategic arsenal well into the next century. Warhead design should be conservative and should not attempt to extend performance beyond well established regimes. More specifically, the warhead design which is developed for this system should:

- (U) Minimize the likelihood of deleterious changes during stockpile life.
- (U) Enhance insensitivity to any changes that may occur.
- (U) Optimize the capability to replicate the design should a warhead rebuild program be required in the future.
- (U) Incorporate new modern safety features to the extent feasible consistent with yield, range and reliability requirements.
- (U) Meet the MC requirements while minimizing the dependence on underground nuclear tests and flight tests, both for development and stockpile surveillance.
- (U) Maximize compatibility with existing DOD hardware and facilities.
- (U) Optimize the producibility of the design consistent with potential limited weapon production capabilities.

2. (U) REENTRY BODY/WARHEAD TRADEOFFS

(U) 2.1 General. During the course of development, tradeoffs among competing reentry body/warhead characteristics shall be made with the guidance of the Project Officers Group to optimize overall system performance. Tradeoffs that could significantly alter the ability to meet the Military Characteristics set forth herein shall require prompt notification to the NWC.

([redacted] 2.2 Yield.

b(3) DOE DTRA

[redacted] 2.3 Physical Characteristics.

b(3) DOE DTRA

3. (U) FUNCTIONAL CONSIDERATIONS

(SFRD) 3.1 Fuzing Options. The warhead shall be compatible with the fuzing options of air burst, near surface burst, and contact burst.

(U) 3.2 Environmental and Survivability Considerations

(U) 3.2.1 Normal Environments. The warhead shall be able to withstand the normal environments stated in the Stockpile-to-Target Sequence (STS) and meet the reliability stated in Paragraph 3.3 and the premature probabilities stated in Paragraph 3.4.6.

(U) 3.2.2 Hostile Environments. In addition to the normal environments, the warhead shall be capable of surviving the hostile environments stated in the STS and a) meet the premature requirements stated in Paragraph 3.4.6 and b) perform without severe degradation of the reliability stated in Paragraph 3.3.

(U) 3.2.3 Abnormal Environments. The warhead shall be able to withstand the abnormal environments stated in the STS and meet the premature probabilities stated in Paragraph 3.4.7.

(U) 3.2.4 Fratricide Environments. In addition to the normal environments, the warhead shall be capable of surviving the fratricide environment stated in the STS and perform without severe degradation of the reliability stated in Paragraph 3.3.

[redacted] 3.3 Reliability Considerations.

b(3) DOE DTRA

(U) 3.4 Safety Considerations. Nuclear weapons safety must be the maximum achievable consistent with operational requirements.

[redacted]

(U) 3.4.1 In the event of a detonation initiated at any single point in the high explosive system, the probability of achieving a nuclear yield greater than four pounds TNT equivalent shall not exceed one in 10^6. This characteristic shall be inherent in the design and achieved without the use of mechanical safing devices.

(U) 3.4.2. The potential for dispersal of hazardous materials shall be minimized by design and operational procedures.

(U) 3.4.2.1 The warhead design shall incorporate modern safety features which minimize plutonium dispersal in fire and other abnormal environments as defined in the STS.

(U) 3.4.3. Multiple independent safety subsystems shall be incorporated that will prevent arming of the warhead firing system in any manner other than the prescribed warhead arming sequence. A positive interruption in the sequence of events necessary to cause warhead firing system arming shall be provided and shall remain effective until the warhead senses a unique environment subsequent to launch. This interruption may be provided by the arming and fuzing subsystem.

(U) 3.4.4. Arming. The warhead shall be designed to allow arming as late as practical in its planned

(U) 3.4.6 In the absence of arming and firing signals, the probability of nuclear detonation for normal and hostile environments specified in the STS shall not exceed:

(U) 3.4.6.1 One in 10^9 per warhead lifetime in the absence of warhead enabling stimuli*.

(U) 3.4.6.2 One in 10^6 per occurrence after application of initial enabling stimuli and in the absence of final enabling stimuli.

(U) 3.4.7 The probability of a nuclear detonation in the abnormal environments specified in the STS shall not exceed:

(U) 3.4.7.1 One in 10^6 per exposure or accident in the absence of warhead enabling stimuli.

(U) 3.4.7.2 One in 10^3 per occurrence after application of the initial enabling stimuli but prior to final warhead enabling stimuli.

---

* (U) The enabling stimuli are generally unique signals or environments that operate safety subsystems. They are selected during weapon system development such that they will not be

DOE

(U) All of the MK4A candidates are compatible with the H1333A and H1333B MK4 RBA Shipping and Storage Containers. With an adapter, the MK4A designs are also compatible with the MK5 container. Therefore, we designed a single container which would accommodate either the MK5A or the MK4A.

(U) Because there are no formal accident resistance requirements for nuclear weapons, for the purpose of this study, we chose some criteria which we considered to be reasonable, as design goals. These design goals could be modified if a reason to do so arose. The design goals we chose are shown in Table C-1.

(U) Our main objectives in selecting these criteria was to assure:
- the exclusion barrier(s) remained intact as long as possible for IND safety;
- the fire resistance of the design would not be degraded by the accident (such as would occur if the FRP were punctured); and
- the entire weapon would remain as one unit and would not be dispersed over a broad area.

(U) Because our candidates have relatively good thermal resistance (fire-resistant pits (FRP) and good thermal weaklinks against IND) but have relatively limited mechanical resistance (which can negate the FRP and bypass IND safety subsystems), we concentrated primarily on providing as much mechanical protection as possible within the footprint and height of the H1514 Container. Designing to fit within the footprint of the existing H1514 container helps maintain compatibility with operations in the storage magazines and service units. The height is limited by the DOE SSTs and SGTs.

b(3)
DOE

Figure C-2 is a sectional view of the container with a MK5 RBA. Figure C-3 identifies the major components and materials.

b(3)
DOE

b(3)
DOE
DTRA

(U) Figures C-6 through C-8 illustrate the clearance between the RBA and the inner surface of the container required to accommodate the RBA lifting and mating fixture ("Four Poster"). This clearance limits the thickness of accident mitigating materials that can be used.

(U) The accident-resistance capabilities of this container are significantly greater than those currently provided by the MK4 and MK5 Shipping and Storage Containers. However, the desire to keep the new container within the existing footprint limits the new container accident resistant capabilities to less than those of DOE's state-of-the-art H1501 Transportation Accident-resistant Container. The H1501 is shown in Figure C-9. The capabilities of the H1501 and the proposed MK5A accident resistance criteria are summarized in Figure C-10. The proposed MK5A criteria cover almost 90 per cent of aircraft accidents.

(U) A MK5A container with H1501 capabilities would be larger and heavier than the proposed design. Also, the H1501 is designed to carry warheads with their long axis oriented horizontally. Either the container would have to be redesigned to orient its long axis vertically or the MK5 and MK4 would have to be qualified for shipment with their long axes horizontal. Because of these considerations and our evaluation that the increased accident resistance was not sufficient to offset the associated drawbacks, we did not pursue the option of achieving the state-of-the-art in accident resistance. This assumes that these weapons will not be transported by air and therefore will not be exposed to the risk of an aircraft crash environment (high speed impact followed by a long duration fuel fire). If the weapon is to be transported by aircraft, then we would strongly recommend the development and use of an H1501A-like container to provide maximum protection in the event of an accident.

TABLE C-2

(U) DIMENSIONS OF STATE-OF-THE-ART ACCIDENT RESISTANT CONTAINER

b(3)
DOE
DTRA

(U) Preliminary structural analysis indicates that the container meets the puncture and impact criteria. The area of most concern for impact is the bolted connection between the upper and lower pieces. This joint will require much more detailed design, analysis, and test to be qualified for these environments. The analysis also indicates that an 0.090 inch thick 304 stainless steel skin is adequate for these criteria. Thicker skin may not be beneficial--the skin would be stronger, but this increase would be offset by higher impact energies in the impact and puncture tests due to the increased weight of the skin.

(U) Preliminary thermal analysis of the proposed accident-resistant container indicates approximately a 10°F temperature rise from the ambient temperature to the outside surface of the RB during normal environments. In an abnormal thermal environment (1850°F fuel fire) the warhead IHE will not reach 319°F (the temperature at which it begins to react exothermically) for at least 50 minutes.

DOE b(3)

1.3.1.2 PAL General Characteristics (U)

(U) In September 1962, the Secretary of Defense approved a set of DoD design guidelines for PAL systems. These guidelines, entitled "General Characteristics for Permissive Devices for Use With Nuclear Weapons," or revisions thereof have served since that time as standards in specifying PAL devices in the MC of new weapons systems. The original guidelines and the four revisions (1969, 1970, 1972, and 1980) are included in Appendix B.

(U) The statement of purpose in the first edition of the General Characteristics of PAL defines:

> (U) "an arming control device for use with designated nuclear weapons which is intended to provide some additional physical means for preventing unauthorized use of nuclear weapons."[18]

(U) A number of specific design requirements are included. Most of these relate to specific operational features of the PAL system or to issues of compatibility with the rest of the weapons system. For instance, the PAL system

- (U) must not degrade weapon safety or reliability
- (U) must he compatible with weapon operational concepts as stated in the STS
- (U) must not significantly lengthen the reaction time for the weapon system

(U) These requirements are restated in all subsequent versions of the General Characteristics. However, as suggested in the Weisner memo, the objective of this system and its reason for existence is based on its ability to protect the weapon against unauthorized use by a potential adversary. Of the twelve specific design requirements stated in the original document, only one relates to the performance of PAL against an adversary.

[redacted]

DOE b(3)

(U) Thus, the objective in terms of an adversary is not specified. However, some bounds are placed on the adversary's capabilities. The *function* of PAL is stated in terms of delay following unauthorized access to a weapon.

(U) In the 1969 edition, the stated purpose is

(U) "To provide general characteristics for permissive action links incorporated in weapons systems to prevent unauthorized nuclear detonation."[19]

[redacted]

DOE b(3)

C b(1)

(U) In 1972, a new edition was prepared to include all existing PAL technology. While the statement of purpose remained essentially the same as in the 1969 edition, PALs are defined as

> (U) "devices and subsystems designed to reduce the possibility of obtaining a nuclear detonation from a nuclear warhead without the use (insertion) of a controlled numerical code, thus reducing the probability of an unauthorized nuclear detonation."[20]

DOE b(3)

Figure 4. M77 Atomic Weapon Locking Device (U)

(U) The W79 8-in. AFAP preceded the W84, entering Phase 6 production in September 1981. Ultimately the W79 will replace the W33 8-in. projectile in stockpile. However, a date for overseas deployment is uncertain at this time. The W79 is equipped with the MC2907 MCCS that provides CAT D PAL protection.

(C) The W85 PII warhead begins Phase 6 production in May 1983. Eventually, the improved PII system will replace many PIs presently deployed to NATO. The W85 is basically a B61-4, CAT F warhead adapted to the warhead section of the PII missile. As such, it is equipped with an MC2907A MCCS.

(C) The W82 155-mm AFAP that will replace the W48 projectile is presently scheduled to enter Phase 6 production in June 1986. No deployment date has been announced. The W82 will be equipped with the MC3764 CAP (Section 4.2). The CAP will provide the same multiple code population and limited-try features as the MCCS, but the W82 will not be maintained in a disenabled state by interrupting warhead circuitry. Instead, the CAP will be located outside the weapon in a Use Denial Lock (UDL). The UDL (Figure 44) is a device which fastens to the nose of the projectile, preventing installation of the fuze. Unlocking the CAP allows removal of the UDL. An Integrated Control Unit (ICU) in the shipping container of each round will provide unlock and relock control of the UDL (Figure 45).

(U) A factory-rebuild program is currently under way to upgrade early versions of the B61. The B61-6 will result from retrofitting the B61-0 with enhanced safety features and the MC2907 CAT D PAL. First Phase 6 production is scheduled for October 1985. The B61-8 represents a safety upgrade of the B61-2 and B61-5. The B61-8 will have an MC2907 CAT D PAL and is scheduled for initial Phase 6 production in January 1988.

(U) Four strategic systems with PAL are planned for the stockpile. Two of these are modifications of existing systems. The B28 (Mods 0 and 1) will be field retrofitted (beginning April 1983); B61-1 will be factory rebuilt (Phase 6 begins September 1985) into the B61-7. Present plans call for an MC2907 CAT D PAL in both systems. Two new strategic systems, the W80-1 warhead for the Air-Launched Cruise Missile (ALCM) (Phase 6 production began February 1982) and the B83 modern strategic bomb (Phase 6 production is scheduled to begin September 1983), also will be equipped with the MC2907 CAT D PAL.

(U) Two new PAL-equipped Navy systems are currently planned. Both the W80-0 warhead for the Tomahawk Sea-Launched Cruise Missile (SLCM) (Phase 6 production is to begin April 1984) and the W81 warhead for the SM-2 fleet air defense missile (Phase 6 production to begin November 1986) will have CAT D PAL (MC2907 or MC3764).

(U) A stockpile projection[31] (Figure 46) shows the planned distribution of PAL-equipped weapons (weapons with no PAL are not shown) through FY 1992. This projection reflects the planned production of weapons equipped with modern CAT D and F PAL devices.

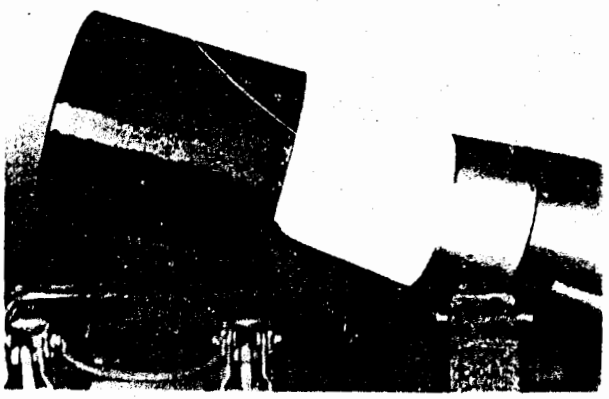

Figure 44. Use Denial Lock (U)

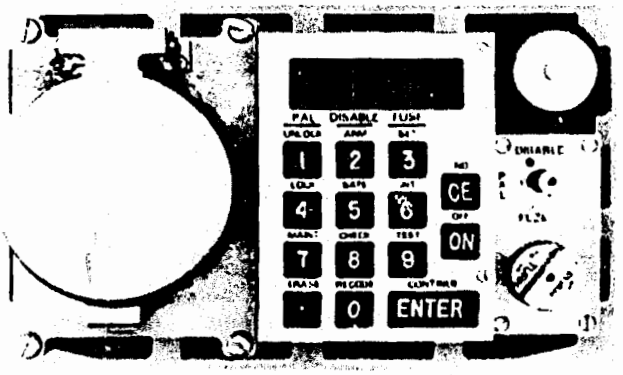

Figure 45. Integrated Control Unit (U)

(U) The HCP (Figure 47) is built around an HP 1000 computer. The system includes a printer, CRT display screen, keyboard, tape and disc storage units, and a cryptographic system. HCP operation is depicted in Figure 48. It has a number of functions. First, it provides access, under two-man control, to encrypted code information from the source data module generated by NSA. In addition, it contains a weapon data base that may be periodically updated.

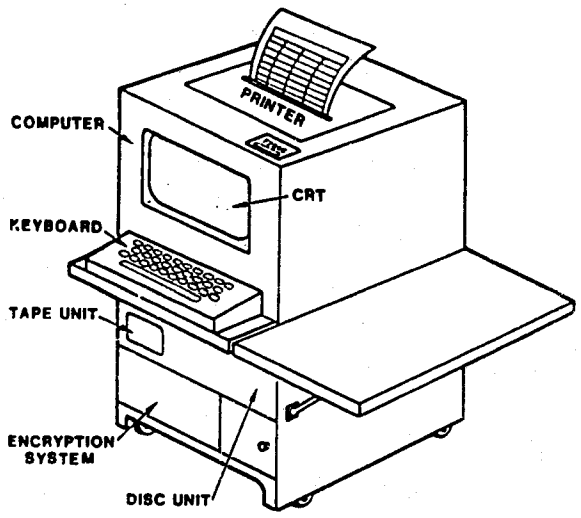

Figure 47. T1565 HQ Code Processor (U)

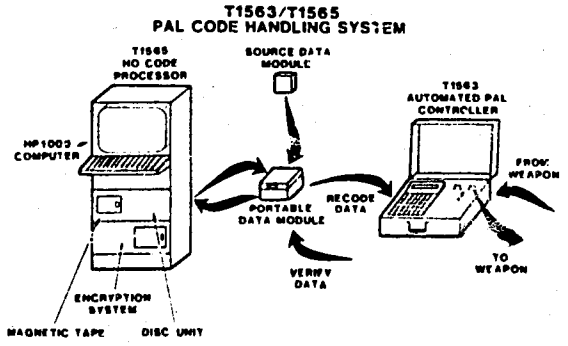

Figure 48. T1563/T1565 PAL Code Handling System (U)

This data base would include, for example, the theater weapon inventory information: mark and mod, serial number, and location of weapons in theater. Utility programs will be available for correlating the data base information with the weapon code information to aid in the construction of theater code plans. Given a theater code plan, the HCP will be able to generate the appropriate portable data modules for use by APCs during recode operations. The HCP will also be capable of reading monitor modules generated by the APC during recode. This may eliminate the need for on-site recode verification by the PMCT in cases where recode can be done with the APC.

THE WHITE HOUSE
WASHINGTON

June 6, 1962

NATIONAL SECURITY ACTION MEMORANDUM NO. 160

TO: The Secretary of State
The Secretary of Defense
The Chairman, Atomic Energy Commission
The Director, Bureau of the Budget

SUBJECT: Permissive Links for Nuclear Weapons in NATO

1. After an examination of the problem of installing permissive links in nuclear weapons dispersed in NATO commands, I have decided we should now make the commitment to procure appropriate devices for all nuclear weapons, now dispersed and to be dispersed to NATO commands, for both non-U.S. and U.S. forces. (See attached memorandum to me from Dr. Wiesner dated May 29. This decision corresponds to Alternative 5 of that memorandum.)

2. This will require a supplementary appropriation for the Atomic Energy Commission budget. The Secretary of Defense, the Chairman, Atomic Energy Commission, and the Director, Bureau of the Budget will work out the details of the budget presentation.

3. At the earliest feasible time, the Secretary of Defense will submit for my approval a schedule for installation of these devices in NATO weapons. In making this schedule, the Secretary should consult with the Secretary of State on the political problems arising from the existence of weapons assigned to U.S. forces and weapons assigned to our Allies.

4. The Chairman, Atomic Energy Commission, in consultation with the Secretary of Defense, will carry out a research program on an urgent basis directed toward an examination of the feasibility and desirability of more advanced permissive link devices with a wider range of capabilities.

/s/ John F. Kennedy

UNCLASSIFIED

APPENDIX A

NSAM-160 and Wiesner Memorandum
Original Document Secret

MEMORANDUM FOR

THE PRESIDENT

At your request, I have reviewed, in consultation with the AEC and the DOD, the technical and cost aspects of equipping nuclear weapons dispersed overseas with permissive link hardware. The object of this review was to establish the program options that were technically available to implement such a program as rapidly as possible, and to determine the amount of supplemental funds that would have to be requested in the AEC FY '63 Budget to accomplish these options.

A decision on this problem involves the following basic policy issues which, while not technical in themselves, are affected by the availability of equipment and the program timing and cost:

(1) Should a permissive link be incorporated at this time in all dispersed nuclear weapons or just in those critical weapon systems with quick reaction, high yield and long range (e.g., Jupiter missiles and quick reaction aircraft)?

(2) Should a permissive link be incorporated at this time in all weapons dispersed to NATO (U.S. as well as non-U.S.) or just to non-U.S. weapons?

(3) Should a permissive link be incorporated at this time in weapons committed to NATO but based in the U.K. as well as weapons based on the European Continent?

These policy issues raised the more basic question as to what objective one is attempting to accomplish by incorporating a permissive link. A permissive link can attempt to meet any of the following objectives, each of which imposes increasingly difficult technical problems:

purpose of this review, I have not attempted to meet a specific objective but rather have analyzed the operational value of the best available equipment and attempted to determine how rapidly it could be incorporated in dispersed nuclear weapons.

While the permissive link equipment presently recommended by the AEC leaves something to be desired and can clearly be much improved with time, I believe that this equipment can be used as the basis for a crash program since development quality hardware exists and initial production and installation could begin in the immediate future.

Specifically the AEC recommends that, if a permissive link program is undertaken on a crash basis, bombs for aircraft and warheads for longer range missiles be equipped with an electro-mechanical lock which would have to receive a prearm numerical code in order to make the weapon operable. In the case of certain bombs which cannot be easily retrofitted with this equipment, as an interim measure pending the development of improved compatible permissive link hardware, mechanical combination locks would be installed to cover a socket into which an arming plug must be inserted. In the case of those bombs as well as short range missiles, such as Honest John and Mike Hercules, and the 8-inch shell, the arming plugs would be stored in self-destruct safes. The proposed program does not include specific hardware for the Davy Crockett missile which presents a particularly difficult problem because of its small size and possible forward deployment.

The numbers which would operate both the electro-mechanical and the combination lock could be held at any echelon or command. If circumstances required, the combination could be held by the U.S. custodial officer himself. This procedure could therefore give the weapons the same state of readiness that they now possess.

In evaluating the utility of this equipment, it must be recognized that it is simply intended to buy time. A specialist with proper equipment might be able to crack the electro-mechanical lock in a few hours time. If he were able to circumvent the self-destruct feature of a safe, a skilled locksmith could open a combination lock relatively quickly. In any event, it would also be possible for skilled technicians familiar with weapons to make these weapons operate in a period of from several hours to weeks, depending on the extent of thier knowledge, by opening the weapons and bypassing the electric circuits. Despite the limitations of this equipment, I believe it would give further (and probably decisive) protection against individual psychotics and would certainly cover unauthorized use by military forces holding the weapons during periods of high tension or military combat. While it would not assure that the weapons could not be used if they were forceably seized by an organized group or a foreign power with technically capable individuals, it would provide in the case of the more important weapon systems equipped with electro-mechanical lock a period of time, varying from hours to days, in which decisions could be made as to what our proper response to the seizure should be. The question of the legal and political requirements of control were beyond the scope of my review.

The question has been raised whether the installation of this development quality hardware on a crash basis might reduce the reliability of the nuclear weapons. However, in view of the simple nature of this equipment and the method of installation, I believe that it is now generally agreed that it would not reduce the inherent reliability of the weapons. The weapons would, of course, not be operable if the combination number were not received from a higher headquarters. This is a communication and management problem, which can be very simple or a very complex, depending on the level of command at which the combination number is held and the degree of control maintained through coding procedures or the use of different combination numbers for different weapons. In its simplest form, it should be possible to handle this procedure wherever a "go code" can be transmitted which is presently a requirement if any control is to exist. In any event, I wish to emphasize that, if circumstances demand, a decision can be made to release the combination number to the U.S. custodian with the field unit and thereby revert to the state of readiness and control that exists today.

At my request, the AEC has estimated the cost and time for completion of the following five alternative programs, which I believe represent the full range of possible application of the permissive link on a crash basis to nuclear weapons dispersed to the European Theater:

The estimated completion date, total cost, and FY '63 for each of these programs is as follows:

Alternative	Estimated Date Completed Installation	Total Cost ($ Millions)	FY '63 Cost ($ Millions)
I	June 1963	3.2	3.2
II	Oct. 1963	11.3	10.6
III	Dec. 1963	13.6	11.7
IV	Mar. 1964	18.6	13.8
V	Aug. 1964	26.9	14.0

A supplemental to the AEC FY '63 Budget would call for obligation of the total cost of the program but expenditure of only the FY '63 cost of the program.

On the basis of this review, I have concluded that it is technically possible to equip on a crash basis all nuclear-weapons dispersed to the European Theater with reasonably effective permissive link equipment at relatively small cost. Therefore, the decision as to the extent to which permissive link equipment should in fact be incorporated in dispersed weapons can be made solely in terms of broad policy considerations as to the desired objective.

Whatever decision is made on the crash program to install permissive link equipment on dispersed nuclear weapons equipment, I would recommend that a vigorous program be undertaken to develop an improved electronic lock which would be incorporated directly in the electronic package associated with all future weapons so that the option of a permissive link would always exist. This program should also include work to develop improved devices to retrofit the bombs and medium range missiles which were equipped with combination locks only as an interim measure in the above crash program. I would also recommend that there be an agressive research program to develop more advanced concepts of the permissive link including mechanics to assure the self-destruction of a weapon if efforts were made to by-pass the permissive link. It is my understanding that the AEC has funds available to cover the R&D necessary for these advanced programs.

Jerome B. Wiesner

APPENDIX B

General Characteristics for PAL Devices
Original Document Secret

Item I

GENERAL CHARACTERISTICS FOR PREMISSIVE DEVICES
FOR USE WITH NUCLEAR WEAPONS (U)

General Characteristics
Approved by the OSD:
13 September 1962

1. Purpose. These General Characteristics define an arming control device for use with designated nuclear weapons which is intended to provide some additional physical means for preventing unauthorized use of nuclear weapons.

2. General Characteristics. The device shall conform to the general characteristics and provide the capabilities listed below:

a. The device shall be capable of repeated enabling, disenabling, and recoding. Further, the device shall be capable of being maintained in either the enabled or disenabled mode.

b. When the device is enabled, a positive indication of enabled condition shall be provided. It is highly desirable that this indication provide no usable information to an unauthorized operator.

c. The time required for authorized enabling of the device shall not add to the weapon system reaction time under any readiness condition. Capability for inflight operation of this device is required for certain aircraft applications.

DOE
b(3)

e. The device and associated equipment shall be designed so that inspection or disassembly of the weapon will not disclose the combination or code.

f. The combination or code shall be transmitable by all standard communications means, and shall be capable of being changed rapidly and accurately by persons having the appropriate equipment and the old combination or code.

g. The device shall be so located and shall function in such a manner that it will permit performance of the required weapon maintenance, retrofit, and test operation throughout the stockpile-to-target sequence, without enabling the device.

h. The device and associated equipment shall be of such quality as not to decrease significantly the weapon reliability.

i. The device and its associated equipment shall be designed so as to permit installation and use of the device in bombs or warheads without degrading weapon safety.

j. The device installed in the weapon itself should not degrade the delivery capability or alter the ballistics of the weapon system.

k. Meters, dials, and switches on device components which are used in the open without blackout protection shall be illuminated in such a manner that blackout will not be violated.

l. The device and its related equipment shall withstand, without functional impairment or reduction of operational reliability, the environmental criteria specified in the applicable stockpile-to-target sequence of authorized weapon applications and in assoicated environmental specifications.

5. Inspection & Maintenance.

a. The system shall be designed so that inspection or disassembly of any component external to the warhead will not disclose the codes.

b. The permissive action link shall be so located and the system shall function in such a manner that it will permit perormance of the required warhead maintenance, retrofit (including internal and external components exclusive of the permissive action link system), and test operations throughout the STS without changing the mode of the device.

c. The system shall be capable of having maintenance performed on it in either the enabled (unlocked) or disenabled (locked) mode.

d. The operational storage life of that portion of the system installed in the warhead shall be no less than that of other warhead components.

6. Control Equipment.

a. Control equipment with the exception of decoders installed in aircraft shall be designed to permit disenabling (locking) and enabling (unlocking) using the "two-man" concept, and recoding using the "two-team" concept.

b. Control equipment shall provide a positive indication of the mode of the permissive action link device. This indication should provide no information regarding the set code.

c. Decoders shall be capable of enabling (unlocking), disenabling (locking), and code checking.

d. Recoders shall be capable of recoding and code checking the system without enabling (unlocking) the device.

e. Design alternatives which combine decoders and recoders are acceptable.

7. Environmental Considerations.

a. Meters, dials, and switches on componenets which are used in the open without blackout protection shall be illuminated in such a manner that blackout will not be violated.

b. The system and its related equipment shall withstand, without functional impairment or reduction of operational reliability, the evironmental criteria specified in the applicable stockpile-to-target sequence of authorized weapon applications and in associated environmental specifications.

Item 3

GENERAL CHARACTERISTICS FOR
PERMISSIVE ACTION LINK SYSTEMS USED WITH NUCLEAR WEAPONS (U)
(Attachment to DDR&E Letter to Chmn, AEC, same subject, 31 Dec 1970.)
(Original Document Secret)

1. Purpose. To provide general characteristics for permissive action links incorporated in weapon systems to prevent an unauthorized nuclear detonation. This document is not intended to inhibit in any way development of improvements beyond the characteristics set forth.

2. General.

[redacted] DoE b(3)

b. The system shall provide for two modes, unlock and lock of the warhead by insertion of one 6-digit decimal code.

[redacted] DoE b(3)

d. The system shall not significantly degrade weapon reliability, nor shall it degrade safety, or delivery capability. The time required for unlocking the device shall not unduly add to the weapon system reaction time under any readiness condition.

3. System Operation.

a. The control equipment must provide visual indications of the status of the system. As a minimum, the equipment must indicate when (a) the number of unsuccessful unlocking attempts is zero, (b) the number of unsuccessful unlocking attempts is greater than zero but less than that required for lockout, and (c) the device is locked out.

b. The system shall be capable of recoding, unlocking or locking at any point in the STS:

(1) in the case of aircraft weapon systems, up to the time of taxi and/or aircraft launch; and enabling (unlocking) or disenabling (locking) after aircraft launch.

(2) in the case of projectiles, at any time up to the time of loading into the weapon breech.

(3) in the case of missile systems, up to the time of final prefire operations.

c. The code shall be capable of being changed rapidly and accurately by persons using the appropriate equipment. Changing of the code will be dependent upon possession of the old (existing) code.

d. At anytime prior to permanent lockout the feature which counts the number of incorrect tries shall reset to zero whenever the proper code is inserted.

e. The system shall be capable of a code check operation which will allow verification of the set code without changing the mode of the device.

4. System Compatibility and Reliability.

a. The system shall be compatible with the weapon operational concepts to include the readiness requirements stated in the STS.

b. The system will be compatible with normal logistical movement in either selected mode.

c. The system shall be electrically compatible with other weapons system circuitry. In the case of aircraft systems it will be compatible with aircraft circuitry during all phases of circuit operation, both ground and air.

d. The design of control equipment shall preclude permanent locking if a permissive action link operation is interrupted by power failure.

e. The system shall incorporate a means of determining electrically, by a T-304 or similar service continuity test equipment, whether the permissive action link device in the unlocked condition.

[redacted] UNCLASSIFIED

Item 4

GENERAL CHARACTERISTICS FOR
PERMISSIVE ACTION LINK SYSTEMS USED WITH NUCLEAR WEAPONS
(Attachment to DDR&F Letter to Chun, AEC, Same Subject, 26 July 1972)
(Original Document Secret)

1. Purpose To provide general characteristics for AEC-produced electromechanical/electronic permissive action link (PAL) systems used with nuclear weapons to prevent an unauthorized nuclear detonation. This document is not intended to inhibit in any way development of improvements beyond the characteristics set forth.

2. Nomemclature

[redacted]

DOE b(3)

3. Definitions

Permissive Action Link (PAL) – A family of devices and subsystems designed to reduce the possibility of obtaining a nuclear detonation from a nuclear warhead without the use (insertion) of a controlled numerical code, thus reducing the probability of an unauthorized nuclear detonation.

Passive Protection – Precludes operation of weapon arming circuits.

Active Protection – Senses attempts to gain unauthorized access to weapon arming circuits, with option to respond by initiating weapon disablement.

Mode – Refers to the protected condition (LOCK) or the unprotected condition (UNLOCK) of the PAL.

State – Refers to the condition of the active protection feature (OFF/TEST/ON).

Unlock Code – A preset code used to unlock the PAL.

Off Code – A preset code used to change state of OFF.

Code Check – Confirms stored code(s) in PAL without affecting weapon PAL mode.

Recode – Allows changing of stored code(s) in PAL.

Code Inhibit – Precludes a second unlock of a PAL with a given code until recode.

Limited-Try – Counts consecutive incorrect code trials and resets to zero on a correct code trial.

Temporary NO-GO – Precludes additional code trial operations without special field equipment after a number of incorrect code trials.

Permanent NO-GO – Precludes additional code trial operations with field equipment after additional incorrect code trials.

4. General Characteristics

A. Category A and Category B [redacted]

DOE b(3)

2. These systems shall provide for two modes, UNLOCK and LOCK of the PAL by insertion of one 4-digit decimal code.

[redacted] UNCLASSIFIED

B. Category B'

DOE
b(3)

3. The system shall provide for two modes, UNLOCK and LOCK of the PAL by the insertion of one 4-digit decimal code.

C. Category C – The characteristics stated above (Category B') apply with the following modifications:

1. The system shall provide for two modes, UNLOCK and LOCK of the PAL by insertion of one 6-digit decimal code.

D. Category D

DOE
b(3)

DOE
b(3)

C. (U) All Categories

(U) 1. The system shall be compatible with the weapon operational concepts to include the readiness requirements stated in the STS.

(U) 2. The system shall be compatible with normal logistical movement in any selected mode.

(U) 3. The system shall not significantly degrade weapon reliability, safety or delivery capability. The time required for unlocking the device shall not unduly add to the weapon system reaction time under any readiness condition.

(U) 4. The system shall be capable of being recoded, code checked, unlocked or locked at any point in the STS up to:

a. (U) In the case of missile systems, up to the time of final pre-fire operations.

b. (U) In the case of aircraft weapon systems, up to the time of taxi and/or aircraft launch, with unlocking or locking after aircraft launch. However, recode is not required after weapon loading on aircraft.

(U) 5. The system shall contain a Master Recode feature to allow recoding of all stored codes using any one of the old codes which has not been inhibited.

(U) 6. The system shall be capable of being recoded rapidly and accurately by persons using the appropriate equipment.

4. (U) CONTROL EQUIPMENT

A. (U) All Categories

(U) 1. The system shall be electrically and mechanically compatible with the weapon system. In the case of aircraft systems, any equipment installed in the aircraft or associated with the weapon will be compatible with aircraft circuitry during all phases of aircraft operation, both ground and air.

(U) 2. The system shall incorporate a means of determining electrically, by service continuity test equipment, whether the PAL is in the unlocked condition.

(U) 3. The control equipment must indicate when (a) the number of unsuccessful trial attempts is zero; (b) the number unsuccessful code trial attempts is greater than zero but less than that required for NO-GO; and (c) the device is NO-GO.

(U) 4. Control equipment shall be provided that will:

a. (U) Allow recoding and code checking without unlocking the PAL.

b. (U) Allow recoding any one or all unlock and off codes using one not inhibited stored code.

c. (U) Allow code checking all stored codes in one operation or code checking any one of the stored codes.

d. (U) Allow unlocking and locking the PAL.

e. (U) Allow PAL unlocking and locking operations in an aircraft to be performed by a single individual.

(U) 5. New control equipment shall minimize potential TEMPEST, tampering, and bugging vulnerabilities. DoE b(3)

5. (U) INSPECTION AND MAINTENANCE

A. (U) All Categories

(U) 1. The system shall be designed so that inspection or disassembly of any component external to the warhead will not disclose the codes.

(U) 2. The PAL system shall function in such a manner that with the active protection OFF, warhead maintenance and test operations can be performed without changing the mode of the passive protection.

6. (U) ENVIRONMENTAL CONSIDERATIONS

A. (U) All Categories

(U) 1. The system and its related equipment shall withstand, without functional impairment or reduction of operational reliability, the environmental criteria specified in the applicable weapon stockpile-to-target sequence.

(U) 2. Meters, dials, and switches on components which are used in the open without blackout protection shall be illuminated in such a manner that blackout will not be violated.

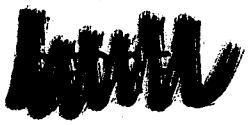
APPENDIX C

Letter from J. P. Wade, Jr., to D. C. Sewell

UNCLASSIFIED

DEPARTMENT OF DEFENSE
MILITARY LIAISON COMMITTEE
TO THE
DEPARTMENT OF ENERGY
WASHINGTON, D.C. 20301

April 18, 1980



Honorable Duane C. Sewell
Assistant Secretary for
Defense Programs
Department of Energy
Washington, D.C. 20585

Dear Mr. Sewell:

(U) Over the past several months a great deal of concern and discussion has surfaced involving the policy for non-violent disablement and what role it should play in nuclear weapon security matters. Specific controversy has centered on questions of: which weapons should have a disable capability?; what level of sophistication should be credited to the threat?; and how long should disablement render the weapon useless against this threat? Department of Defense guidance to the Department of Energy in this area has been presented in systems Military Characteristics and POG meetings, as well as in the Nuclear Weapon Development Guidance. Unfortunately, in many cases it has been less than specific or subject to interpretation in application.

(U) I would like to clarify the existing situation and toward that goal, two transmittals are enclosed. The first is a DoD statement of policy addressing the goals and current assessment needs associated with nuclear weapon disablement systems. The second is a revision of the July 1972 "General Characteristics for Permissive Action Link Systems Used with Nuclear Weapons."

DOE
b(3)

UNCLASSIFIED

(U) The paper "General Characteristics for Permissive Action Link Systems Used with Nuclear Weapons" should be viewed as the basic DoD definitions for PAL systems in acquisition of weapon systems incorporating DoE produced PALs. This paper, that supersedes the original 1972 document and amendments, will be forwarded to DNA for handling in a manner similar to weapon military characteristics, that is DNA will be responsible for publication and maintenance of an up-to-date file including amendments that may occur in the future. Consistent with our intention to work toward standardization of PAL devices and associated control equipment, only three PAL systems, Category D, E, and F are addressed in this update of the paper. Earlier PAL devices continue to remain in the stockpile: however, their acquisition cycle has been completed and therefore they have not been included in this update of the characteristics document.

Sincerely,

/s/ James P. Wade, Jr.
Chairman

APPENDIX D

DoD Directive S-5200.16
September 22, 1970

APPENDIX E

JCS Pub 13, Volume II
(Excerpt From Chapter 7)

APPENDIX F

Excerpt From Amendment 3 to the Military Characteristics for a Nuclear Warhead for the 155 mm Howitzer Projectile (Approved by the MLC 27 April, 1971)

3. Control Devices

3.1 Security Container System (SCS)

An SCS, compatible with projectile and warhead designs, will be used with the M517 on an optional basis. The SCS will be developed under a program separate from the XM517 development program. The SCS shall be designed and function as specified in the SCS Characteristics attached as an Appendix.[2]

3.2. Permissive Action Link (PAL)

The PAL shall conform to the general characteristics outlined in the letter from the Director of Defense Research and Engineering to the Chairman of the Atomic Energy Commission, "General Characteristics for Permissive Action Link Systems Used with Nuclear Weapons," dated 31 December 1970.

3.2.1. The PAL control equipment shall also operate and be capable of recoding the SCS six-digit, limited-try coded switch.

3.2.2. It is desired that the control equipment be compatible with Category B, six-digit single code PAL devices.

3.2.3. The system shall provide for two modes, unlock and lock for the warhead by insertion of one six-digit decimal code. Unlock shall occur upon the insertion of any one correct code of six preset unlock codes. These unlock codes may be preset so that each is unique, or so that redundancies occur among them.

EXECUTIVE SUMMARY

A. Overview

A nuclear weapons stockpile that is totally survivable, secure, safe, and operationally effective with a light logistic burden, all obtainable at a cheap price, represents the ideal world for the military services. This, of course, is an impossibility. As the pendulum of requirements swings in the direction of greater safety and security, survivability necessarily suffers, the nature of the problem being a choice between Scylla and Charybdis.

DOD [redacted] We undertook this study to determine if modular weapon technology offers not a panacea, but a means of improving the overall utility of certain types of nuclear weapon systems. It was intended to produce an essential first-reference document useful in determining the feasibility and utility of modular nuclear weapons, including insertable nuclear components (INCs).

For certain tactical applications, safety is enhanced, and more importantly, this enhancement should allow evolutionary modifications to existing stockpile-to-launch sequences (SLSs) and to administrative regulations that can substantially improve nuclear weapon survivability in the European theater and allow for greater flexibility and operational effectiveness in special theaters.

B. Summary

We reviewed the studies that have addressed modularity, identified potenial requirements for modular weapons, examined the technology needed to support modular weapons development, identified potential applications of modular technology, and evaluated the overall utility of developing and deploying these candidate modular weapon systems.

DOD

Although modular requirements have not been formally specified by the services, they have expressed varying degrees of interest in identifying the costs and benefits associated with incorporating modularity in the development of new tactical and strategic nuclear weapons.

DOD

Ironically some of the earliest nuclear weapons in the stockpile incorporated INCs, then called in-flight capsules.

DOE b(3)

The development of the sealed-pit weapons led to the demise of these early modular weapons around 1960. Technological advances plus increasing concerns for the survivability and security of the nuclear weapon stockpile led to a resurgence of interest in modular weapons during the 1970s that has continued to the present.

DOE b(3)

LDL

Potential system applications for modular technology were evaluated in a matrix that compared families of weapon categories with 34 specific weapon system/warhead characteristics. The strongest contenders for modular technology are tactical systems, the most favorable being a land-launched tactical missile/cruise missile, either convertible or nuclear-only; sea-launched tactical missile/cruise missile, again either convertible or nuclear-only; and an air-launched tactical bomb or air-to-surface missile (ASM) with a nuclear-only capability. Other tactical candidates scored very well but were not selected for the utility analysis: artillery fired atomic projectile (AFAP), torpedo, ADM, and air-to-air missile. Within the strategic categories, the mobile ICBM [surface-to-surface reentry vehicle (RV)] appeared to be a reasonable candidate for modularity, but it was viewed as another good follow-on candidate in view of the political and operational problems associated with mobile strategic systems in the continental U.S. (CONUS) at this time.

[redacted]

UNCLASSIFIED

The utility analysis compared the advantages and disadvantages of modularity with three baseline systems in accomplishing tactical missions for each of the military services. All three candidates are high-value munitions and represent small buys.

- The Army mission analyzed is two-fold:

DOD [redacted] and provide conventional and possibly nuclear air-defense (AD) coverage at medium and high altitudes. The baseline systems are Lance, Hawk, and Nike-Hercules. The generic modular candidate is a convertible surface-to-surface missile/surface-to-air missile (SSM/SAM) system.

- The Navy's mission is to defeat enemy ships, submarines, and shore installations using the [redacted] as the baseline conventional system, and a convertible modular system [redacted] as the modular candidate.

DOD

- The Air Force's mission parallels the Army's first mission of [redacted] the family of B57 and B61 gravity bombs make up the baseline. A dedicated force of nuclear-only TASMs is the candidate modular system.

DOD

[redacted]

DOE b

A secure container with permissive action link (PAL) and command disable (CD) features protects the INC before insertion. The warhead body (WHB) contains the electrical interconnects to the missile guidance system and holds the IHE (or DESTEX for the Navy candidate) necessary to implode the pit. It does not contain RD information. The convertible applications also contain the unitary conventional high explosive (HE) or submunition explosives (or chemicals) in its remaining volume.

The major advantages and disadvantages of modularity as shown by the utility analysis are summarized in the section below. One important caveat t d t d' d 'athenrevs f service regulations in Chapter VI tT

[redacted]

DOD

The advantages and disadvantages are listed below; the service candidate affected is in parentheses.

Pro: (1)

(2)

(3)

DOD

(4)

(5)

Con: (1)

2. Security. Security is a condition that results from the establishment of measures to protect designated information, personnel, systems, components,

and equipment against hostile persons, acts, or influences. Several technical and operational advantages accrue to modular warheads.

DOD

Pro: (1) Command and control requirements are now on components that are individually unable to produce a nuclear yield. (All three candidates)

(2)

(3)

DOD

(4)

Con: (1)

DOE b(3)

(2) Peacetime dispersal to using units (Army) or deployment during crisis/hostilities to collocated air bases or strips (Air Force) for increased survivability means:

a. Exposure to more personnel.

b. Storage at less secure areas than the baseline unless storage wells or shelters are provided.

3. Safety. Safety enhancements are inherent within the INC technologies, regardless of whether or not a favorable administrative and regulatory environment evolves. Two types of safety are analyzed in this report: nuclear detonation safety where an inadvertent detonation gives a nuclear yield in excess of 4 lb HE equivalent, and plutonium-scatter safety where detonation of the HE results in dispersion of plutonium.

Modern nuclear weapons are safe from accidental nuclear detonation, especially those containing IHEs--the U.S. has a perfect record. However, modular warheads are safer before insertion because the INC is physically separated from the HE. The probability of an accidental nuclear yield is zero. Though IHE has greatly reduced the probability of future plutonium

dispersal accidents with standard nuclear warheads, an accident involving the movement of a WHB (less INC) cannot disperse plutonium (it has none); an accident involving an INC would have a much lower probability of plutonium dispersal because of substantially reduced HEs.

Pro: (1) Separation of explosives from nuclear material inherently increases nuclear detonation safety. (All three candidates)

a. Before insertion, modular warheads are safer than the baseline nuclear warheads.

b. After insertion, modular warheads are as safe as baseline nuclear warheads.

(2) Accidents involve lower probabilities of plutonium dispersal. (All three candidates)

(3) Intrinsic radiation concerns can be lessened by storing INCs in shielded containers. (Navy)

a. The INC is stored and transported in strong secure containers with only a small amount of IHE.

b. The WHB body is devoid of plutonium.

Con: (1) Intrinsic radiation concerns are increased because of greater amounts of SNM in INCs if shielding is not adequate. (Navy)

4. Operational Effectiveness. Operational effectiveness as used in the analysis includes mobility, targeting flexibility, enduring capability, storage flexibility, nuclear yield, conventional warhead effects, reliability, range, and foreign political acceptability. The three candidates generally offer improvements over the baseline systems in this area.

Pro: (1) Strategic and tactical mobility for European and special theaters are increased because of the small size and weight of INCs and lack of nuclear materials in the WHB. (All three candidates)

(2) Convertible weapons can provide tremendous targeting flexibility. (Army, Navy)

(3) Enduring capability is available through the rapid logistic resupply of INCs. We think that early dispersal of the missiles and the non-RD WHBs to their field locations will substantially increase their survivability. (All three services)

(4) Convertible weapons allow full nuclear or conventional capabilities where storage areas are limited. (Navy)

Con: (1) Hard fixed-target requirements may necessitate a large and heavy two-stage INC. (Army, Air Force)

(2) Convertible weapons may incur reduced conventional effectiveness because of WHB volume devoted to the nuclear application. (Army, Navy)

DOE b(3)

(3) [redacted] This can be minimal with high production standards, affordable because of the small weapon system buys, and fully acceptable especially in insertion operations within a clean environment. (All three candidates)

(4) Range for the nuclear mode of convertible weapons may be less. (Army)

Unknown: (1) Foreign political acceptability of storing, docking, or overflying INCs and/or WHBs (without INCs) is unclear in areas currently restricted to nuclear weapons. (All three candidates)

5. Logistics. We examined the following subareas: transportation and handling, maintenance and support, storage requirements, special theater movements, training, limited-life component exchange (LLCE), administrative and security regulations, component classification, security personnel, and personnel reliability and inspections. Throughout we used the SLSs that were defined under a favorable environment where the missiles and WHBs do not require RD protection.

Pro: (1) [redacted] DOD DOE b(3)

(2) Size of storage areas requiring special nuclear protection is decreased. (All three candidates)

(3) Training in unit areas and in the field can improve because of the greater availability of INC mock-up trainers and non-RD WHBs. (All three candidates)

(4) Transportation of INCs into special theaters can be more rapid and secure than that of full-up nuclear munitions. (All three candidates)

(5) Limited-life component exchange is easier. (All three candidates)

(6) Maintenance and support workload and handling equipment are reduced for the INC. (All three candidates)

Con: (1) Administrative and security regulations must be adapted to engender viability of modular weapons in all utility areas (except safety, which is inherently increased). (All three candidates)

(2) The WHB must not carry a classification higher than its delivery missile. (All three candidates).

(3) Numbers of security personnel will generally be unchanged unless current storage sites become INC-only sites. Security personnel requirements and storage sites will increase if unit storage is allowed. (Army, Air Force)

Unchanged: (1) Requirements for personnel reliability programs and inspections will probably remain the same. (All three candidates)

(2) Limited-life component exchange intervals and stockpile life will remain the same. (All three candidates)

6. Costs. Life cycle costs including development, production, and operation and support categories were examined in a relative context. Though absolute cost numbers were not estimated, the merit assessment establishes the broad cost trends.

DOD

The Army and Air Force modular candidates are estimated to cost more, primarily because of increases in production, security, and storage costs. However, transportation costs are singled out as a category where substantial cost savings should be realized.

Pro: (1) Costs of a convertible warhead force are less than the costs of a dedicated nuclear plus dedicated conventional force. (Navy)

Con: (1)

DOD 6(3)

(2)

DOD

(3) Production of safe, secure containers and construction of associated storage facilities may be expensive, particularly for the Army system. (All three candidates)

Unknown: (1) Missile system operation and support costs account for about

fifty percent of weapon total life cycle costs. (If delivery unit life-cycle costs are considered, then the costs of INCs become practically negligible in terms of total life-cycle costs.) Costs may rise in certain areas, and fall in others. The overall effect is highly dependent upon INC storage schemes and security regulations, especially for the Army system. (All three candidates)

D. Recommendations

DOD

(1)

(2) Recommend that the Laboratory continue to develop concepts for engineering designs to support modular systems in support of identified or perceived service requirements.

(3) Finally, based upon specific service stated requirements, recommend that the Laboratory be prepared to develop modular warheads for production and deployment.

MODULAR WEAPON SYSTEMS AND INSERTABLE NUCLEAR COMPONENTS

A Compendium of Requirements, Technology, Applications, and Utility (U)

by

Joseph S. Howard II, Edward J. Palanek, John L. Richter, Richard R. Sandoval, Frank L. Smith, Richard H. Stolpe, CDR Larkin E. Garcia, LTC L. Warren

ABSTRACT (U)

This document is to serve as an essential first reference in determining the applicability and utility of modular nuclear weapons, including insertable nuclear components. Potential requirements for modular weapons were identified, past studies were reviewed, and warhead technologies needed to support weapons development were examined. The most promising of the potential applications of modular technology were evaluated in a utility analysis that covered survivability, safety, security, operational effectiveness, logistics, and costs. These analyses indicated potential utility of certain tactical modular applications. Recommendations are made that support continued Los Alamos development work.

UNCLASSIFIED

[redacted]

CHAPTER I

INTRODUCTION

A. Purpose

The purpose of this study is to identify potential requirements for modular nuclear weapons, to review the technology needed to support modular weapons development, and to determine the feasibility, advantages, and disadvantages of developing and deploying one or more generic modular weapons in support of identified service missions.

B. Scope

The scope of this study includes:

- Defining modularity and various system configurations that constitute modularity and other pertinent terms required for understanding the subject area and this study (Chapter I and Glossary).
- Reviewing previous and on-going studies that address modularity and identifying the potential sources of requirements for development and deployment of modular weapons (Chapter II).
- Reviewing modular technology to include the advantages and disadvantages of implementation of the technology (Chapter III).
- Identifying potential applications of modular technology in terms of generic systems and applicable missions (Chapter IV).
- Evaluating potential applications in terms of operational effectiveness: safety, security, and survivability (S^3); design limitations; and cost effectiveness (Chapter V).
- Reviewing publications and regulations that affect the development and deployment of modular weapons (Chapter VI).

C. Objective

The objective of this study is to bring together in one comprehensive document the previous and current work that has been accomplished in the area of nuclear weapon modularity, to evaluate modular technology applications to the missions and requirements of the armed services, and to determine the political and regulatory restrictions that apply. It is intended that this document will serve as an essential first reference in determining whether

modular technology for future weapons should be pursued, identifying weapon types and missions that might use modular technology, and postulating the political and regulatory restrictions that must be overcome.

D. Definition of Terms

Many terms have been used to define the concepts associated with weapons that have alternative warheads or require procedures to ready a complete warhead. In this study, we attempt to establish a set of distinct terms that define the entire spectrum of modularity concepts used here. Other terms used in the study are listed in the glossary.

Modularity - A nuclear weapon design concept that includes insertable nuclear components (INCs), convertible nuclear weapons, and nuclear-only INC weapons.

INC Weapon - A nuclear weapon design concept whereby a nuclear capable warhead can be converted from a nuclear-inert to a live nuclear warhead by inserting a nuclear component. There are two general subclasses of INC warheads: convertible warheads and nuclear-only warheads.

Convertible INC Weapon - An INC weapon that has both a nuclear capability when the special nuclear material (SNM) is emplaced, and a valid conventional or chemical capability when the SNM is removed.

Nuclear-Only INC Weapon - An INC weapon that has only a nuclear capability. It is not designed to have a valid conventional capability when the SNM is removed.

From the definitions above we see that there are two subclasses of INC warheads: (1) convertible warheads and (2) nuclear-only warheads. A convertible warhead is basically a conventional high-explosive (HE) warhead modified so a nuclear assembly, generally called an INC, can be inserted to give the weapon an optional nuclear yield. Convertible warheads may thus have either a nuclear yield or a useful conventional HE yield. With this option, the field commander can choose the yield (either nuclear or conventional) best suited to the delivery system, the battlefield conditions, and the target. Convertible INC designs may make many training and operational requirements

cheaper and simpler because the user need concern himself with just one basic weapon system instead of two. The nuclear-only INC design is used only with a nuclear yield. With either type, the nuclear assembly (the INC) is stored away from the basic weapon most of the time. The INC is inserted only after National Command Authority (NCA) release and, ideally, only after a target is at hand. During almost all the stockpile-to-target sequence (STS), the user does not have a nuclear weapon and thus has no nuclear safety problem, thereby avoiding many problems associated with maintaining, handling, transporting, and guarding nuclear weapons.

B. Overview of Specific Studies

DOD

that time, circa 1970, the nuclear-only INC did not meet with general political acceptance, but it did provide a springboard for the convertible INC. As then envisioned, a conventional warhead, preferably a precision-guided munition, could be simply and cheaply modified to give it a low-yield nuclear option.

2. Convertible Antiship Killer (CASK).[3]

DOD

A

CASK warhead was proposed to greatly increase large ship kill probability when operated in the nuclear mode.

DOD

(7) Personnel would not be exposed to radiation hazards as they are with present nuclear weapons aboard submarines.

(8) Perturbations to the DoD-developed warhead would be minimum, and the consequent reduction in kill radius for the conventional mode, depending on the design selected, would be no more than about 5%.

(9) The entire allowance of INCs could be safely secured in a properly designated vault or safe.

DOD The conventional _____ torpedo was in production when the study was conducted. This was a major disadvantage in considering a nuclear option. Incorporation of an INC option would probably have necessitated a redesign of the arming, fuzing, and firing (AF&F) circuitry, relocation of interior warhead components, and rework of the production facilities. This situation may have been the reason the Navy did not proceed with a convertible _____ DOD DOD torpedo. However, with the _____ torpedo being completely upgraded, the Navy may again examine convertibility. Hughes Aircraft is retrofitting the total Navy inventory of over 2000 Mk 48s.

4. Field Command, Defense Nuclear Agency (FCDNA) Insertable Nuclear Component (INC) Report.[5] This is the earliest source document that addresses various aspects of the then advanced nuclear-weapon design technology associated with the INC concept, both convertible and nuclear only. By this time the AEC had tested several INC design concepts at NTS and had completed several conceptual (Phase 1) studies _____ ACM, CASK, DOD DOD CADMUS, and _____ antiship missile).

This report discusses the effects of the convertible and nuclear-only INC concept on: (1) command and control, (2) custody and logistics, (3) operational readiness, (4) safety, (5) security, (6) administrative aspects of the four safety standards (DoD Directive 5030.15 of 10 June 1960), (7) relative costs, and (8) political ramifications.

5. Phase 2 Feasibility Study for Atomic Demolition Munitions (ADMs).[6]

DOE b(3) DOD

DOD

This led the DOE design laboratories to respond with a variety of design proposals that appeared feasible. The problems associated with integrating a nuclear option (convertible INC concept) into the warhead and circuitry of the Harpoon were addressed in subsequent studies.

Conclusions resulting from Phase 2 and Phase 2A studies included:[9,10]

- A nuclear-only replacement warhead compatible with the Harpoon weapon system is technically feasible and could be developed with little technical risk while satisfying modern nuclear weapons safety standards.
- [redacted] DOE b(3) DOD
- [redacted] DOD DOE b(3) Therefore, the performance characteristics, safety, and reliability of such a concept have not been fully evaluated. DOE b(3)
- Various containers (shipping, storage, destruct) for the INCs have been identified.

The Phase 2A study[10] covered cost, commonality, and additional technical issues from the Phase 2 and resulted in a study recommendation for a convertible [redacted] nuclear warhead with design considerations for future adaptation to the [redacted] antiship missile. DOD DOD The cost analysis concluded that: (1) excluding cost of special nuclear material, there is no significant cost difference between convertible and nuclear-only designs, and (2) a convertible warhead is more cost effective than a nuclear-only system in terms of operational flexibility. In summary, the convertible nuclear [redacted] DOD benefits clearly outweigh those of the baseline nuclear [redacted] The DOD commonality analysis concluded that a high commonality level could be

achievable for Navy low-yield warhead applications and would reduce Navy and DOE costs because of common weapon development and production. The two main technical issues were resolved by actual tests; that is, the convertible warhead survived in the conventional mode, and the Navy conventional HE (DESTEX) could be used in the convertible nuclear warhead. Phase 3 development engineering could be initiated immediately for either a nuclear-only or a convertible warhead for the [redacted] weapon system. The technical risks associated with developing either a nuclear-only or convertible warhead were judged low.

8. Convertible Concepts for the Mk 84.[11] The Air Force, with the participation of the DOE design laboratories conducted a study on the utility of giving the Mk 84 bomb a convertible INC option, especially when using the guided glide bomb (GGB) derivatives of the Mk 84: GBU-8, GBU-10, GBU-15 (V). The study included six proposals ranging from self-contained nuclear weapon add-ons to small capsule-type nuclear components. The designs were selected to illustrate the possibilities of the convertible INC concept and to show that application is highly system-dependent. Though several distinct benefits were identified, a formal requirement did not materialize.

"Convertible Concepts for the Mk 84" was the forerunner of a large and comprehensive study effort by the Directorate of Aerospace Studies entitled "A Utility Analysis of Convertible Nuclear Weapons."[12,13] The two study efforts overlapped to some degree but the Mk 84 study is narrower in scope. Much of the information furnished by the then ERDA laboratories for this effort was used in "A Utility Analysis of Convertible Nuclear Weapons."

9. A Utility Analysis of Convertible Nuclear Weapons.[12,13] This report investigated the operational feasibility of convertible nuclear weapons (CNWs) and analyzed their utility in comparison with standard nuclear weapons (SNWs). The concept was found feasible for lower-yield ranges. The CNWs also used new protective devices and storage facilities more effectively than SNWs because of their small size and the separability of the nuclear explosive package from the HE of the conventional weapon.

DOD 10. Nuclear Convertibility for the [redacted] --An Analysis.[14] The main conclusions of this FCDNA analysis provide one of the best condensed DOD overviews of convertible nuclear [redacted] advantages, including a matrix checklist of advantages and disadvantages. The general conclusion states: DOD "The total cost for the convertible nuclear [redacted] compared to the baseline

nuclear [redacted] is about equivalent. The convertible nuclear [redacted] benefits clearly outweigh those of baseline nuclear [redacted]."

11. Phase 1 Study for the GBU-15 Planar Wing Weapon (PWW).[15] This study examined the concept of equipping the GBU-15 Planar Wing Weapon (PWW) with a nuclear capability. The nuclear GBU-15 PWW would have great commonality with the conventional PWW. [redacted] One can see the possibility of a wide range of employment configurations for the GBU-15 PWW.

12. The Effectiveness of a Convertible Warhead. The effectiveness of a convertible warhead, when used in the conventional HE mode, compared with that of the original unmodified conventional warhead was addressed by Los Alamos in an outgoing telecommunication message to ATSD(AE) on August 1, 1977.

The blast effectiveness of a conventional HE warhead is proportional to the cube root of the mass of HE. When such a weapon is modified to make it convertible, its yield, and consequently its effectiveness, may or may not be reduced from that of the original unmodified warhead, depending on the convertible design used. [redacted]

It is possible to design INC convertible warheads that are fully equal in effectiveness to the unmodified conventional warhead. [redacted]

13. Insertable Nuclear Component (INC) Weapon Technology Applications Study.[16,17] The first part of this study examined all feasible current and

developmental U.S. tactical weapon systems, both nuclear and conventional, for use as INC systems. From all of these systems, six were selected as candidates for the second part which compared the cost and feasibility of using a convertible INC warhead with a mix of conventional and standard nuclear warheads. The six candidates chosen in Part 1 were: DOD tactical [redacted] sea-launched cruise missile (SLCM), CONDOR, [redacted] torpedo, advanced lightweight torpedo (ALWT), and standoff missile (SOM). Part 1 also identifies other weapons with significant operational advantages if deployed as convertible weapons.

Part 2 concludes that the INC weapon concept offers an attractive alternative for obtaining greater capability within a constrained budget. Additional savings are possible if the same INC can be shared among various convertible weapon systems (INC commonality).

14. Recent Work on Insertable Nuclear Component (INC) Warhead Designs.[18] This report summarizes the Los Alamos design and development work on INCs to the year 1977.

[redacted]

DOE b(3)

DOD

DOE b(3)

DOE b(3)

[redacted]

Some concerns the report mentions are:

(1) [redacted]

(2) Existing ERDA classification rules affecting the nonnuclear portion of the warhead might need revision to accommodate the warhead when the INC is not in place.

(3) [redacted]

(4) Production plans for the weapon might need altering in order to accommodate INC needs.

(5) Cost studies of convertible warheads vs conventional HE/regular warheads and the cost of the SNM must be determined because cost is an important consideration in the overall evaluation of the weapon.

15. Implications for Theater Nuclear Forces of a Design Concept Using Separable Nuclear Components.[19] This study provides an initial but detailed qualitative assessment of a nuclear weapon design concept termed the "separable nuclear component (SNC) concept" and focuses on military rather than technical factors. Advantages and disadvantages of SNC weapons in comparison with standard sealed-pit nuclear weapons are analyzed, and their dependence on policy, posture, and weapon design factors is examined. The value of the SNC concept under four postulated theater nuclear force postures is analyzed. Potential applications of the SNC concept to delivery systems are considered and ranked as to potential merit. Political and other implications of introducing SNC weapons are discussed.

a. Conclusions. The study recommends that SNC weapon programs at the nuclear weapon laboratories should be reviewed to ensure that they are properly oriented and that factors such as military advantages, design feasibility, and costs are evaluated and constantly updated to allow for the latest developments in the field. The report suggests that DOE should continue conceptual design efforts on the SNC while emphasizing warheads for

[redacted]

theater-level ORA mobile missile systems and should try to get an SNC weapon where the RWC would not have a restrictive security classification. Further, the DoD should work closely with the DOE in evaluating the political-military utility of SNC weapons and in evaluating delivery systems which now appear to have high merit--specifically GLCM, MRBM, Pershing II and ADM.

16. Tactical Air-to-Surface Munition (TASM). The Air Force, with the assistance of the DOE laboratories, completed a pre-Phase 1 study of a nuclear air-to-surface SOM during 1976-1977.[20,21] A Phase 1 study was then conducted during the period of 1979-1980.[22] The results indicated substantial payoff when attacking mobile and fixed targets with an SOM as compared with nuclear gravity bombs. Though the study did not address INC systems, prelaunch survivability was a major concern with sealed-pit weaponry because of their constrained storage at main operating bases (MOBs). An INC weapon system may allow a large gain in survivability by deployment to numerous collocated operating bases (COBs) and alternate airstrips during crises.

17. Compendium of Convertible Technology.[23] This report is designed to provide an overview of the convertible concept by extracting from previous Navy studies the perceived advantages and disadvantages of the convertible concept. The [redacted] Phase 1, 2, and 2A studies are examined because they are the only studies that attempted to quantify the advantages and disadvantages; these studies also recommended that a convertible system proceed to Phase 3, development engineering. The conclusions of the [redacted] effort are reiterated and those conclusions that are system-independent are highlighted.

Table II-I, extracted from the report, provides a trade-off evaluation of convertible versus standard nuclear weapons. [redacted]

On the other hand, (1) convertible weapons are less costly taken overall than standard nuclear weapons, (2) designs can be modified so that

TABLE II-I

TRADE-OFF EVALUATIONS

Competing Characteristics	Choice	Rationale

DOD

DOE
6(3)

and reliability of the weapon after INC insertion in the field that need resolution.

DOE b(3)

[redacted]

19. Advanced Intercontinental Ballistic Missile (AICBM). A weapon concept currently being investigated concerns small intercontinental ballistic missiles (ICBMs) deployed under different basing concepts. The primary concept is a road-mobile system, but air-mobile, air-transportable, and silo basing concepts are under consideration.

DOE b(3)

[redacted] To increase survivability, the system could be deployed as a mobile system over a road network. Because of the proximity of the warhead to the missile propellant, significant safety concerns are raised when using standard sealed-pit warheads. Security concerns are of an equally severe magnitude because a full-up nuclear warhead is away from a fixed site.

DOE b(3)

[redacted] Accidental nuclear detonation would be an impossibility unless the system was properly mated.

C. Summary of Service Requirements

In October 1977, the National Security Council (NSC), in reviewing the underground nuclear test program proposed by DOE/DoD, held approval of two tests in abeyance pending the DoD submission and interagency review of the military utility and arms control implications of INCs.

DOD

[redacted] Several aspects of the NSC request proved so contentious within DoD that no response was provided.

Certain offices in the Office of the Secretary of Defense (OSD) objected

DOD

to the Navy rationale for a nuclear [redacted] At that time, there was substantial opposition in OSD to any sea-based tactical nuclear weapons. Accordingly, the Navy suspended consideration of a nuclear

DOE

capability [redacted] and DOE terminated active programs related to INCs pending resolution of the impasse between the DoD and the NSC over the

military utility study.[25] The DOE recently rescinded its freeze on testing of INCs and is allowing laboratory development to proceed.[26]

There is growing interest in the potential advantages of INCs within DoD and DOE, evidenced by the Army request for inclusion of INC warheads in the CSWS/JTACMS program. Another indication of interest in INC is the Chief of Naval Operation's (CNO's) memorandum stating the Navy policy to support further research and development of INC technology, to determine its full capabilities, and to consider incorporation of INC technology in development of new weapon systems.[27]

During the same time frame, gun-assembled (GA) weapons were deployed. Figure III-2 shows a cutaway of the Mk 33 8-in. projectile, which is still deployed in large stockpile numbers. [redacted]

DOD

DOE b(3)

[redacted]

C. Benefits of Early IFI and GA Weapons

The IFI weapon bodies were flown on alert and there were accidents that involved scatter of SNM. Without delving into details, the IFI designs prevented large-scale health hazards or loss of life because of the separation of the INC from the remainder of the bomb body. The results from an air crash involving an IFI weapon were: loss of life and aircraft, intact survival of

[redacted]

DOE b(3) DOD

the secondary (if there was one), and scattered uranium at barely detectable levels if an HE explosion or fire occurred. The nature of ionizing radiation allows one to conclude that if it is not detectable with modern instruments, then it is not hazardous to life. Uranium has very feeble radioactivity: 4.5×10^9 year half-life for ^{238}U and 0.71×10^9 year half-life for ^{235}U. In order to put into perspective the hazard of uranium scatter, we note that commercial airliners use depleted uranium as a counterweight material for control surfaces; a Boeing 747 uses about 500 lb of ^{238}U. Unfortunately, airliners crash and burn and sometimes scatter ^{238}U. Whether society is aware of it or not, it has accepted the (infinitesimal) peril of uranium scatter.

[redacted]

DOE b(3)

[redacted]

DOE b(3)

D. Disadvantages of Early IFI and GA Weapons

The IFI weapons were fielded with increasingly complex mechanisms for effecting in-flight insertion. During alert flights, the real bomb bodies were mated with the cores, and the Air Force literally wore them out. Many of the IFI bombs required a weapons officer in the bomb bay. As modern aircraft were developed, the presence of a man in the bomb bay became impossible.

The GA weapons were supplied with trainer weapon bodies as well as mock-up oralloy. The still-in-service W33 is assembled from the ground up in the field. A special truck with an officer and two specialists are required to

assemble an 8-in. weapon. Couple this with the need for a cordon of guards and one has an awkward logistical problem. A highly proficient team can assemble an 8-in. weapon in 45 min; then they handcarry the assembled weapon to the nearby 8-in. howitzer.

E. Sealed-Pit Technology

DOE b(3)

DOE b(3)

The convenience of the all-up round without having to assemble the hardware is very attractive to the military.

The first sealed-pit weapons entered service in 1958, causing production of IFI weapons to cease. The safety crisis came in early 1966 with the accident at Palomares, Spain. A B-52 bomber on airborne alert collided with a KC-135 during a routine refueling operation. Four B28 weapons either fell out or were jettisoned from the falling bomber. One of the bombs fell into the Mediterranean Sea and was recovered relatively intact after about two months. Another soft-landed on the ground because the parachute deployed. The HE of one of the other B28s that hit the ground deflagrated, and the HE of the last one detonated. There was no nuclear excursion from either of the last two, but the plutonium was scattered around the area. Plutonium is pyrophoric, and if it is heated in the presence of air, it will burn and form an aerosol of plutonium oxide. Plutonium ingested through breathing or cuts is a very serious health hazard.

DOE b(3) DOD

Several acres of topsoil were scooped into barrels and buried at the Savannah River site in South Carolina.

About two years later in early 1968, another airborne-alert B-52 caught fire. The pilot dropped the crew by parachute and then rode the airplane down to a burning crash on an ice floe in North Star Bay, Greenland. The contaminated iceberg was cleaned up at greater cost than the contamination at Palomares. As a result of these accidents, the U.S. stopped flying alert bombers. Work to prevent future Palomares- and Thule-type accidents continues. One important result is the introduction of IHEs. [redacted] However, IHE is extremely insensitive and provides much greater safety. A modern, high-performance, nuclear weapon primary with IHE weighs considerably more than similar technology with the HMX-based explosive. Although many new tactical weapons (except the AFAPs) are being designed with IHE, there is no hint that alert bombers will take to the air with IHE bombs on a routine basis.

DOE b(3)

The use of IHE and Cat F PAL (see Cat F PAL in Section F.1.a below) in modern weapons is increasing. These features undeniably increase safety but can result in decreased weapon effectiveness. That is, for a given weight, volume, or SNM usage, the yield may be less. The INC, or modular, weapon can fulfill safety requirements for reduced plutonium scatter without IHE and can protect the separate, vital weapon components without a Cat F PAL built into the weapon. For these reasons, the INC may be a more attractive alternative than the ever more complicated all-up weapon.

F. Current Concepts for Modular Weapons

1. Modern Weapon Systems Architecture. Essentially all nuclear weapons can be considered to be "insertable" in a sense. The B61 is a full-fuzing-option tactical bomb. [redacted] Another example of a weapon that could be considered insertable is the Pershing missile. It has a removable warhead section that is stored separately from the missile. The warhead will not function unless it is mated to the missile and properly launched. Or as a final insertable example, an

DOE b(3)

AFAP will not operate unless it is properly fired from a howitzer. But while these systems are modular in this sense, they are not truly INCs according to the definition in Chapter I.

a. Cat F PAL. A new feature included in many modern nuclear weapons is the Cat F PAL. This is a feature built into the weapon to protect it from unauthorized use.

DOE b(3) DOD

b. Emergency Destructs (EDs). The DoD also has developed Standard Operating Procedures (SOPs) for emergency destructs.

DOE b(3)

2. Recent Separable Component Concepts.

DOE b(3)

a. Figure III-3 shows the convertible concept offered by Los Alamos for the

DOE b(3) DOD

With only a trivial reduction in HE

DOE b(3) DOD

Fig. III-3. Los Alamos Harpoon Proposal 3A warhead.

weight, the weapon body can be used in the conventional role.

[redacted]

The test device did not include INC attributes because the testing of INC weapons had been banned by Presidential Order in 1977.

DOE b(3)

DOD

[redacted]

Fig. III-5. [redacted] DOE b(3)

[redacted]

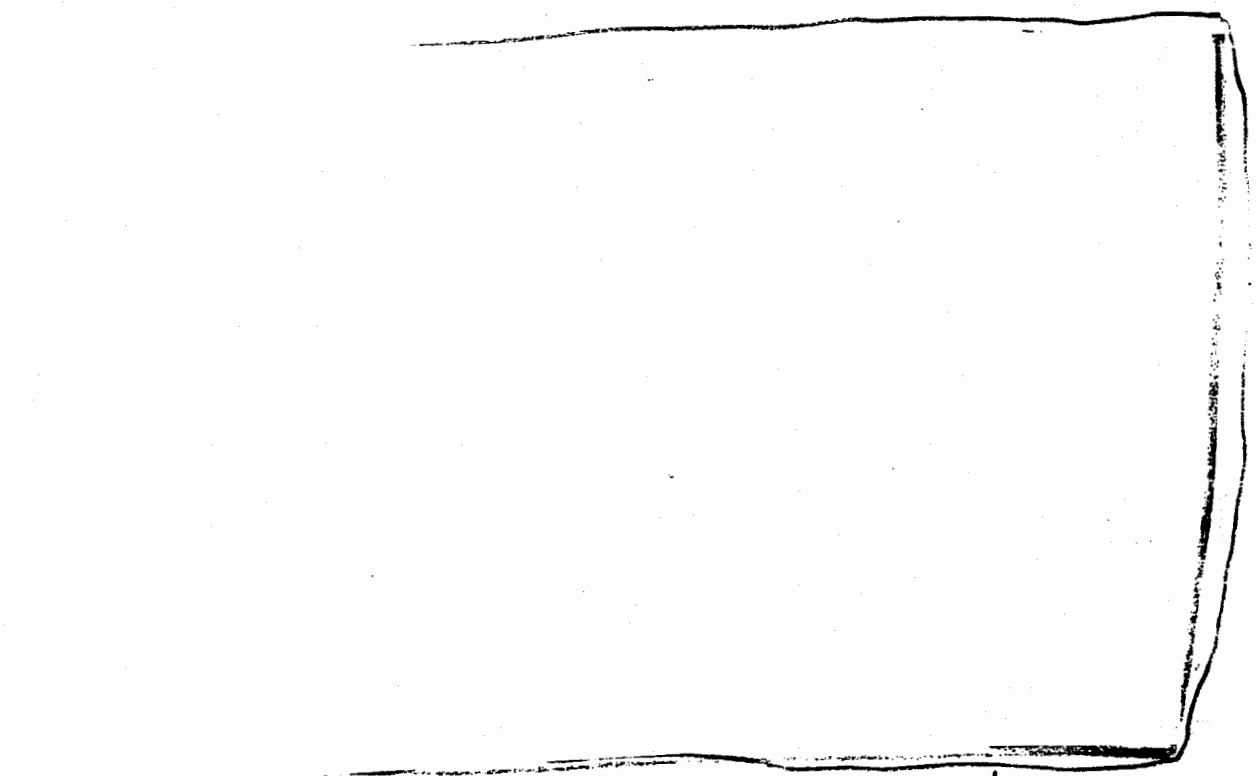

Fig. III-6. [redacted]

[redacted] Two problems associated with the concept are reliability and efficient use of SNM.

e. Two-Component Insertable Nuclear Component (INC). Figure III-7 shows the LLNL concept (Waxwing) for the CSWS/JTACMS. The concept involves a nondescript cavity in the warhead. First, the INC hardware package is installed; then the remaining volume is filled with paste HE. The objective is that the nondescript cavity will be unclassified.

[redacted] The road-mobile missile may eventually use HMX-based propellant, so HMX in the warhead might become acceptable, especially with the separation of the INC. [redacted]

G. INC/Convertible Warhead Observations

The IFI and GA weapons were of the era when the AEC developed weapons with less consideration for logistics or employment than is now possible, given their experience and knowledge. It is safe to say that the detailed concept

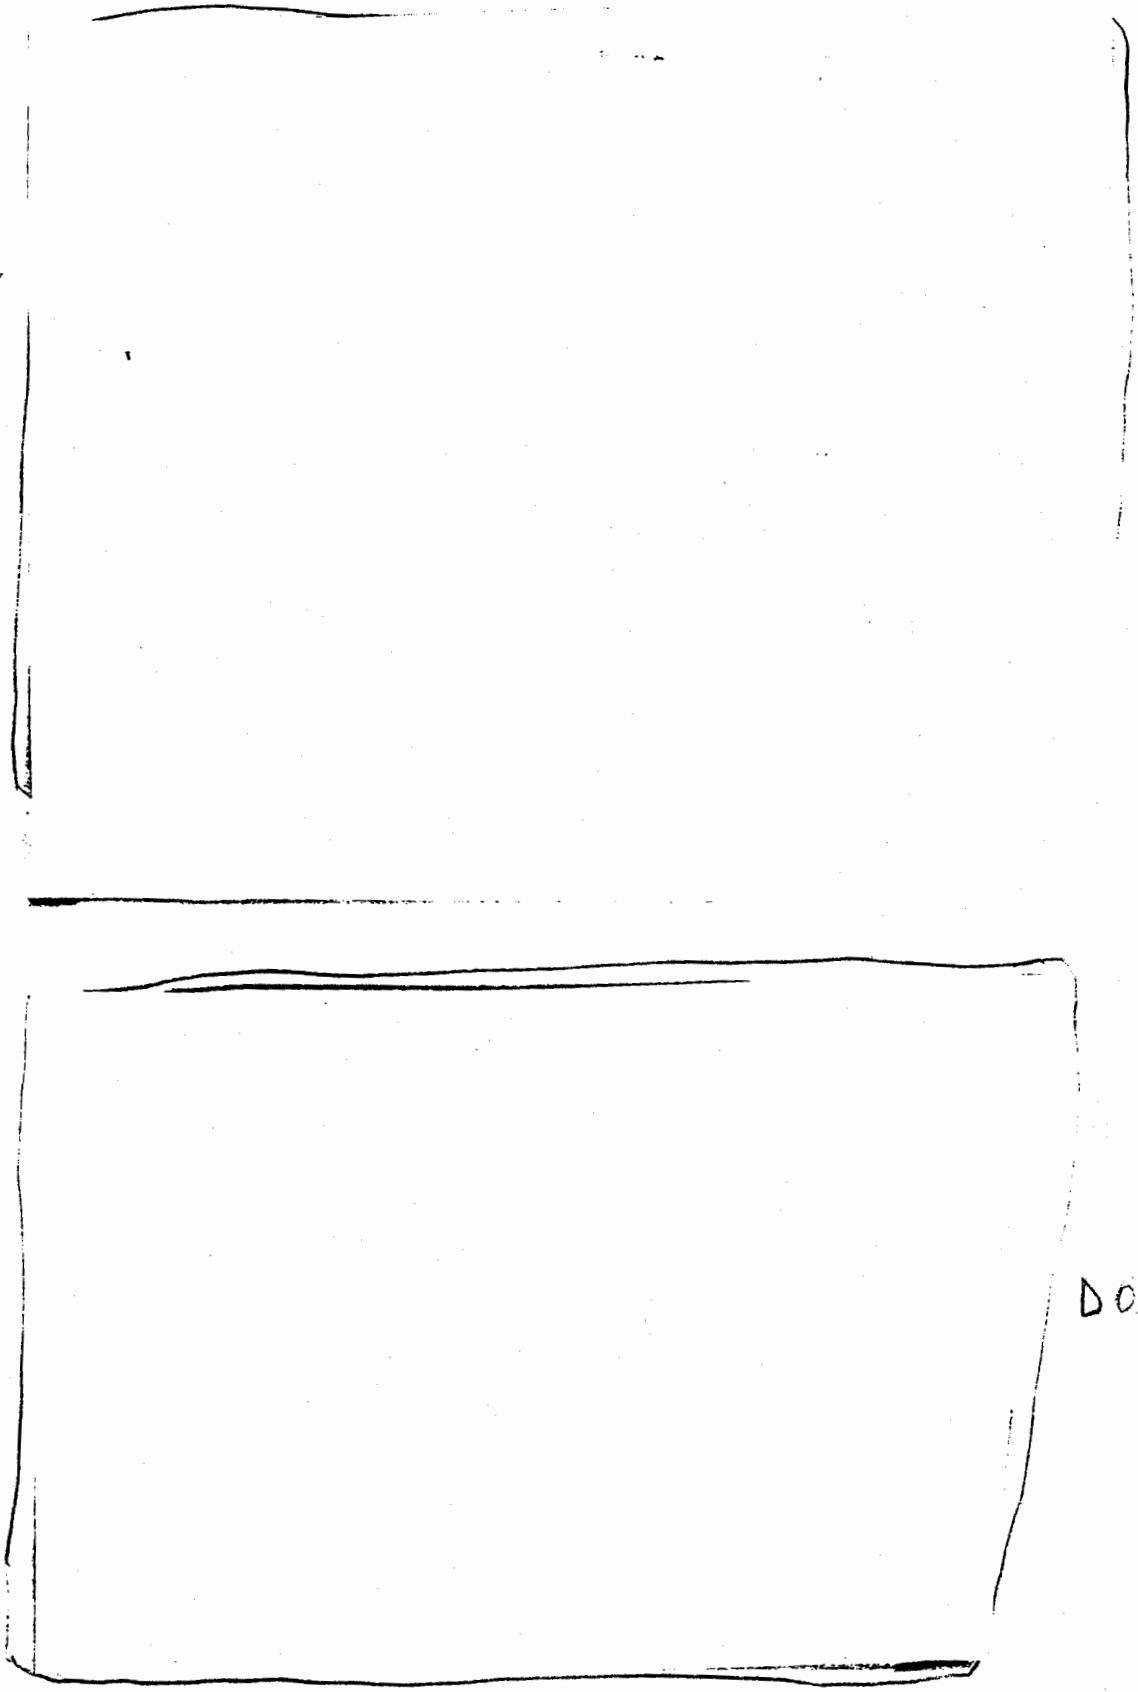

Fig. III-8. Los Alamos conceptual design for AICBM warhead.

formulation guidance was drafted to avoid problems that were evident during the presealed-pit era.

During the 1970's INC convertible warhead studies were done on [redacted] and [redacted] torpedoes, modular guided glide bomb (MGGB) with the Mk 84 2000-lb general-purpose (GP) bomb as the munition, [redacted]. Selective observations can be made concerning each of these INC efforts.

Unwritten nuclear weapon employment doctrine infers that only specified targets will be attacked. [redacted]

[redacted] The tritonal was cast into the "low-value" Mk 84 bombs with little concern for product uniformity but with great regard to cost. There were questions about whether a mill run Mk 84 bomb, modified for convertibility, would operate reliably.

The high-value (classified and expensive) weapons are protected much more carefully by the services than low-value weapons. The latter category includes rifles, cartons of Composition C, artillery ammunition, and GP bombs. Since high-value munitions are protected because of cost, classified components such as guidance, and the threat of misuse, it may be that adequate precautions are already in use to protect a convertible or INC.

CHAPTER IV

POTENTIAL APPLICATIONS OF MODULAR TECHNOLOGY

A. General

The objectives of modular technology are to increase the military utility of applicable weapon systems with minimum operational burden and cost to the user. These objectives are achieved through weapon design which is system dependent. Therefore, it was determined that the advantages and disadvantages of modular technology must be analyzed by comparing a set of weapon system/warhead characteristics with weapon categories that group "like" types of weapons into specific strategic and tactical categories.

It has been found in the past that evaluation of generic systems for adaptation of modular technology has not been successful because of the uinique character of each system. To minimize the impact of this problem, the weapon system/warhead characteristics and weapon categories where chosen so as to provide a reasonably definitive weapon "type" without actually selecting a system either deployed or in development.

B. Approach

A single matrix was developed for a generalized list of weapon categories and an assessment was made concerning the impact of modularity on the weapon system/warhead characteristics. The following assessment factors were used:

- Very positive impact
- Some positive impact
- No change
- Netgative impact
- Not applicable

For the assessment, certain assumptions were made and additional factors considered in determining the impact of modularity on systems within the weapon categories developed. The systems were evaluated on the basis of the STS of like-type systems currently deployed. From this evaluation, which is qualitative rather than quantitative, three of the most promising candidates were selected for a more detailed utility analysis.

1. Weapon Categories. The widely-used lists of strategic and tactical weapon systems were grouped into like types of weapons in specific strategic and tactical categories. This was done to develop a workable matrix and to more readily identify categories of systems that might benefit from modular technology. The weapon categories used in the assessment are as follows:

Strategic

Surface-to-Surface Reentry Vehicle

- Fixed
- Mobile

Air-to-Surface

- Bomb
- Cruise Missile

Air-to-Air-Missile

Strategic Antiballestic Missile

Tactical

Surface-to-Surface

- Projectile
- Reentry Vehicle
- Cruise Missile
- Short Range Missile

Air-to-Surface

- Bomb
- Cruise Missile

Antisubmarine Warfare

- Cruise Missile
- Torpedo

Surface-to-Air-Missile

Air-to-Air Missile

Atomic Demolition Munition

2. Weapon System/Warhead Characteristics. The advantages and disadvantages of modular warhead technology were analyzed for each weapon category by comparing their impact on 34 specific weapon system/warhead characteristics. These competing weapon system/warhead characteristics are intended to establish a broad set of measures encompassing a relatively complete range of attributes desirable for nuclear weapons. These weapon system/warhead characteristics, and their definitions, are as follows:

Command and Control (C^2). Those features that limit warhead/warhead section use only to authorized personnel during circumstances specifically designated by proper authority. Features such as PAL and nonviolent disablement are specifically included.

Convertible Weapon (Dual Capability). A type of INC weapon that has both a nuclear capability when the SNM is emplaced and a valid conventional or chemical capability when the SNM is removed. (The fact that an HE plug, specific submunition, or chemical agent must be emplaced in the cavity intended for the INC, to attain a valid conventional/chemical capability in some designs, does not eliminate those designs from the convertible weapon category.) (Technical Publication, TP 4-1)

Cost. Actual or potential expenditure of dollars and SNM required to develop, produce, and support a weapon capability throughout its life.

Design Impact. The impact of nuclear design on the weapon system when considering the following design requirements.

- Primary only
- Primary with boost

DOE 6(3) [redacted]

- Classification of WHB
- LLC considerations (the impact of modular technology on LLCs and changeout periods)

DOE (b)(3)

•

Desired Yield Range. The capability of modular technology to provide the required yield range.

Destruct (Violent).

(TP 4-1)

Disablement Nonviolent. Nuclear weapons disablement which, through the destruction or disassociation of one or more key warhead or warhead section or atomic projectile components, temporarily destroys a weapon's ability to be used in its intended mode or as an ADM. (TP 4-1)

Economy of Nuclear Material. Judicious design of active materials and designated special weapons materials whose possession and use are licensed and controlled by the Nuclear Regulatory Commission (NRC).

Explosive Ordnance Disposal (EOD). Activities involved in render-safe procedures and the safe removal of explosive ordnance.

INC Weapon. A nuclear weapon design concept whereby a nuclear-capable warhead can be converted from a nuclear-inert warhead to a live nuclear warhead by inserting a nuclear component. There are two general subclasses of INC warheads--convertible and nuclear-only.

Intrinsic Radiation. Nuclear radiation intrinsic to a weapon and emitted through the weapon's outer surface.

Maintenance. The actions necessary to maintain material in the desired state of operational readiness throughout its life cycle. Maintenance functions include checkout, servicing, crew augmentation, replacement, modification, and depot maintenance. (U.S.A. TRADOC PAM 71-12)

Mobility. The capability of the system to be easily moved in an operational environment.

Operational Effectiveness (OPS Effect). The capability of a system to perform the missions for which it was designed.

Personnel and Training. The number of personnel required and skills necessary to operate, maintain, and support the material system in its operational environment throughout its life cycle. Training includes the identification of personnel skills, training devices and aids, instructions, training documentation, and manuals required to support a material system. (U.S.A. TRADOC PAM 71-12)

Range. The impact of modular technology on system range.

Regulations and Directives. Official DOE, DoD, and armed services publications that establish or implement policies or procedures governing all phases of the life cycle of a nuclear weapon.

Reliability. The probability (without reference to countermeasures) that a weapon will detonate when it has been delivered to its target. (TP 4-1)

Risk (Technical). The degree of probability that a technical goal will be achievable in the system considered.

Safety (Munitions). The prevention of the initiation of energetic materials by normal or abnormal inputs of energy when initiation is not desired. This should include nuclear, HE, and plutonium-scatter safety.

Security. A condition that results from the establishment of measures which protect designated information, personnel, systems, components, and equipment against hostile persons, acts, or influences. (JCS PUB 1)

Stockpile Life. The period of time a warhead is available for employment by DoD.

Stockpile-to-Target Sequence Environment. The aggregate of all external conditions and influences affecting the weapon throughout the STS, including transportation, maintenance, storage, and launch. Factors included are

temperature, humidity, and contaminants of the surrounding air; physical location and operating characteristics of the surrounding equipment and occupants; operational procedures such as acceleration, shock, vibration, heating effects, and radiation. (TP 4-1)

Support/Maintenance Facilities. Facilities to support the material system. Examples are: physical plant, real estate, portable buildings, concrete pads, revetments, roads, runways, housing, shops, depots, test sites, computers, training facilities, and storage areas.

Survivability. The capability of a system to withstand a manmade hostile environment without suffering abortive impairment of its ability to accomplish its designated mission. (TP 4-1)

Testing. The procedures and equipment required of DoD personnel (at any level) to certify the reliability of the system, or any of its components, in contrast with the more "conventional" nuclear system.

Transportation and Handling. The procedures, equipment, materials, and facilities needed for packing and crating; the use of reusable containers; supplies necessary to support packaging, preservation, storage handling, and/or transportation of prime equipment; support and test equipment needed; repair parts and supply support; personnel; technical data; publications; and facilities. (U.S.A. TRADOC PAM 71-12)

Vulnerability. The characteristics of a system that cause it to suffer a definite degradation as a result of having been subjected to a certain level of effects in an unnatural (manmade) hostile environment. (TP 4-1)

3. Assumptions and Additional Considerations. In development and assessment of the matrix of potential modular applications, certain assumptions and considerations were applied.

(1) Evaluations were made on the basis of providing something better with modular technology than currently exists in a standard nuclear warhead design.

(2) Certain warhead characteristics were weighed more heavily than others in this assessment. These were

design impact

operational effectiveness

safety

security

survivability

transportation and handling

(3) It was assumed that modular design technology would use relatively higher amounts of SNM; therefore, economy of SNM would reflect a "negative" in most generic system considerations.

(4) Generally, a reduction in reliability can be expected in most modular technology designs and was so reflected for all generic system categories.

(5) Deployment of modular systems would necessitate a restructuring of current regulations and directives addressing nuclear weapon storage, transportation, and handling, and therefore reflect a negative impact.

C. Assessment

1. General. Evaluation of the matrix found in Fig. IV-1 indicates that the strongest contenders for modular technology are tactical systems. Those tactical systems that appear to be the most favorable modular candidates but still allow adaptation to other tactical uses include the following:

(1) Land-launched tactical missile/cruise missile (SSM/SAM), either convertible or nuclear-only

(2) Sea-launched tactical missile/cruise missile (SSM), again either convertible or nuclear-only

(3) Air-launched tactical bomb or air-to-surface missile with a nuclear-only capability

These three candidates can cover a wide variation of STS environments and system variations. Other systems identified for future consideration in modular technology applications include the strategic mobile missile system (AICBM), an air-to-air missile (for strategic or tactical use), and several tactical-only systems.

2. Specific Assessment Considerations. A number of observations can be made in reviewing the matrix and resulting evaluation.

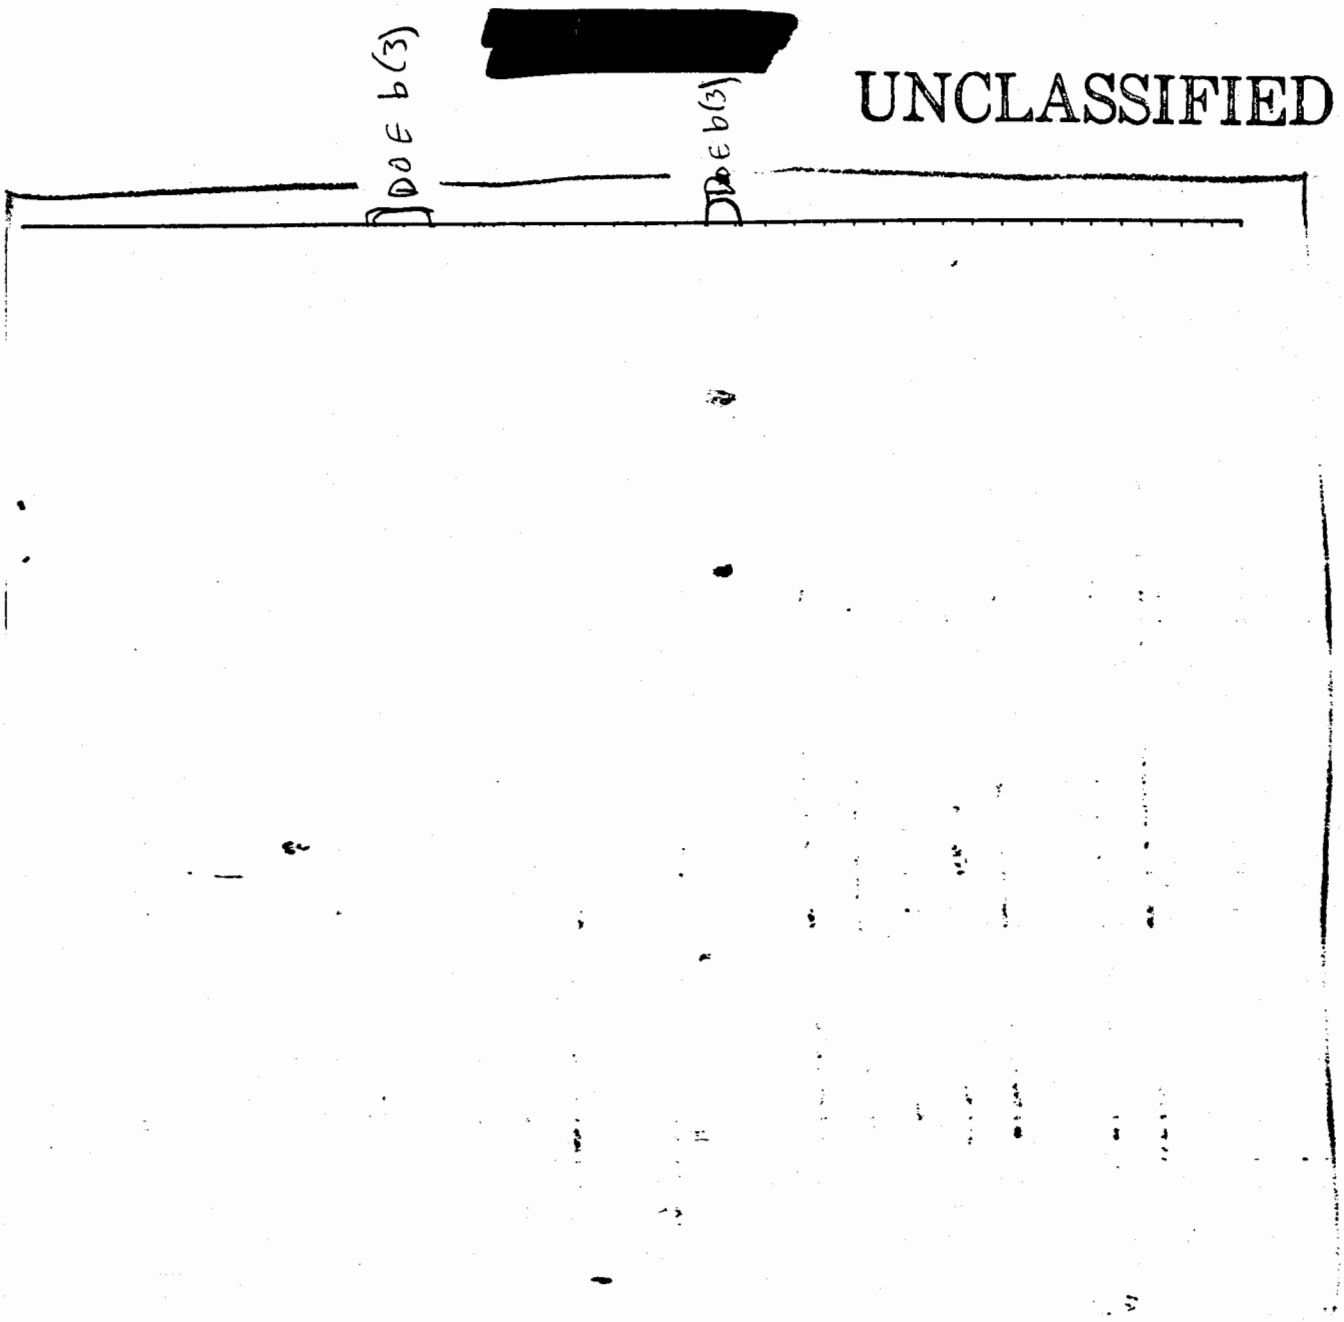

Fig. IV-1. Assessment matrix.

(1) Certain characteristics reflect strong support for modularity technology in all weapon categories. These include

destruct (violent)

disable (nonviolent)

explosive ordnance disposal (EOD)

These three categories encompass security measures designed to ensure against theft or unauthorized use of nuclear weapons. By separation of components, the modular concept provides inherent improvement in security during peacetime and in crisis against the threat of theft

or unintended use. Standard nuclear weapons are not generally amenable to such methods of use denial except through design and operational measures that are relatively cumbersome in comparison to component separation.

(2) Those tactical systems that appeared to be the most favorable candiates for application of modular technology reflecting strong support in the following additional warhead characteristic categories.

command and control

yield range

mobility

safety

security

small volume/lightweight

stockpile-to-target sequence environment

support/maintenance facilities

survivability

transportation and handling

vulnerability

design impact (primary and boost)

(3) [redacted]

DOE b(3)

DOE b(3)

DOD

(4) Some tactical candidates scored very well but were not selected.

DOD

Projectile. [redacted] it was considered improbable that a new projectile would be considered for development in the near term.

Torpedo. A new nuclear torpedo has been under development consideration for several years but is still in question. There is a good possibility that modular technology would have application for

the selected candidate systems, either a new torpedo or in retrofit of [redacted] torpedoes.

Atomic Demolition Munition. The development of a new ADM is questionable at this time. [redacted]

Air-to-Air Missile. The requirement here could have Air Force and Navy applications but does not appear to have the urgency that the selected candidates reflect in meeting projected DoD needs. This would be a good follow-on candidate for modularity consideration.

(5) Within the strategic categories, the mobile ICBM [surface-to-surface reentry vehicle (RV)] appeared to be a reasonable candidate for modularity, but in view of the political and operational problems associated with mobile strategic systems in the CONUS at this time, it was viewed as another good follow-on candidate.

CHAPTER V

UTILITY ANALYSIS

A. Introduction

This chapter examines the utility of modular nuclear warheads within the context of three generic candidates, one system for each of the military services. What we have attempted to do is address the advantages and disadvantages offered by these kinds of warheads. We recognize that hardware is only one aspect of the military equation; the conclusions we reach here must be tempered by the existing political and military doctrinal environment and especially by the current administrative framework. Many factors, including the element of political and military strategy, leadership, personnel training, application of the principles of war, and modus operandi of the STS, are major parameters that ultimately drive the real worth of these systems whether in peacetime deterrence or wartime application. Admittedly, the focus is within the European environment where the survivability of our nuclear forces has been and continues to be severely questioned. We see that modular nuclear weapons potentially offer a substantial increase in survivability, particularly for the Army and Air Force candidates. But turning away from our potentially most important war area to those areas of the world where wars may be more likely, a force of Army or Navy convertible systems offers tremendous flexibility to respond conventionally and to deter nuclear responses within special theaters. Several advantages, including the all-important increase in survivability, also accrue to the Air Force candidate modular system that is dedicated to the nuclear role.

Let no one doubt that obstacles must be overcome to field successfully these kinds of warheads. The technical challenges, however, are not high risk. Reliable and safe modular warheads can be built using present design and engineering capabilities. It is their impact upon the well-established administrative, security, and surety community that involves major ramifications. If modular systems are treated as "business as usual," then only safety advantages result from the separation of plutonium from the HE during most of a warhead's life. Instead, the logistic and regulatory community should modify the peacetime logistic system in order to realize a survivable nuclear system, even with the probability of an increase in costs. Increases in survivability should be

the primary reason for developing, producing, and deploying modular nuclear warheads. Though the benefits of having safer warheads are of great importance, we realize that modern standard warheads have an unblemished safety record regarding accidental nuclear detonation;

DOD

The real benefits in safety improvements lie in allowing changes in the transportation and storage of nuclear weapons that, in turn allow greater dispersion and enhanced survivability. Personnel training needs high emphasis, not only in the obvious mechanics of inserting the nuclear component into the WHB or in installing additional submunitions in a field environment, but also in the total tactics of moving from unit kasern to field locations, or in deploying to collocated Air Force bases, or in changing missile capabilities afloat, as the service case may be.

Beyond the scope of this analysis are several important areas that will have an impact on modular warhead deployments. We do not examine the arms control ramifications which are always of concern to military planners when trying to field new hardware. We also do not examine the strategic and tactical doctrine under which the Armed Forces operate. Both of these factors can affect the ultimate utility of modular weapon systems. In this utility analysis, we assume away the arms control problem and accept the major tenets of the present doctrinal framework (such as flexible response) in applying our logic. We do modify some of the underlying tenets to exploit the utility of modular weapons.

Other political and military considerations, more microscopic in nature, do require treatment. In this analysis, we treat these considerations under a generally favorable environment in order to determine the advantages and disadvantages of modular systems.

We initially describe the generic weapon systems, then take the characteristics used in Chapter IV to identify potential modular applications and examine them through a taxonomical structure consisting of sections on safety, security, survivability, operational effectiveness, logistics, and costs. Relative utility numbers are generated for each section and then aggregated to try to quantify the advantages and disadvantages; the reader can accept or reject this tool yet still support the findings in the summary section which ends the chapter. The conclusions and recommendations that emerge from this utility analysis are given in Chapter VII.

B. Weapon Description and Stockpile-to-Launch Sequence (SLS) Differences

1. General. The approach of this section is to describe initially the candidate modular warheads, then to describe the three modular weapon candidates, and finally to compare their SLSs with the baseline systems. All three candidates are low-quantity buy, high-value munitions.

2. Candidate Modular Warheads. Two warhead candidates are chosen to satisfy potential tactical yield requirements. We vastly prefer the first candidate because of its smaller size, lower weight, and simple design.

a. Warhead Candidates #1. [redacted] The second component is the WHB. For the nuclear application, [redacted] Convertible weapons would also contain additional volume in the WHB for conventional munitions, either sub or unitary. Further investigations in the areas of costs, range, safety, and reliability are needed to determine if a conventional HE filler plug for the cavity in the WHB is warranted for conventional missions and if the conventional munitions normally in the WHB should be removed before firing a nuclear mission. The WHB body would not contain RD. [redacted]

[redacted] The INC would contain the nuclear materials, primary, secondary, IHE, and warhead electrical system. Its main disadvantage is in the large size and heavy weight of the INC. [redacted]

c. Discussion. These modular warhead designs present some technical development and production difficulties, especially in trying to ensure that the WHB contains no RD. Some low risks face the warhead designers. The biggest challenge is to design and produce a highly reliable system that must undergo field insertion. Probably the major challenge is the successful interconnect of the WHD electrical system with the missile fuzing system. Of course present day Lance and Pershing warheads are field mated to their missiles and they possess high relability. Nevertheless, the INC must undergo, in the field, an operation--the mating of explosives and the pit--that is normally done at a DOE plant. Though reliability may be less, designers are confident of providing a highly reliable system by using proper technology and assuming suitable user training in adverse environments, such as sandy southwest Asia or cold and damp northwest Asia.

3. Army Requirements. The Army missions for the analysis are

- Conventional fires to [redacted] primarily by using submunitions (and perhaps a chemical round) against armored and other tactical vehicles
- Nuclear fires to do the same mission
- Conventional air-defense at medium to high altitude, possibly tactical nuclear ABM defense, and back-up SSM nuclear fires

Current baseline systems are the Lance with conventional warhead for the first mission, the [redacted] nuclear warhead for the second, and the Improved Hawk and Hercules for parts of the last mission. The Lance suffers from several shortcomings: it is manpower inefficient, range-limited, old and increasingly difficult to maintain, and relatively inaccurate and unresponsive because of its time-consuming warhead mating operation. The Improved Hawk, though still one of the best medium-range air-defense systems in the world, is being replaced by the Patriot. The Patriot will also replace the very old Nike-Hercules. The Hawk and the Patriot are not fielded with a nuclear capability.

The AD batteries would generally use a unitary conventional warhead, but these units would also possess a number of missiles that could deliver back-up surface-to-surface nuclear and/or tactical nuclear antiballistic missile (ABM) fires. The field artillery would be dedicated to the ground role, with the capability to deliver nuclear warheads or conventional submunitions (and possibly chemicals). Whether or not these missiles should be convertible in the AD role (unitary conventional or nuclear) and convertible in the field artillery (FA) role (submunition or nuclear) depends upon cost and operational effectiveness trade-offs. We propose a dual-capable missile, however, for two reasons: (1) the greater economics from developing and producing the missile in a joint program and (2) increased survivability through deployment of back-up INCs and SSM missiles to AD units.

Figure V-1 shows the SLSs in peacetime. Fig. V-2 shows these sequences in alert or during wartime.

What are the major differences between the baseline systems and the modular candidate within their SLSs? Table V-I succinctly shows the main differences.

Baseline Lance
(wartime)

DOD

Modular convertible SSM/SAM
(alert/wartime)

E/L

Fig. V-2. SLS of Army systems (wartime).

DOD

4. Navy Requirements. The Navy missions are:

- Conventional fires against ships, submarines, and shore installations
- Nuclear fires against the above

The current baseline system is the a conventional system that can be launched from submarines, airplanes, and ships.

The Phase II and IIA studies presented several design approaches with this yield. A number of conventional could be produced with DESTEX, leaving a cavity for insertion of an INC (nuclear application) or a filler component of additional DESTEX (conventional application). Existing ship-board launchers would be used and modified to allow rapid change-out of INCs and conventional filler plugs. A safe secure container would be built and stored away from the crew to For comparative stockpile-to-launch purposes, we configure an expanded baseline consisting of conventional and dedicated standard nuclear Figure V-3 graphically presents the SLS of the Navy system. Table V-II then depicts the differences between the mixed force of Harpoons and a modular convertible force.

5. Air Force Requirements. The Air Force has identified a tactical mission of with nuclear munitions. The Army and Air Force are currently staffing joint interdiction procedures.

[redacted]

UNCLASSIFIED

TABLE V-II

COMPARISON OF NAVY BASELINE AND MODULAR CANDIDATES

	Procedure	Baseline Conventional Plus Dedicated Nuclear Harpoon	Convertible Harpoon
1.	Production	All-up canisterized conventional weapon All-up canisterized nuclear weapon	Force of canisterized missiles with HE (WHB) and emplaced conventional plus
2.	Warhead Transportation and Storage	On missile within canister (conventional and nuclear)	Conventional warhead on missile within canister. INC transported and stored in secure storage container away from canisterized missile and shielded away from crew
3.	Missile Storage	Conventional: In canisters with warheads at storage areas or in ship magazines/launchers Nuclear: In special storage areas or in special ship magazines	Missile stored as conventional Harpoon is today
4.	Peacetime Dispersal of WR Warheads	Full-up warheads on missiles in magazines afloat or in special storage	INCs (away from missiles) are in magazines afloat or in special storage areas
5.	Wartime Dispersal of WR Warheads	Onto launchers	Onto launchers; INC inserted into missile
6.	PAL Unlock	Upon message receipt and authentication	Same

An INC TASM could provide a means of increasing weapon survivability if operational procedures and security regulations can be modified (Fig. V-4). An INC separate from the WHB, though still an RD item, is not a nuclear weapon. By dispersing the WHB (less INC) to separate locations in peacetime and storing the INC and its containers in underground storage vaults/wells at both MOBs and COBs, the enemy targeting requirements have risen greatly. Crisis conditions may see the flushing of INCs and exportable shelters to some of the 600 plus airstrips in Europe that can handle F-111 or smaller fighters as ea

C. Approach

The summary section at the end of this chapter lists the major advantages, disadvantages, and unknowns that are associated with S^3, operational effectiveness, logistics, and costs.

TABLE V-III

COMPARISON OF AIR FORCE BASELINE AND MODULAR CANDIDATES

We have stressed the importance of a favorable regulatory and administrative environment upon the potential utility of the modular candidates. Except for the case of safety where modular weapons are inherently more safe than standard nuclear weapons, a favorable environment is necessary to realize fully the advantages of modular weapons and to minimize the potential disadvantages. Environment is used here in the broadest sense of the word and includes major external factors--political, economic, technical, administrative, or military--that may have an impact upon the three modular candidates.

Combining the advantages and disadvantages intuitively into a decision to proceed or not to proceed with development and engineering is difficult. We provide a simple scheme for aggregating the advantages/disadvantages into an overall quantitative merit value. We then use this scheme to present our quantitative numbers as a guide (see tables at the end of each subsection). The steps in the scheme are:

(1) Assign a number from zero to three based upon relative evaluation of the value/importance (VI) of each subarea and major area.

- 0: Unimportant
- 1: Some importance
- 2: Very important
- 3: Extremely important

(2) Evaluate the utility/worth (U) of the modular warhead as compared to that of the the baseline system in meeting the subarea's requirements.

- -1.0: Much inferior to baseline
- -0.5: Inferior to baseline
- 0: Same as baseline
- +0.1: Insignificantly better than baseline
- +0.2: Slightly better than baseline
- +0.4: Somewhat better than baseline
- +0.5: Better than baseline
- +0.7: Substantially better than baseline
- +1.0: Much better than baseline

(3) As a conclusion to each major area (for example Safety) discussion, calculate the average merit for all subareas (N in quantity) within that major area.

(4) Repeat step 3, above, to aggregate all major areas into a final worth.

$$\frac{\sum_{i=1}^{N} \left(VI_i \times U_i\right)}{\sum_{i=1}^{N} VI_i}$$

D. Safety

Safety is the prevention of the initiation of energetic materials by normal or abnormal inputs of energy when initiation is not desired. We distinguish between two types of safety: (1) nuclear detonation safety where an inadvertent detonation gives a nuclear yield in excess of four pounds HE equivalent and (2) plutonium-scatter safety where detonation of the HE results in dispersion of plutonium. Even in an unfavorable regulatory and administrative environment, modular warheads engender increased safety levels.

1. Nuclear Detonation

a. Statement

Separation of explosives from nuclear material inherently increases nuclear detonation safety. (All three candidates)

- Before insertion, modular warheads are safer than the baseline nuclear warheads.
- After insertion, modular warheads are as safe as baseline nuclear warheads.

b. Discussion

Modern nuclear weapons are safe from accidental nuclear detonation, especially those containing IHEs--the U.S. has a perfect record. However, modular warheads are safer before insertion because the INC is physically separated from the HE. The probability of an accidental nuclear yield is zero. After the INC is inserted into the WHB, the modular warhead candidates are as safe as the baseline warheads and can meet the stringent military requirements. INCs would incorporate modern safety features such as weak-link/strong-link circuits and would be stored in safe secure containers. The Army and Air Force candidates would use IHE; the Navy would use DESTEX for their convertible system.

As an example for the first merit estimation and to indicate our logic, we rate the VI of nuclear detonation safety as 3 (extremely important). Compared

to the baseline systems which already afford high nuclear detonation safety, we assign a U of +0.2 (slightly better than baseline).

c. Merit Estimation

Candidate	VI	U	VI x U
A, N, AF	3	+0.2	+0.6

2. Plutonium-Dispersal

a. Statement

Accidents involve lower probabilities of plutonium dispersal. (All three candidates)

b. Discussion.

The two accidents at Thule, Greenland; and Palomares, Spain, in the 1960's required significant cleanup operations and caused much greater political results (such as changes to B-52 alert operations). Future accidents that cause plutonium scatter, especially if in populated areas, could create tremendous problems. The use of IHE for some of our stockpiled weapons has greatly reduced some of these concerns. Nevertheless, the sheer number of nuclear weapon movements leaves the door open for future plutonium dispersal accidents. An accident involving the movement of a WHB (less INC) would not disperse plutonium (it has none) nor should it be called a nuclear weapon accident or incident. An accident involving an INC would have a much lower probability of plutonium dispersal because of substantially reduced HEs. This is because the IHE used in the INC is minimal. Also, the secure container could generally be stronger than the shipping containers and canisters of the baseline systems, meaning less chance for rupture.

c. Merit Estimation

Candidate	VI	U	VI x U
A, N, AF	3	+0.4	+1.2

3. Intrinsic Radiation

a. Statement

Intrinsic radiation concerns can be lessened by storing INCs in shielded containers. (Navy)

Intrinsic radiation concerns are increased because of greater amounts of nuclear materials in the INCs if shielding is not adequate. (Navy)

b. Discussion

The proximity between crew living and working quarters aboard Navy ships and particularly submarines is a real health concern. In some cases aboard submarines, the crews "live" on top of the nuclear weapons. Intrinsic radiation from nuclear warheads might subject crews to levels above that permitted by medical regulations. An all-up nuclear canistered Harpoon is not easily shielded or stored away from crews; a small INC is. Already shielded by its container, additional shielding can be easily provided to the INC because of its small volume. The second concern deals with exposures when handling the INC out of its container. The time intervals are so short that the radiation effect is minimal. Finally, intrinsic radiation concerns are of much smaller magnitude in the Army and Air Force considerations because of personnel separation from the nuclear munition.

c. Merit Estimation

Candidate	VI	U	VI x U
N	2	+1	+2
A, AF	0	+1	0

4. Total and Average Merit Under Safety.

Candidate	Total Merit	Average Merit
A	+1.8	+0.3 (somewhat better than baseline)
N	+3.8	+0.5 (better than baseline)
AF	+1.8	+0.3 (somewhat better than baseline)

E. Security

We define security as a condition that results from the establishment of measures to protect designated information, personnel, systems, components, and equipment against hostile persons, acts, or influences. Several technical and operational advantages accrue to modular warheads.

1. Command and Control

a. Statement

Command and control requirements are now on components that are individually unable to produce a nuclear yield. (All three candidates)

b. Discussion

Command and control is defined as those features that limit warhead use only to authorized personnel during circumstances specifically designated by

proper authority. Baseline systems are protected by PALs and are stored in special nuclear storage areas. One of the reasons for this is the fact that the baseline nuclear round is a full-up nuclear round. An INC in its secure storage container (with PAL, etc.) and the WHB are not full-up rounds by themselves.

c. Merit Estimation

Candidate	VI	U	VI x U
A, N, AF	2	+0.7	+1.4

2. Nonviolent Disablement

a. Statement

Nonviolent disablement measures are more compatible with a secure container than a full-up munition or missile. (All three candidates)

b. Discussion

[redacted]

DOD

DOE b(3)

c. Merit Estimation

Candidate	VI	U	VI x U
A, N, AF	1	+0.2	+0.2

3. Emergency Destruct

a. Statement

Emergency destruct of nuclear capability and design information is more readily conducted within the secure container. (All three candidates)

b. Discussion

DOE

[redacted] the greater quantities of HE make the probability of plutonium dispersal greater than zero. However, design information may still be inferred. The modular candidates would have their INCs stored in a command-destruct secure container. It would be so designed as to contain the destruction of the INC, maintain its integrity, and yet eliminate design information.

c. Merit Estimation

Candidate	VI	U	VI x U
A, N, AF	2	+0.7	+1.4

4. Safe Secure Container

a. Statement

The safe secure container is virtually secure and reduces concerns for HE protection. (All three candidates)

b. Discussion

DOE b(3)

[redacted]

DOE b(3)

[redacted]

ICL

c. Merit Estimation

Candidate	VI	U	VI x U
A, N, AF	1	+1	+1

5. Vulnerability to Theft

a. Statement

DOE b(3)

[redacted]

DCI

b. Discussion

The INC within its container, while not portable by a single man, is certainly easier to move than a missile, W81 or W70 warhead, or B57 or B61 bomb. This particularly may apply to the Army candidate and to a lesser extent the Air Force and the Navy candidates, according to the number of sites and potential exposure to security threats.

DOE (b)(3)

[redacted]

This may do wonders for security but it has a negative impact upon operational effectiveness and survivability.

c. Merit Estimation

Candidate	VI	U	VI x U
A	2	-0.4	-0.8
N	1	-0.2	-0.2
AF	2	-0.4	-0.8

6. Peacetime Dispersal

a. Statement

Peacetime dispersal to using units (Army) or deployment during crises/hostilities to collocated air bases or strips (Air Force) for increased survivability means:

- Exposure to more personnel
- Storage at less secure areas than the baseline unless storage wells or exportable shelters are provided

b. Discussion

By personnel, we mean authorized and unauthorized military plus civilians.

Dal

Storage aboard Navy ships and submarines would also be modified to account for shielding of the INC containers and storage away from the crew. The negative impact of dispersal upon Naval security should be very small.

c. Merit Estimation

Candidate	VI	U	VI x U
A	2	-0.4	-0.8
AF	2	-0.4	-0.8
N	1	-0.1	-0.1

7. Total and Average Merit Under Security

Candidate	Total Merit	Average Merit
A	+2.4	+0.2 (slightly better than baseline)

3. Deployability

a. Statement

INCs can be rapidly deployed to alternate locations during wartime. (All three candidates)

b. Discussion

c. Merit Estimation

Candidate	VI	U	VI x U
A	2	+0.5	+1.0
AF	2	+0.5	+1.0
N	1	+0.2	+0.2

4. Concealability

a. Statement

INCs are less visible and more easily concealed. (Army, Air Force)

6. Insertion Times

a. Statement

Insertion of the INC into the warhead body requires time. (All three candidates)

b. Discussion

DOD

c. Merit Estimation

Candidate	VI	U	VI x U
N, AF	1	-0.4	-0.4
A	1	-1.0	-1.0

7. Total and Average Merit Under Survivability

Candidate	Total Merit	Average Merit
A	+8.0	+0.6 (substantially better than baseline)
N	+1.1	+0.1 (insignificantly better than baseline)
AF	+7.6	+0.6 (substantially better than baseline)

G. Operational Effectiveness

Broadly defined, operational effectiveness means the capability of a system to perform the missions or functions for which it is designed. This definition could then include survivability and security. To limit the scope, we narrow operational effectiveness to include mobility, targeting flexibility, enduring capability, storage flexibility, nuclear yield, conventional warhead effects, reliability, range, and foreign political acceptability. The three candidates generally offer improvements over the baseline systems in this area.

1. Mobility

a. Statement

Strategic and tactical mobility for European and special theaters are increased because of the small size and weight of INCs and lack of nuclear materials in the WHB. (All three candidates)

b. Discussion

The baseline nuclear weapons constrain the defense transportation system in its ability to move the weapons rapidly in large numbers. Part of the reason is physical: The baseline nuclear warheads are larger, weigh more than the INCs, and contain significant amounts of SNM next to a large amount of HE. The other part is political: The baseline warheads are full-up nuclear rounds. For example:

(1) Strategic mobility suffers because

- [redacted]
- [redacted]

(2) Tactical mobility also suffers because

- [redacted]
- [redacted]

At the risk of overt repetition, [redacted]

c. Merit Estimation

b. Discussion

c. Merit Estimation

Candidate	VI	U	VI x U
A	2	+0.5	+1
N	3	+1.0	+3
AF	1	0	0 (not convertible)

3. Enduring Capability

a. Statement

Enduring capability is available through the rapid logistical resupply of INCs. (All three candidates)

b. Discussion

DOD

surviving missiles and WHBs than the resupply of a full-up nuclear warhead and missile.

The advantages to the Air Force dedicated TASM are not as large. The number of missiles and WHBs will equal the number of INCs as this is not a convertible candidate. Nevertheless, loss of an INC without concomitant loss of WHBs and missiles will make resupply of INCs stockpiled out of theater easier than resupply of a full-up baseline gravity bomb.

c. Merit Estimation

Candidate	VI	U	VI x U
A, N	2	+0.7	+1.4
AF	2	+0.4	+0.8

4. Storage Flexibility

a. Statement

Convertible weapons allow full nuclear or conventional capabilities where storage areas are limited. (Navy)

b. Discussion

c. Merit Estimation

Candidate	VI	U	VI x U
N	3	+1	+3
A, AF	0	0	0

5. Nuclear Yield

a. Statement

b. Discussion

Secondary missions for the Army SSM and Air Force TASM modular candidates might require destruction of relatively hard fixed targets. This more probably would be the case for the Air Force in its interdiction mission. If these fixed-target requirements are imposed, and other nuclear systems (B61 gravity bomb, GLCM, Pershing IA or II) are not deemed sufficient to cover this target set, then we would strongly recommend the development of a terminal correlation module to be used by some of the SSMs and/or TASMs to get CEPs down to about 30 meters.

DOE bC

[redacted]

DOE bC

DOD

[redacted] It would be heavy, cumbersome, and difficult to handle. Many of the advantages that we discussed earlier would erode or disappear. To minimize the impact, assign the mission to only one of the services, say the Air Force, and assign only a part of the TASM force (and use a full-up nuclear munition instead of a modular one). Keep the remaining TASM force modular with one-stage INCs.

DOD bC

The merit numbers below assume that the Air Force is assigned the additional fixed-target mission and either builds only part of the TASM force with INCs (the rest are two-stage standard TASMs) or builds additional GLCMs and/or B61s. The yields of the Army candidate would then be sufficient.

c. Merit Estimation

Candidate	VI	U	VI x U
AF	3	-0.5	-1.5
A,N	3	0	0

[redacted]

6. Conventional Warhead Effects

a. Statement

Convertible weapons may incur reduced conventional effectiveness because of WHB body volume devoted to the nuclear application. (Army, Navy)

b. Discussion

LCL

DOE b(3)

[redacted] A conventional filler plug could be developed, but this would require careful study of the trade-offs between increased effectiveness versus the logistic effect of another component upon the STSs.

The Army's problem is more serious with regard to its conventional SSM role (no major implications are seen in the SAM role which uses a unitary HE warhead). This mission of conventionally stopping the enemy second-echelon forces requires the use of submunitions. [redacted]

DOD

[redacted] This volume is lost to submunitions and may make the convertible SSM ineffective and too costly. If so, the dual-purpose SSM/SAM should still receive consideration for AD batteries, although the field artillery batteries would then have both full-up conventional SSMs and dedicated modular nuclear SSMs.

c. Merit Estimation

Candidate	VI	U	VI x U
N	2	-0.1	-0.2
A	2	-0.5	-1.0
AF	0	0	0

7. Reliability

a. Statement

A reliability degradation is expected. This can be minimal with the use of high production standards, affordable because of the small weapon system buys, and fully acceptable, especially in insertion operations within a clean environment. (All three candidates)

b. Discussion

DOD

[redacted]

DOE 1.0. |

The convertible warheads, when used conventionally, intuitively should have reliabilities almost identical to the conventional baseline systems. This is normally driven by the reliability of the missile. The cavity within the WHB itself can be designed to have a negligible reliability effect.

Reliability of the modular candidates when used in a nuclear mission is of greater concern, particularly when mated to a convertible missile that is produced with reliability levels acceptable just to conventional applications. The cost of building and certifying all the missiles and WHBs to reliability levels necessary for nuclear use will have to be incurred whether the missile system application is nuclear-only or convertible. Since the candidates are all relatively low-buy, high-value munitions, this cost should be relatively small over the total life cycle.

Reliability of the INC built at the DOE production plants, however, should still be very high. A good and simple one-stage design that underwent adequate development, testing, and production, would seem to ensure a very high reliability. In the field, the sealed INC would undergo simple electrical checks to ensure its positive status. The real question is the successful ability to insert the INC, ensure that the proper electrical interfaces have been made, check the overall weapon status, and then be ready to launch a reliable missile, all within about 15 minutes. One can imagine a very difficult environment--dry insertion in rolling seas and pitching decks or on a dark, rainy, dirty, muddy battlefield; or a rather benign environment--a shelter at a collocated Air Force base. One should keep in mind, however, that today the current Lance and Pershing 1A missiles require a physical and electrical mating of the nuclear warhead in field environments.

We think that good operational procedures can result in modular warheads with at best reliability as high as the baseline nuclear warheads, and at worst a slight degradation that is fully acceptable (especially in light of the lower missile reliability). But pending actual reliability testing of mockups and WR warheads, and given the reliability of the missile itself, we conservatively take a pessimistic view in the merit analysis with regard to system reliability.

c. Merit Estimation

Candidate	VI	U	VI x U
A	3	-0.7	-2.1
N	3	-0.5	-1.5
AF	3	-0.2	-0.6

8. Range

a. Statement

Range for the nuclear mode of convertible weapons may be less. (Army)

b. Discussion

The Navy convertible system is not range-affected because the convertible and nuclear applications

DOD

The Army system, however, may or may not carry the submunitions in a nuclear role. Downloading the submunitions would give a full nuclear range, but at a cost of time and affecting survivability, operational effectiveness, and logistics. Again, it may be more cost-effective, as noted above, to have a dedicated modular SSM for the nuclear mission instead of a convertible.

c. Merit Estimation

Candidate	VI	U	VI x U
N	2	0	0
A	2	-0.5	-1.0
AF	2	0	0

9. Deployability

a. Statement

DOD

b. Discussion

DOD

The perception of this rationale by the political leaders and populous of the host nations may be the exact opposite of this study's perception. They may believe instead that "a nuclear weapon is a nuclear weapon..." We have no idea as to the merit of modular warheads as related to these concerns except that there is now a possibility of storing, docking, and overflying modular warheads, while there is not with the baseline systems.

10. Total and Average Merit Under Operational Effectiveness

Candidate	Total Merit	Average Merit
A	+1.3	+0.1 (insignificantly better than baseline)
N	+8.7	+0.4 (somewhat better than baseline)
AF	+1.7	+0.1 (insignificantly better than baseline)

H. Logistics

The broad area of logistics includes transporation and handling, storage requirements, training, special theater movements, LLCE complexity and intervals, administrative and security regulations, component classification, maintenance and support, security personnel and storage sites, and personnel reliability and inspections. We find that in the area of logistics each of the three candidates show potential improvements over the baseline, albeit small in degree in the aggregate.

1. Transportation and Handling

a. Statement

[redacted] DDE LC

D. Discussion

Significant advantages accrue in the normal day-to-day logistical transportation and handling of INCs. The INCs can be moved easily by air or ground shipment. Convoy sizes can be reduced in numbers of vehicles and personnel because of the lower physical transportation requirements and the inherent safety of INCs. Likewise, transportation costs for initial deployment and operational and maintenance movements during the warhead's life should fall dramatically.

c. Merit Estimation

Candidate	VI	U	VI x U
A, N, AF	2	+1	+2

2. Storage Requirements

a. Statement

The size of storage areas requiring special protection is decreased. (All three candidates)

b. Discussion

Our premise is that only the INC will contain RD information. Unlike the baseline nuclear munitions that require special nuclear storage of the entire nuclear warhead or an entire nuclear warhead mated to its missile, the nuclear storage requirements of INCs are minimal, whether it be at Army special storage sites or barracks arms rooms, Navy special magazines, or Air Force special storage sites and MOBs/COBs.

c. Merit Estimation

Candidate	VI	U	VI x U
A, N, AF	2	+1	+2

3. Training

a. Statement

Training in unit areas and in the field can improve because of the greater availability of INC mock-up trainers and non-RD warheads. (All three candidates)

b. Discussion

The availability of training devices for the baseline munitions is limited. This limitation, plus the size and weight of the trainers, restricts the quantity and quality of hands-on training.

This problem is particularly acute for the Army baseline system. Though alert exercises train and test the units in their ability to move from the barracks environment to a full field environment,

[redacted] The design of the INCs allows for the production of numerous cheap trainers. By having these trainers at the firing unit area, the soldiers during peacetime can receive excellent training in their use by deploying to the field with their missiles, WHBs bodies (drawn from conventional ASPs), and INC trainers. The artillerymen can then train in the insertion of the INCS in the field.

Many of the same benefits accrue to the realistic training for the Navy and Air Force modular candidates. Greater availability of trainers and practice exercises can do much to alleviate the reliability problems and time requirements that we examined previously.

c. Merit Estimation

Candidate	VI	U	VI x U
A, N, AF	2	+1	+2

4. Special Theater Movements

a. Statement

Transportation of INCs into special theaters can be more rapid and secure than full-up nuclear munitions. (All three candidates)

b. Discussion

[redacted]

c. Merit Estimation

Candidate	VI	U	VI x U
A, AF	3	+1	+3
N	2	+1	+2

5. Limited-Life Component Exchange (LLCE) Complexity

a. Statement

Limited-life component exchange is easier. (All three candidates)

b. Discussion

[redacted] This operation has a sizeable impact upon logistic efforts and operational readiness.

The small size and weight of INCs plus their greater accessibility for maintenance is an advantage over the baseline system. The change-out process can be conducted more rapidly and with less maintenance man-hours.

c. Merit Estimation

Candidate	VI	U	VI x U
A, N, AF	1	+1	+1

6. Administrative and Security Regulations

a. Statement

Administrative and security regulations must be adapted to engender viability of modular weapons in all utility areas (except safety, which is inherently increased). (All three candidates)

b. Discussion

The overall utility to be derived from the candidate modular systems largely depends upon modifying current administrative and security regulations. Current restrictions come mainly from the DoD Directive on security criteria.[29] As currently written, this policy means that all components of a modular warhead would inherit the same restrictions as the baseline nuclear systems: two-man rule, large security forces, substantial storage requirements, and concentrated storage at special sites.

We think that our preferred one-stage design approach can satisfy all the safety and security objectives behind current administrative regulations within the SLSs sequences noted previously. We also believe that the intent of the regulations and directives can be fully satisfied by using the modular systems under a newly adapted set of regulations and directives. Nevertheless, we recognize that institutional inertia within the security community (which is common to all large organizations) to keep the same administrative and logistic systems must be overcome. Probably the best way is to provide mock-up point designs (paralleling the DOE Phase 2 and 3 efforts) to the safety, security, and logistic experts who would determine acceptability and work out these modifications. Evolutionary change of these regulations is the only forseeable path that is politically acceptable at this time. Nevertheless, failure to adapt regulations to account for the singular differences of modular weapons from those of standard nuclear weapons would result in disutility greater than that indicated by the merit estimation in this subarea.

c. Merit Estimation

Candidate	VI	U	VI x U
A, N, AF	3	-1	-3

7. Component Classification

a. Statement

The WHB body must not carry a classification higher than its delivery missile. (All three candidates)

b. Discussion

This concern parallels the one above, but needs to be spelled out to allow early field and collocated base deployment of the Army and Air Force candidates.

Current classification is:

[redacted]

DOE 6(3)

[redacted]

DOE 6

[redacted] This is not critical since it will be on a secure container for most of its life.

[redacted]

DOE 6

This is not to say that NCA release and reliable secure communications will no longer be needed to insert the RD INC into the WHB. Sealed authenticators will still be required along with PAL devices on the INC container and even possibly on the complete warhead system after release is granted.

c. Merit Estimation

Candidate	VI	U	VI x U
A, N, AF	3	-1	-3

8. Maintenance and Support

a. Statement

Maintenance and support workload and handling equipment are reduced for the INC. (All three candidates)

b. Discussion

A primary logistic consideration is maintenance. The one-stage design approach should mean that the using unit would only need to make visual inspection and simple electrical checks to ensure that no unauthorized actions had occurred. By keeping the design of the WHB body and INC as simple as possible, maintenance workload should be reduced because of easier access and less sophisticated tests. Normal stockpile maintenance and testing of the interfaces between the explosives and warhead electrical system would be eliminated until mating of the INC occurs during war. Large handling equipment requirements would no longer exist for maintenance of the INC because of its small size. The Navy candidate may also result in some maintenance (and transportation) reduction by not having to send the whole canistered nuclear Harpoon back to depot as the baseline system requires. The dispersal of Army INCs to unit arms rooms (or within security wells, safes, etc.) might require transient maintenance sections to visit the dispersed locations. However, the reduction in workload at the special nuclear sites should offset the personnel requirements for the transient sections. Another alternative is to assign these "go/no-go" checks to the operational crew at the firing units.

Maintenance may rise, however, because additional equipment will be deployed for modular warhead support:

Army INC containers, secure storage at firing batteries (wells, safes, etc.), test equipment

Navy INC containers, test equipment

Air Force INC containers, deployable secure storage assets (transporters, moveable igloos, etc.), test equipment

Additional procedures and administrative guidance would be needed. The modular systems would require their own checklists, repair parts, and special tools.

c. Merit Estimation

Candidate	VI	U	VI x U
A	2	+0.2	+0.4
N, AF	2	+0.4	+0.8

9. Security Personnel and Storage Sites

a. Statement

Numbers of security personnel will generally be unchanged unless current storage sites become INC-only sites. However, security personnel requirements and storage sites will increase if unit storage is allowed. (Army, Air Force)

b. Discussion

As long as the number of storage sites remain constant and include baseline nuclear weapons, then the number of guards will remain unchanged.

The use of the Army modular candidate would cause the dispersion of SSM INCs away from current fixed sites into the arms rooms of the firing units. The fixed sites, however, would still require protection for the AFAPs, ADMs, and Pershings. We see no hope for reductions in guard forces at these sites, unless these sites are consolidated (with a loss of survivability) or some weapons are removed back to CONUS. An argument can be made that security forces may increase, as the quantity and quality of arms rooms guards might be insufficient. Given current FA and AD artillery TOEs, this concern is a valid one.

Security manning for the Navy modular system afloat would remain the same. Peacetime security for the Air Force system would also parallel present requirements; however, crisis deployment to COBs and/or airstrips would have to draw on additional personnel.

Security during normal peacetime transportation movements could be reduced as noted earlier. Convoy security force requirements (infantry units) are substantial and detract from normal training.

c. Merit Estimation

Candidate	VI	U	VI x U
A, AF	2	-0.7	-1.4
N	3	0	0

10. Personnel Reliability and Inspections

a. Statement

Requirements for personnel reliability programs and inspections will probably remain the same. (All three candidates)

b. Discussion

The same high level of personnel competence that currently exists for the baseline warhead systems would apply to the modular candidates. Personnel involved in the authentication system and insertion of the nuclear component would still remain in critical nuclear duty positions. Those involved in the security of the INC would still be in controlled nuclear duty positions. The need for records, operational procedures, and maintenance would have an impact on the three modular candidates to the same degree as it presently does.

c. Merit Estimation

Candidate	VI	U	VI x U
A, N, AF	2	0	0

11. LLCE Intervals

a. Statement

LLCE intervals and stockpile life will remain the same. (All three candidates)

b. Discussion

No differences can be identified between the modular warhead candidates and the baseline nuclear systems in regard to LLCE intervals or stockpile life.

c. Merit Estimation

Candidate	VI	U	VI x U
A, N, AF	1	0	0

12. Total and Average Merit Under Logistics

Candidate	Total Merit	Average Merit
A	+3.0	+0.1 (insignificantly better than baseline)
N	+3.8	+0.2 (slightly better than baseline)
AF	+3.4	+0.2 (slightly better than baseline)

[redacted]

c. Merit Estimation

Candidate	VI	U	VI x U
N	3	+1	+3
A, AF	N/A		

2. SNM Requirements

a. Statement

Convertible warheads require slightly higher amount of SNMs than non-convertible warheads of the same yields. Nuclear-only INC warheads, however, are about as efficient in the use of SNM as standard nuclear warheads. (All three candidates)

b. Discussion

Previous studies have indicated that INC warheads require more SNM than standard warheads, all other things being equal. [redacted]

Two resource considerations also apply to SNM usage--cost and supply/demand. The costs are set by decree and may not reflect SNM's true value. [redacted]

[redacted]

DOE

Clearly, major changes in RD&T costs have little impact upon life-cycle cost. With a straightforward simple design, nuclear testing can be held to a minimum. We do not foresee much change in RD&T costs as compared to baseline nuclear system costs. [redacted]

DOD [redacted]

Production costs for the warheads (DOE and DoD) may show some additional cost expenditures over the baseline systems. This is due to producing a "different" type of warhead. New tooling and facilities will be necessary. Direct unit costs of manpower and material for the warhead will probably be very similar to the costs of baseline systems. Cost savings may be realized through using a simpler and less expensive final assembly at the Pantex Plant.

c. Merit Estimation

Candidate	VI	U	VI x U
A, N, AF	2	-0.2	-0.4

4. Safe Secure Containers and Storage Facilities

a. Statement

Production of safe secure containers and construction of associated storage facilities may be expensive, particularly for the Army system. (All three candidates)

b. Discussion

As noted in the Harpoon studies,[10,30] the real crux of production cost increases lies in the requirements for safe secure containers (all three modular candidates), construction of new storage facilities (wells, igloos, air-transportable shelters), and secure transporters. [redacted]

DOD

[redacted] The Navy requirement for this extra equipment is less than the Air Force's or Army's. [redacted]

[redacted]

DOD [redacted] Perhaps C-130 transportable shelters could be procured, or perhaps C-130 transportable versions of safe, secure trailers could be used. (The TASM with WHB less INCs would be carried by the flushed fighter aircraft).

DOD [redacted]

c. Merit Estimation

Candidate	VI	U	VI x U
N	2	-0.2	-0.4
AF	2	-0.4	-0.8
A	2	-0.7	-1.4

5. Missile System Operation and Support Costs

a. Statement

Missile system operation and support costs account for about [redacted] of DOD weapon total life-cycle costs. (If the delivery unit life-cycle cost is considered, then the cost of INCs becomes practically negligible in terms of total life-cycle cost.) The cost may rise in certain areas and fall in others. The overall effect is highly dependent upon INC storage schemes and security regulations, especially for the Army system. (All three candidates)

b. Discussion

Operation and support include the areas of security, maintenance, transportation, reliability testing, and staff support. As noted previously, about DOD [redacted] of the life-cycle cost is for operation and support and [redacted] of DOD operation and support costs are security related. The impact upon operation and support costs by the modular candidates will be a function of the percentage of stockpile that is converted to modular systems, the distribution of them among storage sites, and the type of storage and operational concepts adopted.

DOD [redacted] DOE 6(3)

DOE b(3)

DOL

Transportation is one operation and support area where significant savings should be realized. First- and second-destination transportation, operational moves, and transportation to depot for maintenance are expensive in dollars and transportation assets. Convoy sizes and aircraft sortie requirements can fall greatly because of the small INC volume and weight, [redacted] and the inherent safety and security by having the nuclear material separate from the main explosives.

Reliability testing and stockpile support will probably remain the same.

c. Merit Estimation

For the merit analysis, we use the relative importance of each subcategory:

Candidate	VI	U	VI x U
Security			
A	2	-1.0	-2.0
N	2	0	0
AF	2	-0.5	-1.0

[redacted]

Maintenance			
A	1	-0.5	-0.5
N	1	0	0
AF	1	0	0
Transportation			
A, N, AF	1	+1.0	+1.0
Reliability Testing/ Staff Support			
A, N, AF	1	0	0

6. Total and Average Merit Under Costs

Again for the merit analysis, we use the relative importance of each cost category.

Candidate	Total Merit	Average Merit
A	-3.7	-0.3 (somewhat worse than baseline)
*N	+2.8	+0.2 (slightly better than baseline)
AF	-1.6	-0.2 (slightly worse than baseline)

*Fewer modular missiles procured because of convertibility.

J. Summary Merit Analyses

Preceding sections have described the advantages and disadvantages of the three modular weapon candidates. At the end of each section we summarized the quantitative merit based upon the analyzed information. For convenience, the data on average merit are presented below.

Area/Candidate	VI	Army	Navy	Air Force
Safety	2	+0.3	+0.5	+0.3
Security	2	+0.2	+0.5	+0.2
Survivability	3	+0.6	+0.1	+0.6
Operational Effectiveness	1	+0.1	+0.4	+0.1
Logistics	1	+0.1	+0.2	+0.2
Costs	1	-0.3	+0.2	-0.2

By combining the major area average merits, we can arrive at a summary ranking that is useful for comparison between the modular candidates themselves and for comparisons between the baseline weapon systems. First we must

rank the worth of the areas; then we must carry out the simple math. We maintain that the area of survivability is of overriding importance, and we assign a VI of 3, or "extremely important". We rank safety and security next with a VI of 2, or "very important." Operational effectiveness, logistics, and costs are considered to be of "some importance" and are assigned a VI of 1. We arrive at the following figures by multiplying the VI times the average merit for each area, sum the six areas, and divide by the sum of the VIs (10).

Candidate	Average Merit
A	+0.27 (somewhat better than baseline)
N	+0.31 (somewhat better than baseline)
AF	+0.29 (somewhat better than baseline)

There is a striking similarity in average merit between the modular candidates, perhaps because they all have tactical missions and many subareas show utility regardless of the application (for example, plutonium-scatter safety). All three candidates display good potential towards improving the tactical nuclear stockpile; any or all bear continued consideration for addition to the inventory.

CHAPTER VI

REVIEW OF PERTINENT REGULATIONS AND DIRECTIVES

A. General

Providing for safety in handling nuclear weapons is a joint responsibility of the DoD and DOE. The DoD is also responsible for providing secure custody of the nuclear weapons under its control. [redacted] The facilities and procedures prescribed by these directives are accordingly elaborate and require substantial resources. The question raised by the possibility of deploying weapons with INCs is whether the required resources for ensuring safety and security could be thereby materially reduced. That question is discussed in this chapter. A bibliography is shown below:

against the presumed disadvantages of making procedural exceptions. The advantages of modular systems are discussed in earlier chapters of this study. Each service would identify for itself the disadvantages of allowing departures from practices that have long been followed in the care and handling of its nuclear weapons.

C. Expectation for Change in Handling Procedures

It does not seem likely that the military services will change their procedures for handling nuclear weapons before a modular system is fielded. Therefore, the first modular system cannot be designed to accommodate changes that will be made in those procedures after the system is fielded, if any such changes are made. It does not appear that the development of modular technology is hindered by present directives or procedures. If modular systems are designed to be handled exclusively in accordance with presently prescribed methods, however, the presumed advantages of fielding such systems will not be fully realized.

The preferred SLS for the Army modular candidate would continue the present practice of deployment of missiles and launchers to survivable field locations during training and alerts. The non-RD WHB would also deploy on the missile with the units.

2. Security. Security is a condition that results from the establishment of measures to protect designated information, personnel, systems, components, and equipment against hostile persons, acts, or influences. Several technical and operational advantages of varying importance accrue to modular warheads. The primary operational advantage lies in the fact that, for most of their life, security requirements are on components that are neither full-up nuclear weapons nor able to produce a nuclear yield.

Security Merit Assessment

Army	= +0.2	Slightly better than baseline
Navy	= +0.5	Better than baseline
Air Force	= +0.2	Slightly better than baseline

movements, training, LLCE, administrative and security regulations, component classification, security personnel, and personnel reliability and inspections. Throughout the study we used the SLSs that were defined under a favorable environment and found slight improvements in the three modular candidates.

Logistics Merit Assessment

Army	= +0.1	Insignificantly better than baseline
Navy	= +0.2	Slightly better than baseline
Air Force	= +0.2	Slightly better than baseline

6. Costs. Life-cycle costs including development, production, operation, and support were examined in a relative context. Though absolute cost numbers were not estimated, the merit assessment qualifies the broad cost trends. The Navy's convertible force should cost less than the baseline if fewer Harpoon missiles are procured for the convertible force. The Army and Air Force modular candidates are thought to cost more, primarily because of increases in production, security, and storage costs.

Costs Merit Assessment

Army	= -0.3	Somewhat worse than baseline
Navy	= +0.2	Slightly better than baseline (fewer modular missiles procured because of convertibility)
Air Force	= -0.2	Slightly worse than baseline

7. Merit Assessment Summary

By combining the major area average merits, we can arrive at a summary ranking that is useful for comparisons between the modular candidates themselves and for comparisons between the individual baseline weapon systems. We maintain that the area of survivability is of overriding importance, followed next by safety and security. Operational effectiveness, logistics, and costs are of lesser relative importance.

There is a striking similarity in merit between the modular candidates; all are deemed to be "somewhat better than baseline." The Navy modular candidate gives a summary merit of +0.31, followed closely by the Air Force and Army modular candidates at +0.29 and +0.27, respectively.

C. Recommendations

Increases in survivability should be the primary reason for developing, producing, and deploying modular nuclear warheads. In addition, safety stands out as the single area where INC benefits are unequivocal regardless of the administrative and security environment that evolves for modular warheads. Although the benefits of having safer warheads are of great importance, we realize that modern standard warheads have an unblemished safety record regarding accidental nuclear detonation; however, [redacted] The real benefits in safety improvements lie in allowing changes in the transportation and storage of nuclear weapons that can result in greater dispersion and enhanced survivability.

Several earlier studies and the analyses conducted here indicate the potential utility of a modular system. A careful and logical development process for any of the three modular candidates can lead to exploiting the benefits noted while minimizing the disadvantages. Three specific recommendations are made:

(1) Recommend that the Los Alamos National Laboratory (Los Alamos) develop mockups or point designs for appropriate service generic systems to enable the services to evaluate the operational, logistic, safety, security, survivability, and system cost impacts of INC or convertible systems.

(2) Recommend that Los Alamos continue to develop concepts for engineering designs to support modular systems in support of identified or perceived service requirements.

(3) Finally, based upon specific service stated requirements, recommend that Los Alamos be prepared to develop modular warheads for production and employment.

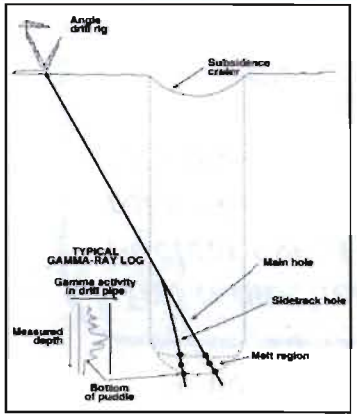
Presentation to the LANSCE User Group, January 9, 2012

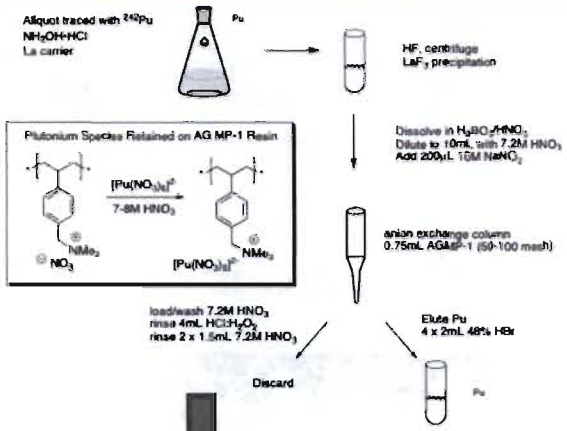


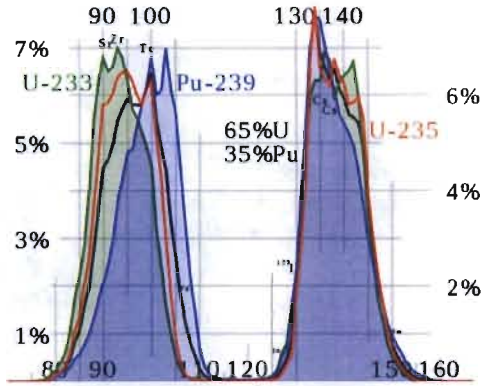
So What's All The Hubbub, Bub?
The Gaps In Our Understanding Of Nuclear Science

- **Nuclear science plays a key role in both the physics of nuclear weapons performance and the diagnostics used to quantify the same**
- **In an era of no nuclear testing, reduced uncertainties are required on many nuclear physics parameters**
  - Both to achieve the required simulation accuracy and to interpret experimental data
- **While there is a rich history within the field, measurements of many quantities show significant discrepancies and measurements still do not exist for many key quantities**
  - For example, the fission product yields
- **There is still much to be done**

I'm multiplyin', Doc! I'm multiplyin!

Radiochemical Analysis Process





Sample recovery

Collections consist of complex mixtures:

- **Homogenization**
- **Dissolution**
- **Separation**
- **Assay**

Not really this simple – other corrections apply

$$e = \frac{\text{fissions}}{\text{Original atoms of fuel}}$$

$$e = \frac{F}{F + p}$$

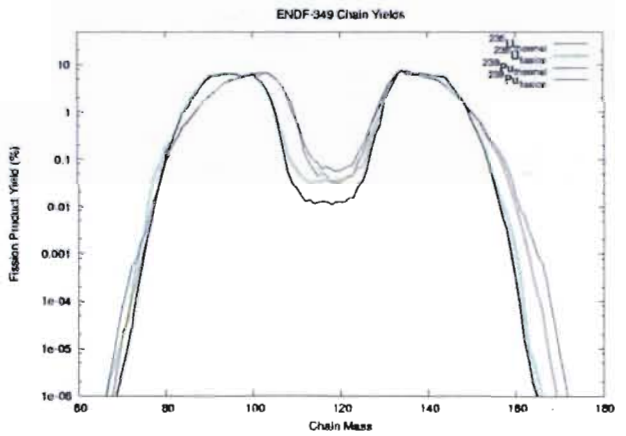
If total fuel known, can calculate total fissions (F_T), or energy release

"*Measure fissions*" in the sample, F

Measure unburned fuel atoms, p

UNCLASSIFIED

Radiochemical Quantifies Device Performance



- **Radiochemical diagnostics are time integrated measurements**
- **There are three major classes of analytes that are determined by radiochemistry**
  - Actinides
  - Fission Products
  - Activation Products

The radiochemical interpretation of a nuclear event from fission products relies on the ability to determines fissions :

$$N_i = FY_i \qquad F = N_i / Y_i$$

N_i = *number of atoms of fission product i*
Y_i = *cumulative fission product yield*

FPY (fission product yield) %

Thermal Neutron Spectra from an Underground Nuclear Explosion with Special Consideration of Spectral Modification due to Bomb Debris Motion

by

Henry A. Sandmeier and Gordon E. Hansen

ABSTRACT

The neutron flux from an underground nuclear explosion has recently been used to measure nuclear cross sections. For the experimenter it is of interest to know the neutron spectrum and intensity emerging from the top of the pipe leading to the nuclear device.

A short time following the nuclear explosion and after many fast neutrons have escaped, the local neutron spectra in the bomb debris will be in thermal equilibria. The spectrum of neutrons leaking from this debris will depend on a superposition of these local Maxwell Boltzmann distributions each with its characteristic drift velocity $\vec{v}_o$.

Theoretical expressions are derived for the low energy neutron spectrum emerging from a long narrow pipe. The theoretical predictions agree reasonably well with measurements obtained from the Parrot Shot in Nevada in the Spring of 1965.

ACKNOWLEDGMENT

We would like to thank our colleagues, Walter Goad and George Bell, for their help in this investigation.

I. INTRODUCTION

The problem to be solved is: given a spherical ball of bomb debris moving radially outwards with material velocity $\vec{v}_o$ and containing neutrons in local thermal equilibria, then what is the neutron spectrum on top of a long narrow pipe of length R and radius η (Fig. 1). It is assumed that the debris density has become so small that no further neutron collisions will occur; in other words, the neutrons do not find a diffusive medium anymore. The neutrons are therefore liberated from a moving source containing "bottled up" neutrons with local Maxwell Boltzmann distributions. The spectrum on top of the pipe will depend on how much one "sees" of the bomb debris sphere looking down the long narrow pipe. This problem has been discussed previously by Nordheim,[1] as well as Bell.[2] This paper looks at the problem in a more general way, and the case treated by Nordheim and Bell becomes here a special case where the observer looking down the pipe sees only a "pencil" of the bomb debris sphere.

[2] G. I. Bell, private communication, August 19, 1964.

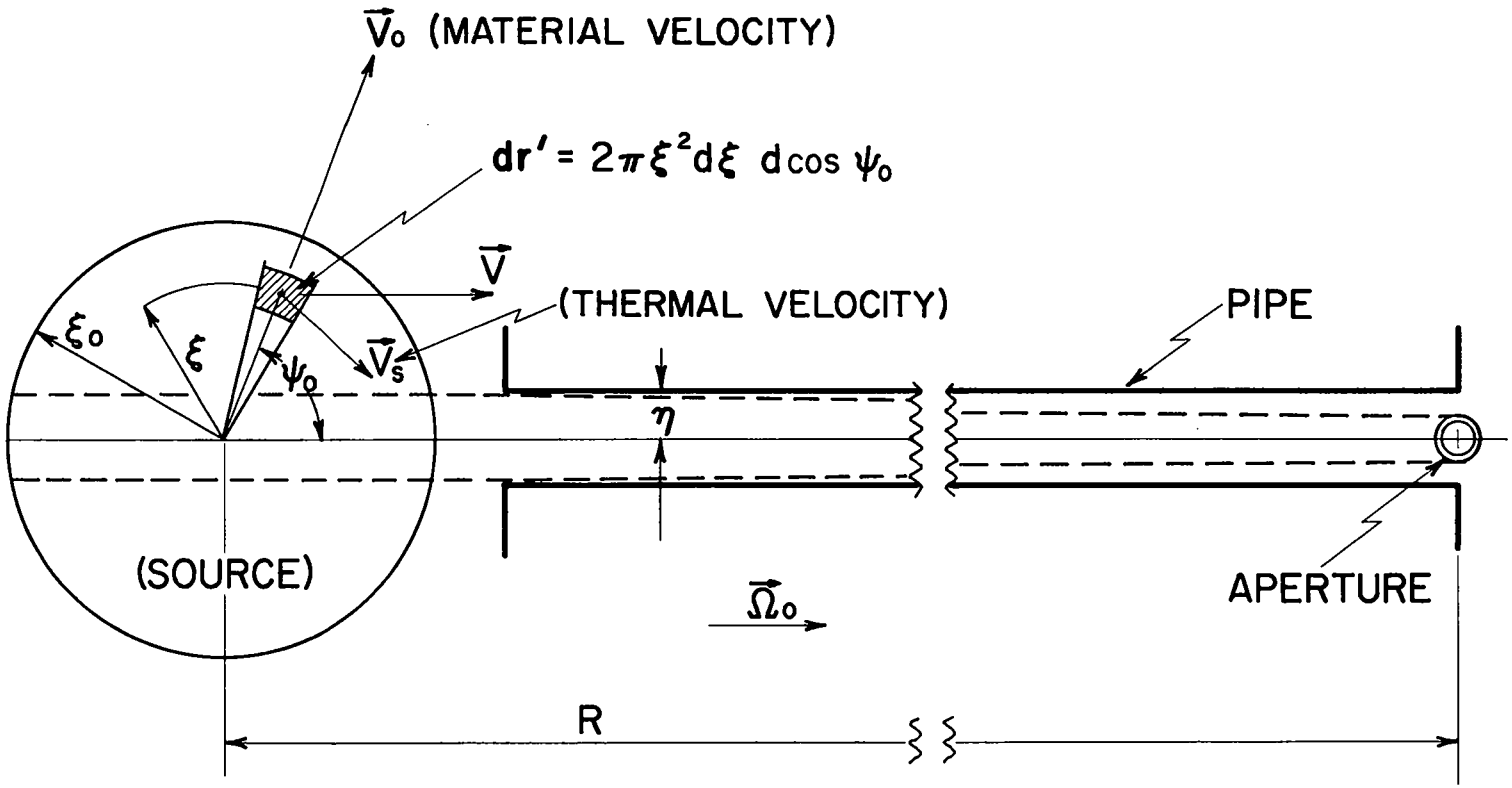

FIG. 1. SCHEMATIC OF DEBRIS SPHERE AND PIPE.

II. THERMAL NEUTRON SPECTRA FROM A RAPIDLY EXPANDING MATERIAL SPHERE

The initial neutron density in the debris is assumed to be a Maxwell-Boltzmann distribution.

$$n(\vec{v}_s) = ce^{-\frac{1}{2}m\frac{(\vec{v}-\vec{v}_o)^2}{KT}} = ce^{-\frac{1}{2}\frac{m\vec{v}_s^{\,2}}{KT}} \qquad \text{EQN 1}$$

Here the drift velocity is equal to the material velocity $\vec{v}_o$, and $\vec{v}_s$ is the neutron velocity relative to $\vec{v}_o$. In Appendix A we derived an expression for the number of neutrons passing through the unit area perpendicular to direction $\vec{\Omega}_o$ at R (Fig. 1) in the time interval ΔT about T. The initial neutron population $n(\vec{r}',v,\vec{\Omega}_o,0^+)$ in Eqn. A-14 created by the δ-function source becomes

$$n(\vec{r}',v,\vec{\Omega}_o,0^+) = c(\vec{\xi})e^{-\frac{1}{2}\frac{m}{KT}[v^2+v_o^{\,2}-2vv_o\cos\psi_o]} \times v^2 \qquad \text{EQN 2}$$

and Eqn. A-14 becomes

$$J_o(\vec{r},T)\Delta T = \int_{\text{source}} 2\pi\xi^2 d\xi\, d\cos\psi_o\, c(\vec{\xi})e^{-\frac{m}{2KT}[v^2+v_o^{\,2}-2vv_o\cos\psi_o]} \times v^2 \frac{\Delta v}{R^2} \qquad \text{EQN 3}$$

V. NUMERICAL EVALUATION OF "PARROT" ESCAPE SPECTRUM

The experimental set-up (Fig. 5) has been described in the open literature.[3]

The numerical values for the quantities shown in Fig. 5 are listed below. These values are subsequently used to numerically evaluate Eqn. 14 "pencil" model and Eqn. 16 "sphere" model.

$N_o = 0.06848 \times 10^{24}$	"Parrot" neutrons released in thermal equilibrium
$V_o = 5.24 \times 10^5$ cm^3	Bomb debris "sphere" volume at time of neutron release
$U_o = 3.24 \times 10^4$ cm^3	Bomb debris "pencil" volume at time of neutron release
R = 182.18 m	Distance bomb debris center to fission foil detector of area $\pi r^2 = 1.037$ cm^2 pipe radius $\eta = 10.16$ cm
Y = 1.2 KT	Total yield of "Parrot"
KT = 474 ev	Bomb thermal temperature
$v_o = 0.3$ cm/sh	Material velocity

These individual quantities shown in Fig. 5 will now be discussed briefly.

---

[3] "Neutron Time of Flight Experiments Using Nuclear Explosions," B. C. Diven. Submitted and to be published in Oct. 1965 issue of SCIENCE.

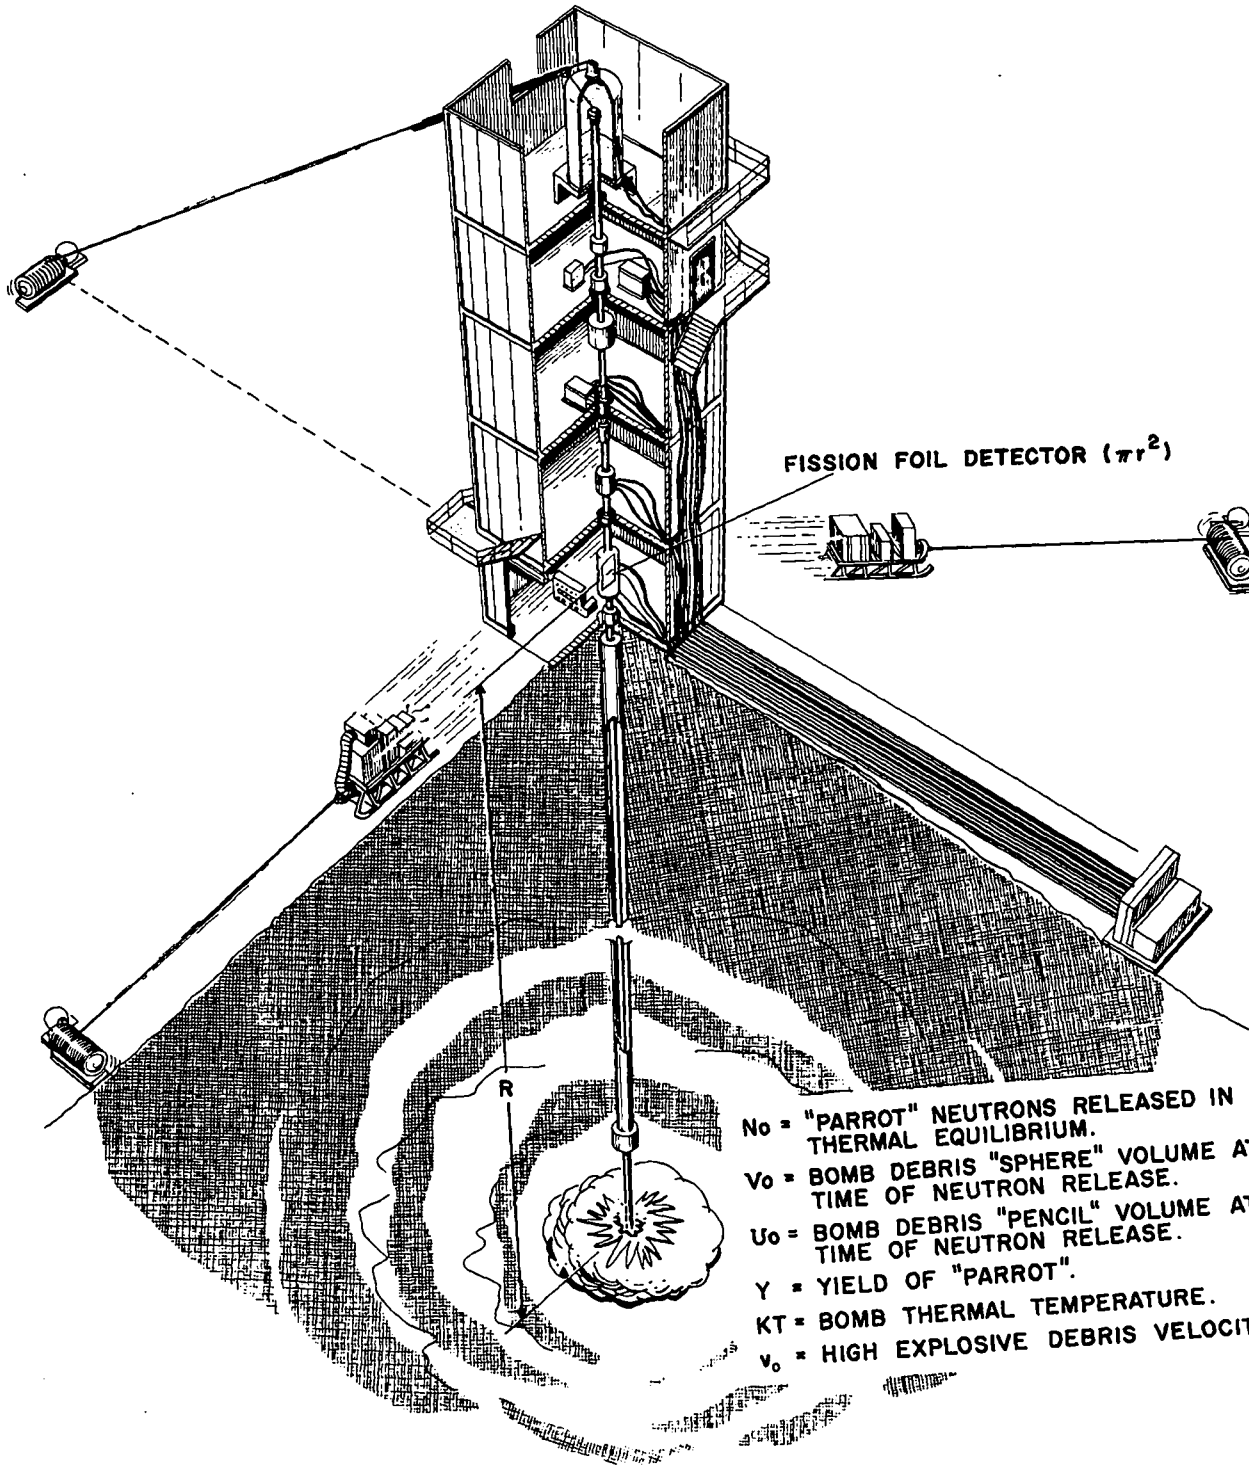

FIG. 5. UNDERGROUND NUCLEAR TEST "PARROT."

a. N_o, Parrot neutrons released in thermal equilibrium; v_o, debris velocity and KT, Parrot bomb thermal temperature.

In a nuclear device a configuration of fissionable material is driven together by exploding the surrounding high explosive layer.

The assembled configuration will reach supercriticality and the released fission energy will cause the rapid expansion of the bomb. The debris will move radially outward, including the hydrogeneous remnants of the high explosive layer. Before the high explosive moderator or reflector moves away, it is assumed that the fission neutrons born have come to a thermal equilibrium by collisions with the bomb debris.

During the expansion phase a time will be reached where the surrounding moderator (high explosive remnants) comes to such a low density that the thermal neutrons will cease to make collisions with the high explosive debris. We are therefore confronted with the problem to determine the neutron spectrum coming from a moving source, as seen in the Laboratory system. The material velocity v_o of the debris becomes the source velocity of the "bottled up" thermal neutrons.

From coupled hydrodynamics--neutronics calculations--the number of thermal neutrons N_o can be determined as well as the velocity v_o of the high explosive debris. A reasonable estimate of the HE debris velocity v_o at the time of thermal neutron release is 0.3 cm/shake. The debris temperature may now be deduced by using the fact that, behind a strong shock, internal energy per gram equals kinetic energy per gram: for the

essentially completely ionized HE components, this translates to $v_o \simeq \sqrt{2KT/m}$ with m still representing the mass of one neutron. We thus obtain $KT \simeq 474$ ev.

b. Pencil and sphere volume, V_o and U_o.

The volume of the debris sphere U_o, as well as the pencil volume V_o, is determined from the same calculations mentioned previously. The sphere volume V_o is the configuration in which the mean free path for thermal neutrons in the high explosive remnants becomes so large that it will no longer act as a diffusive medium for thermal neutrons.

c. Depth of underground nuclear explosion, R.

The quantity of interest in this report is R = 182.18 m and the foil area $\pi r^2 = 1.037$ cm^2. The fixed aperture area just below ground level is 0.9698 cm^2. The fission foil is a few feet above ground level.

d. Evaluation of "pencil" and "sphere" neutron spectrum.

Equations 14 and 14a, and Eqns. 16 and 16a are evaluated for even steps in the dimensionless variable $\upsilon = v/v_o$ (Table 1). For $\upsilon = 1$ the neutron velocity v traveling up the pipe is equal to v_o, the debris velocity. Table 1 assumes a bomb thermal temperature of 474 ev. Columns 2 through 8 are evaluated from the following relationships

$$v = \upsilon \times v_o = 0.3\upsilon \text{ (cm/sh)}$$

$$\Delta v = \Delta\upsilon \times v_o = 0.3\Delta\upsilon \text{ (cm/sh)}$$

$$E(\text{Mev}) = \frac{[v(\text{cm/sh})]^2}{(13.827)^2}$$

$$\Delta E(\text{Mev}) = v(\text{cm/sh})\ \Delta v(\text{cm/sh})\ \frac{2}{(13.827)^2}$$

$$T(\text{sh}) = \frac{R(\text{cm})}{v(\text{cm/sh})} = \frac{1.8218 \times 10^4}{v(\text{cm/sh})}$$

$$\Delta T(\text{sh}) = \frac{R(\text{cm})\Delta v(\text{cm/sh})}{[v(\text{cm/sh})]^2} = \frac{1.8218 \times 10^4\ \Delta v(\text{cm/sh})}{[v(\text{cm/sh})]^2}$$

Note that the intervals Δv, ΔE and ΔT follow from the arbitrarily chosen interval $\Delta \upsilon$.

The numerical expression to evaluate $J_o(\vec{r},T)$ in Table 1 for all models and assumptions are listed below.

"Pencil" model; $v_o = 0.3$ cm/sh; $v_o = \sqrt{\frac{2KT}{m}}$

Table 1, Column 9. $KT = 474$ ev.

From Eqn. 14 we get

$$\pi r^2 J_o(\vec{r},T)\Delta T = 1.1878 \times 10^{12}\ \upsilon^2 \Delta\upsilon \left[e^{-(\upsilon-1)^2} + e^{-(\upsilon+1)^2} \right] \qquad \text{EQN 17}$$

- -

"Pencil" model; $v_o = 0$, Maxwellian; $\sqrt{\frac{2KT}{m}} = 0.3$ cm/sh

Table 1, Column 10. $KT = 474$ ev.

From Eqn. 14a we get

$$\pi r^2 J_o(\vec{r},T)\Delta T = 8.7985 \times 10^{-11}\ v^2 \Delta v e^{-1.1111 \times 10^{-15}\ v^2} \qquad \text{EQN 18}$$

"Sphere" model; $v_o = 0.3$ cm/sh; $v_o = \sqrt{\frac{2KT}{m}}$

Table 1, Column 11. $KT = 474$ ev.

From Eqn. 16 we get

$$\pi r^2 J_o(\vec{r},T)\Delta T = 9.6047\times10^{12}\, \upsilon^2 \Delta\upsilon \left\{\frac{1}{\upsilon}\left[e^{-(\upsilon-1)^2} - e^{-(\upsilon+1)^2}\right]\right\} \quad \text{EQN 19}$$

"Sphere" model; $v_o = 0$, Maxwellian; $\sqrt{\frac{2KT}{m}} = 0.3$ cm/sh

Table 1, Column 12. $KT = 474$ ev.

From Eqn. 16a we get

$$\pi r^2 J_o(\vec{r},T)\Delta T = 1.4263\times10^{-9}\, v^2 \Delta v\, e^{-1.1111\times10^{-15} v^2} \quad \text{EQN 20}$$

For our case $\pi r^2 = 1.037$ cm^2 and ΔT is taken from Table 1.

The last four columns of Table 1, as well as the experimental data, are plotted in Fig. 6.

The experimental data agree reasonably well with the calculated pencil model values. The neutron flux is "contaminated" with "reflected" neutrons which are not included in our calculations. The first peak at 18 ev is probably due to reflected neutrons from the bottom of the hole which picked up some energy from the "pre-heated" lining of the cavity. At higher energies above 3 kev we get the neutrons which have been slowed down from higher energies. This energy range is not included in this discussion, as we limited ourselves to the thermal part.

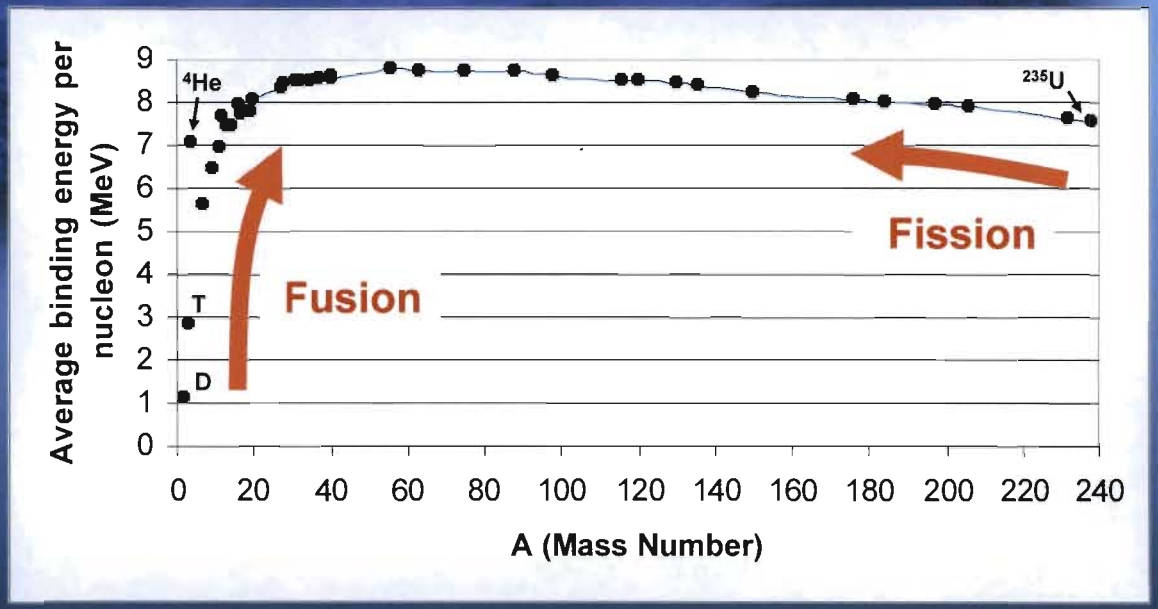
Title:	Nuclear Weapons Fundamentals
Author(s):	James Bradley Beck
Intended for:	PONI (Project on Nuclear Issues) Presentation to Staff Washington, DC July 20, 2011

Los Alamos
NATIONAL LABORATORY
EST. 1943



Los Alamos National Laboratory, an affirmative action/equal opportunity employer, is operated by the Los Alamos National Security, LLC for the National Nuclear Security Administration of the U.S. Department of Energy under contract DE-AC52-06NA25396. By acceptance of this article, the publisher recognizes that the U.S. Government retains a nonexclusive, royalty-free license to publish or reproduce the published form of this contribution, or to allow others to do so, for U.S. Government purposes. Los Alamos National Laboratory requests that the publisher identify this article as work performed under the auspices of the U.S. Department of Energy. Los Alamos National Laboratory strongly supports academic freedom and a researcher's right to publish; as an institution, however, the Laboratory does not endorse the viewpoint of a publication or guarantee its technical correctness.

Form 836 (7/06)

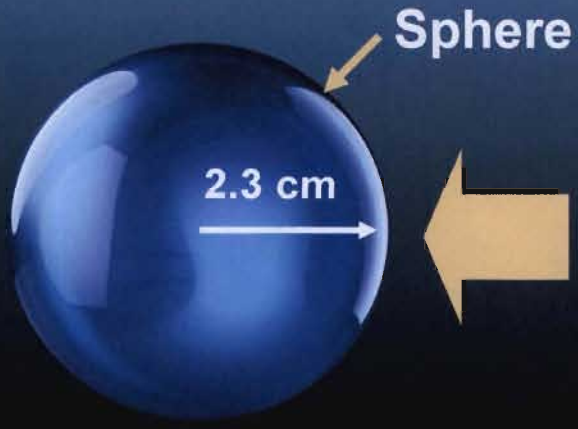
Binding Energy

Fundamental Law:
The rearrangement of a system to a more tightly bound state results in the release of energy

Energy released is equal to the change in binding energy

An example, fission energy release:

$^{235}U + n \rightarrow {}^{236}U \rightarrow$ 2 Fission Fragments + 2n



Mass (235U + n): 1996.0 MeV

Mass (after Fission): 1793.6 MeV

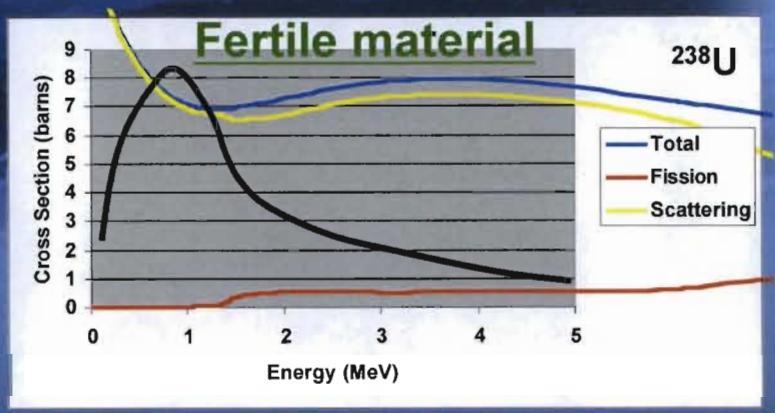
Change in B.E. = 202.4 MeV per fission

Comparative Energy Release

	Energy/Reaction	Energy density*
Combustion (Chemical)	4 eV	4.1×10^4 J/cm^3
Fission	200 MeV	1.5×10^{12} J/cm^3

	Energy Available*	100 Watt (J/s) bulb would burn for:
72 g coal	2.2×10^6 J (~1 lb. TNT)	~6 hours
or		
1 kg U	80×10^{12} J (19 kt TNT)	~25,370 years

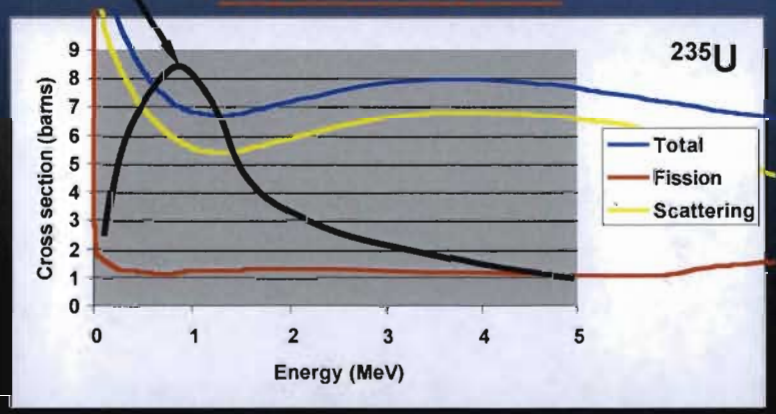
* Complete combustion or fission is assumed



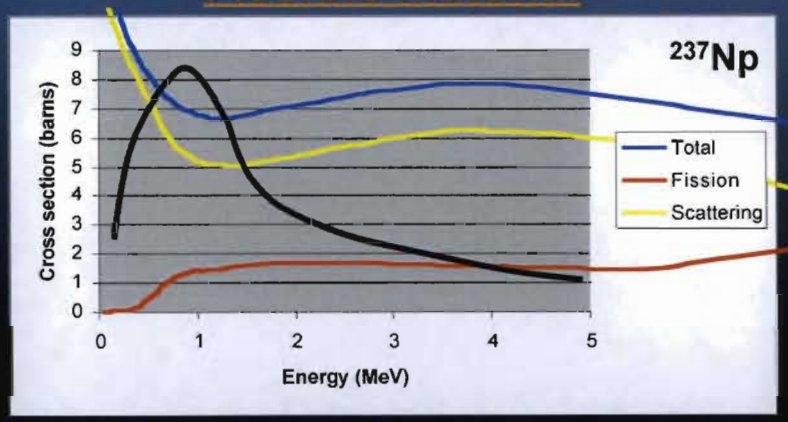
Neutron Cross Sections

(related to probability of reaction)

Fissile material



Fertile material



Fission neutron spectrum

Fissile material

Fissible material

1 barn = 10^{-24} cm^2

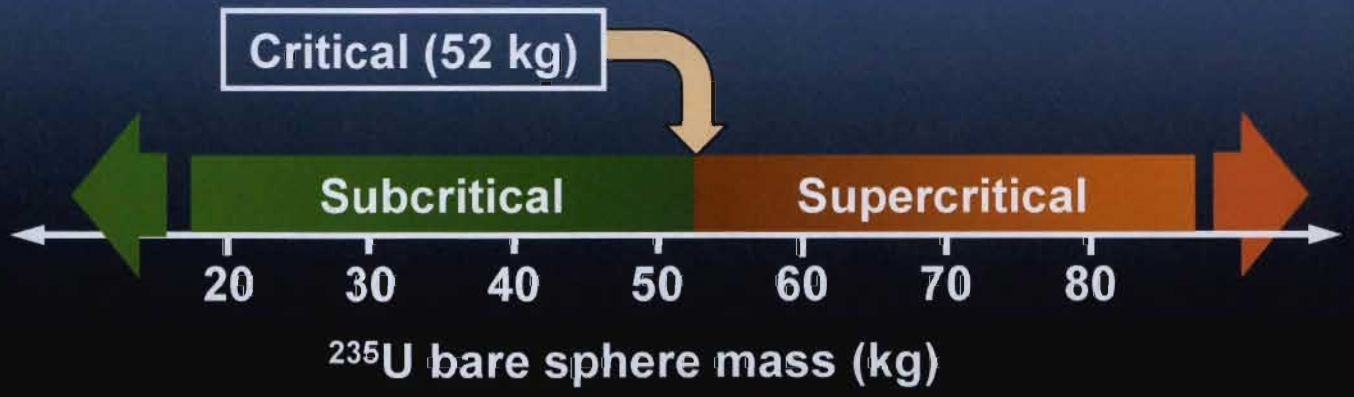
Factors Affecting Critical Mass

Critical mass – amount of material needed to just sustain a fission chain reaction (and constant neutron population)

Material - ^{239}Pu has a smaller critical mass compared with ^{235}U

Bare sphere critical mass

^{235}U
52 kg



^{239}Pu
10.5 kg

* Colors not indicative of true material

Factors Affecting Critical Mass (Cont.)

Mass – for a given shape and density, a larger mass of material has a higher criticality

Factors Affecting Critical Mass (Cont.)

Compression – increases in material density result in smaller critical mass

Bare sphere ^{235}U critical mass

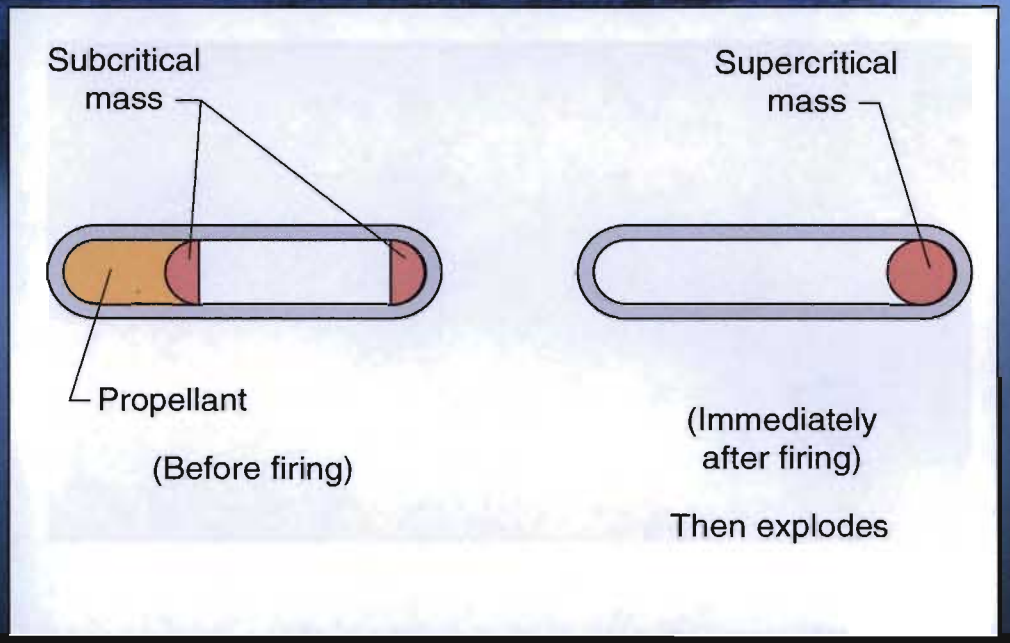
Factors Affecting Critical Mass (Cont.)

Surroundings – surrounding a system by a strong neutron reflector results in a reduced critical mass

Explosive Fissionable Material

- Any material that can be assembled into a supercritical mass, supporting a fast neutron chain reaction
  - » Weapon-grade materials
    - highly enriched uranium, >93% ^{235}U
    - weapons-grade Pu, ^{239}Pu with 6% ^{240}Pu
  - » Alternatives
    - ^{233}U
    - reactor-grade Pu
    - uranium with < 93% ^{235}U
    - fissible isotope ^{237}Np (neptunium)

Plutonium



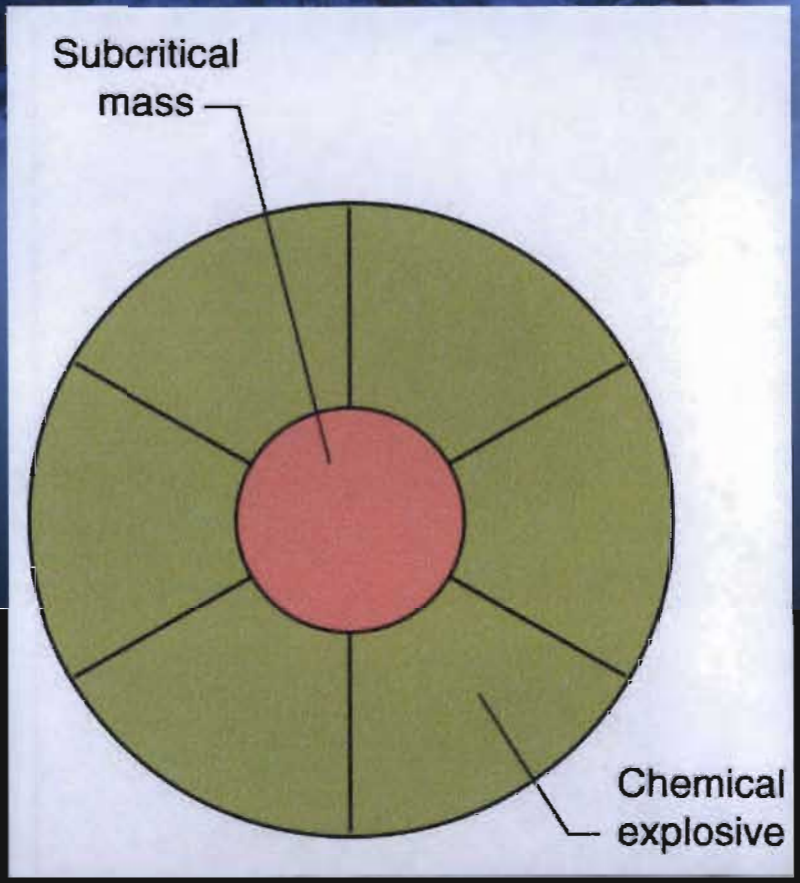
- Essential material to make a nuclear weapon
  - » 25 kg ^{235}U or 4 kg Pu can be enough

Fission Weapons

- A system for rapidly transforming a mass of 'explosive fissionable material' from a subcritical configuration to a highly supercritical configuration
- Initiation of a runaway neutron chain reaction while in supercritical configuration
- Maintain supercritical configuration long enough to allow large fission energy release

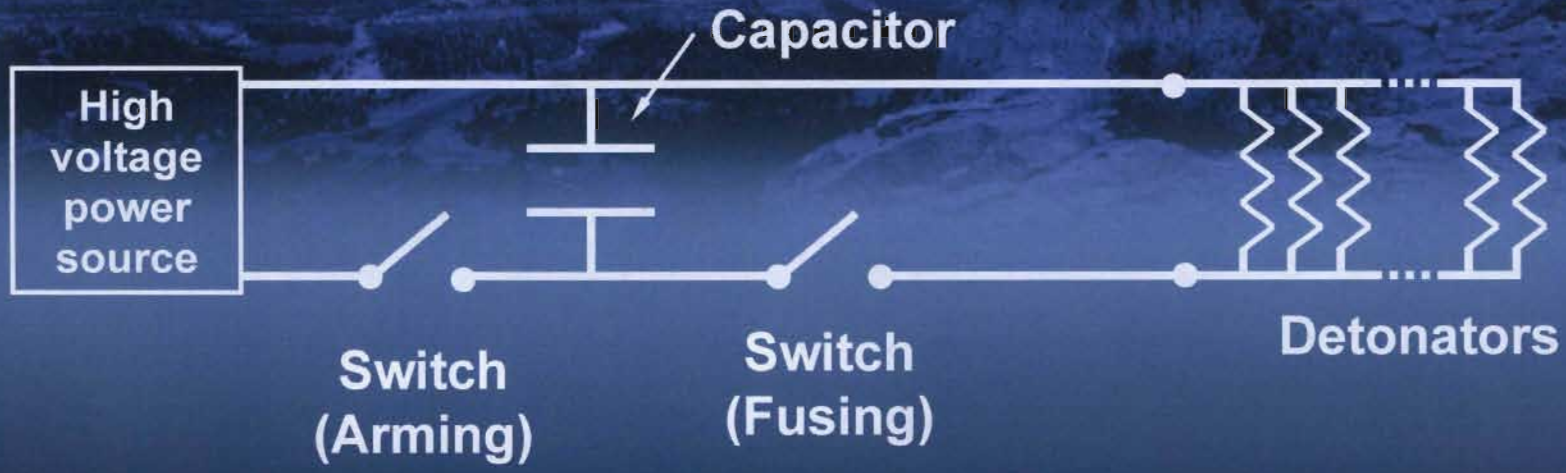
Gun Assembly

- Simple design
- Assemble subcritical masses together into a supercritical mass using propellant
- Inefficient use of material
- Slow assembly time necessitates use of a material with a very low neutron background (e.g., ^{235}U) to avoid pre-initiation; plutonium is precluded



Compare:
HEU : ~1 neutron/kg/second
WGPu : ~60,000 neutrons/kg/second

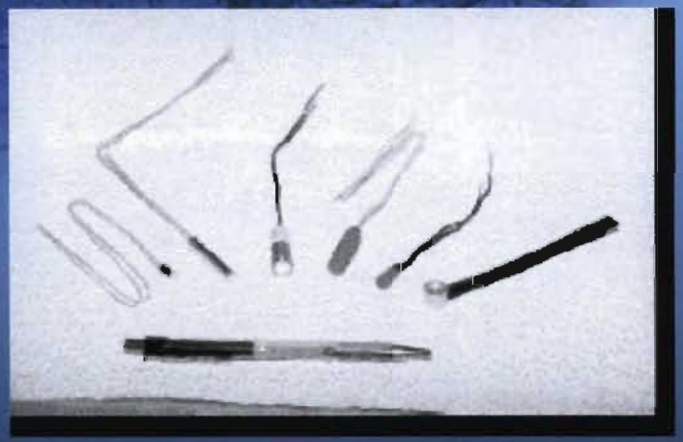
Ivy/King – tested on 11/15/52 at Enewetak; largest US fission only device (500 kt)



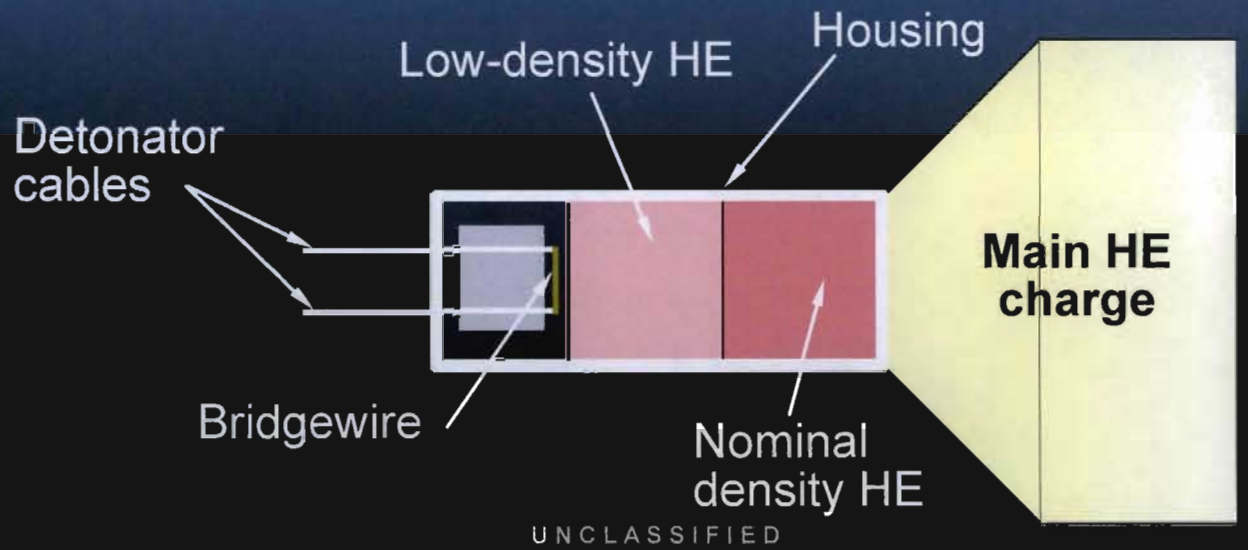
Implosion Assembly – before firing

- Must symmetrically initiate outer surface of high explosive charge
  - » Firing system
  - » High explosive lenses

Simplified Firing System



- Arming signal closes switch resulting in slow charging of capacitor
- Fusing signal closes "fast" switch, rapidly delivering stored capacitor energy to detonators



Detonators

- Used to initiate larger high explosive charges
- Convert electrical power into high explosive detonation
- Repeatability must be within small fraction of a second

Exploding Bridgewire (EBW) Detonators

- Large pulse of electric current vaporizes thin bridgewire, producing shock wave
- Shock wave initiates adjacent low-density HE pellet
- Detonation propagates thru HE pellets, strengthening in nominal density HE
- Initiation of main HE charge follows

High Explosives (HE)

- Castable
  - » TNT (trinitrotoluene)
  - » Composition B-3 (60% RDX, 40% TNT)
- Plastic-bonded
  - » mostly HMX or RDX based
  - » hydrostatic or isostatic press
- Final machining required for both types

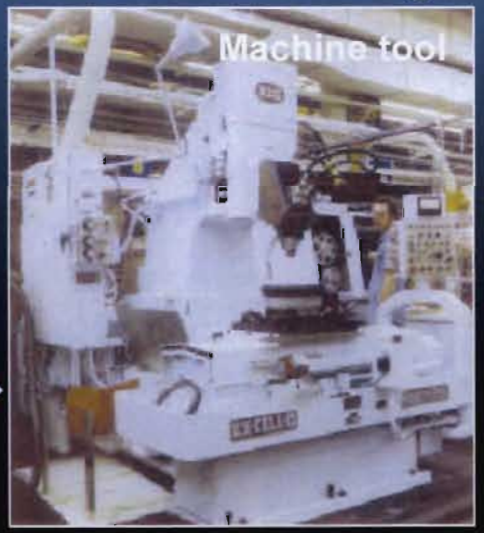
HE melting kettle

Hydrostatic press

Pit Fabrication

Explosive Fissionable Material

Melting & Casting



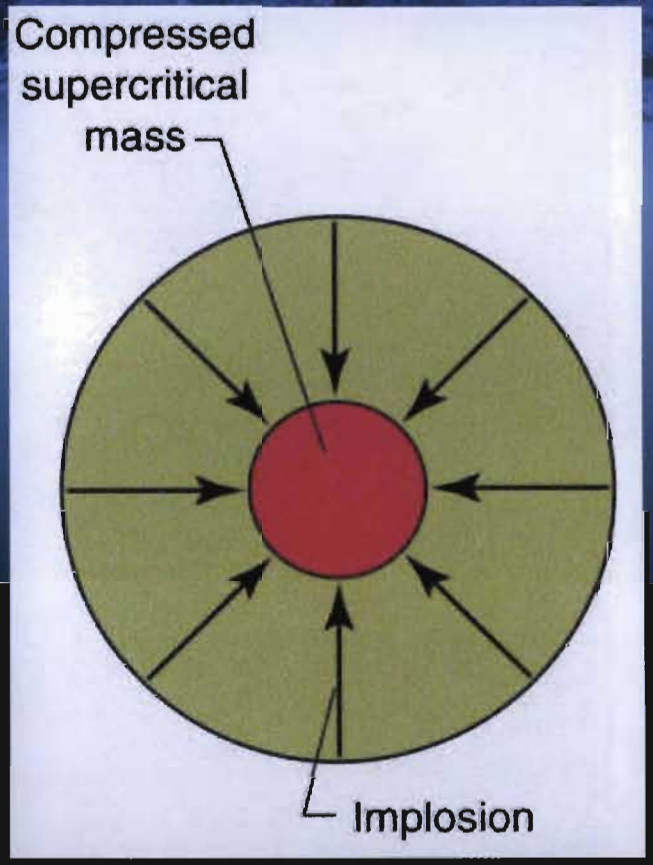
Billet

Cast Part

Rolled & Hydroformed

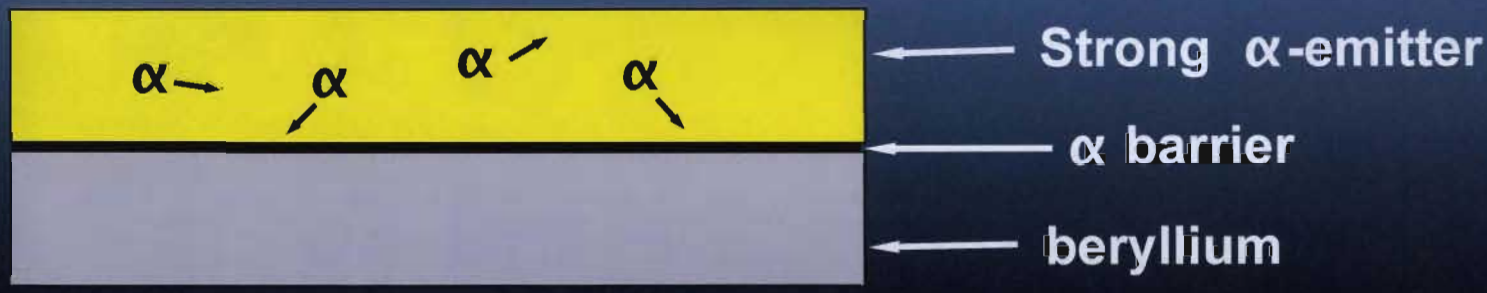
Finish machining

Inspection



Final Part

Note: Plutonium operations performed in glovebox

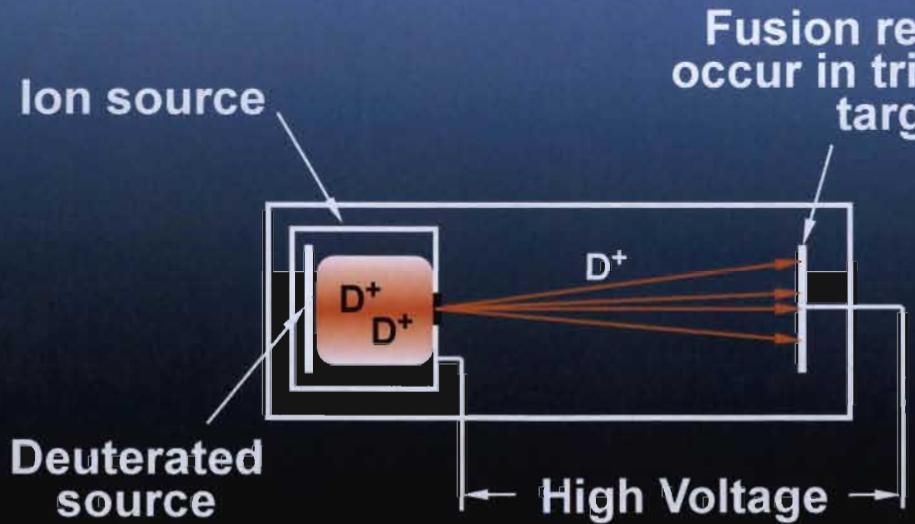


Implosion Assembly – after firing

- Following implosion, pit will reach a point of maximum supercriticality
- At this time, neutrons must be introduced into pit to begin fission chain reaction (this is called neutron initiation)
  - » Internal initiators
  - » External initiators

Internal Neutron Initiators

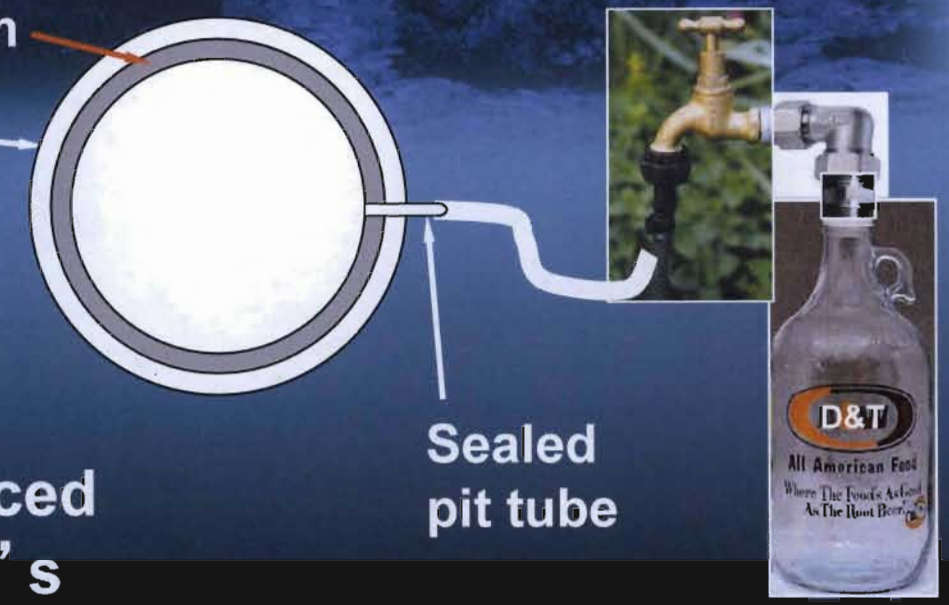
(α,n) Initiator – based on the reaction in which α particles from a radioactive isotope (e.g., polonium-210) interact with a light element (e.g., beryllium), thereby releasing neutrons



$$^{210}_{84}Po \rightarrow {}^{206}_{82}Pb + \alpha(^{4}_{2}He) \rightarrow \alpha + {}^{9}_{4}Be \rightarrow {}^{12}_{6}C + n$$

External Neutron Initiators

Neutron generator tube - based on fusion of deuterium and tritium produced in a small accelerator



Note: tritium is radioactive and must be replenished

Boosted Fission Weapons

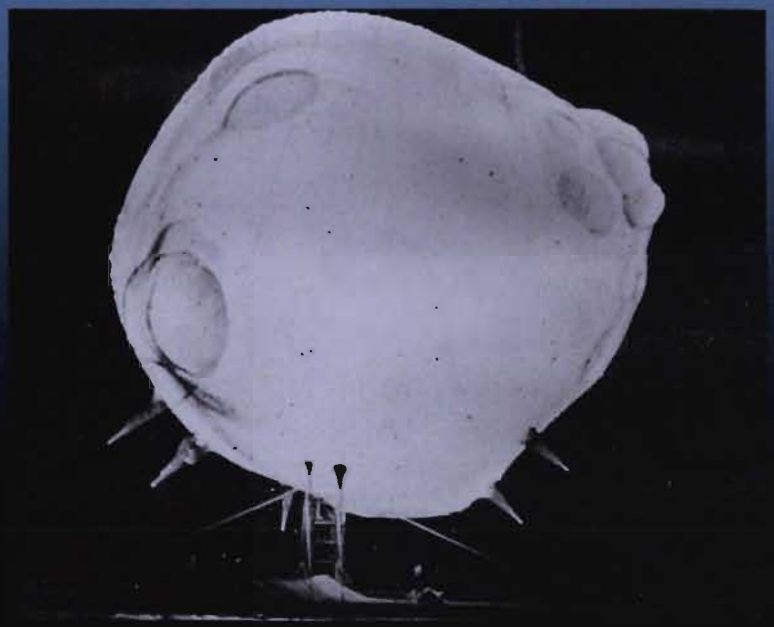
- Fusion produces energetic neutrons which cause further fission. This is called *boosting*.
- Boosting is used in primaries of thermonuclear weapons and can also be used in fission only weapons.

Boosted Fission Weapons (Cont.)

1. Mixture of deuterium and tritium (boost gas) is introduced from a reservoir to pit's central cavity
2. During implosion, boost gas is compressed along with the fissile material

Boosted Fission Weapons (Cont.)

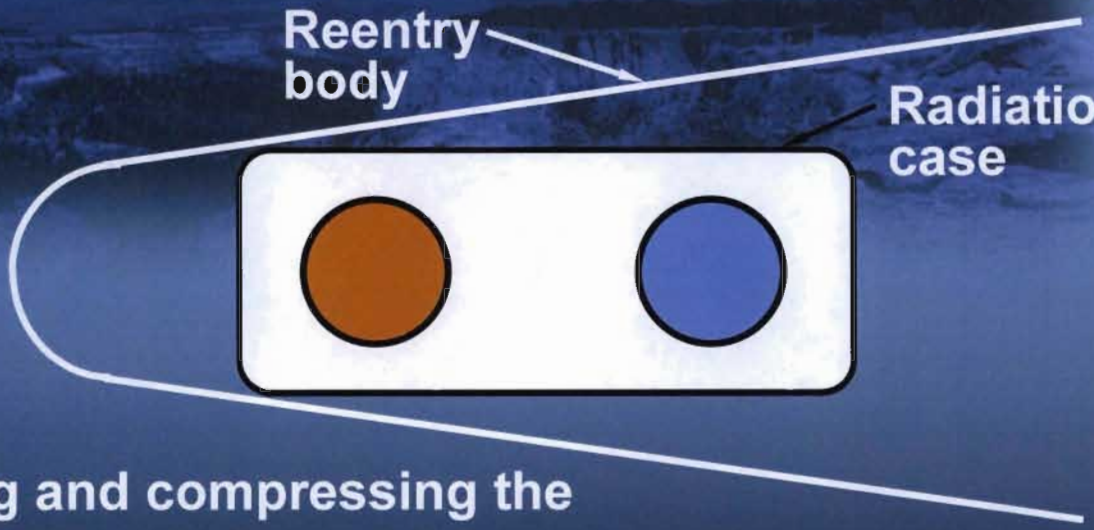
3. Driven by energy from fission, D-T fusion occurs, flooding compressed pit with high energy neutrons
4. These neutrons produce additional fissions, driving nuclear yield to much higher values



Note: Bulk of the yield is from fission; thermonuclear fusion yield is a few percent of the total

Greenhouse/Item – tested on 5/24/51 at Enewetak
First US boosted device (45.5 kt)

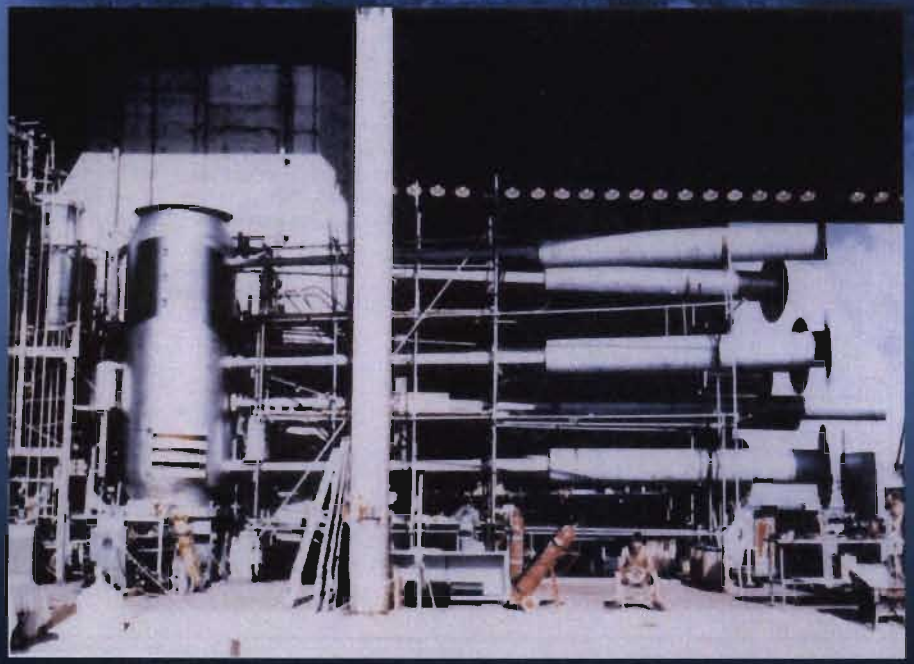
Additional Nuclear Physics



- Isotopes of lithium absorb neutrons resulting in the production of tritium

$$^{6}_{3}\mathrm{Li} + n \rightarrow T + {}^{4}_{2}\mathrm{He} + 4.8\ \mathrm{MeV}$$

$$^{7}_{3}\mathrm{Li} + n \rightarrow T + {}^{4}_{2}\mathrm{He} + n - 2.5\ \mathrm{MeV}$$



- Tritium can undergo subsequent fusion with deuterium
- Unlike tritium, lithium is a stable compound

Thermonuclear Weapons

- Radiation energy produced by primary stage is contained by radiation case
- X-ray energy flows toward and around the secondary stage heating and compressing the thermonuclear fuel (e.g., lithium deuteride)
- While thermonuclear fuel is undergoing heating and compression, neutrons are interacting with lithium, creating tritium
- Tritium and deuterium subsequently undergo fusion producing high-energy neutrons, producing additional fissions and tritium

Ivy/Mike – tested on 10/31/52 at Enewetak/Elugelab; 10.4 Mt

- "Experimental" thermonuclear device
- TN fuel was liquid deuterium
- Complex and bulky cryogenic equipment

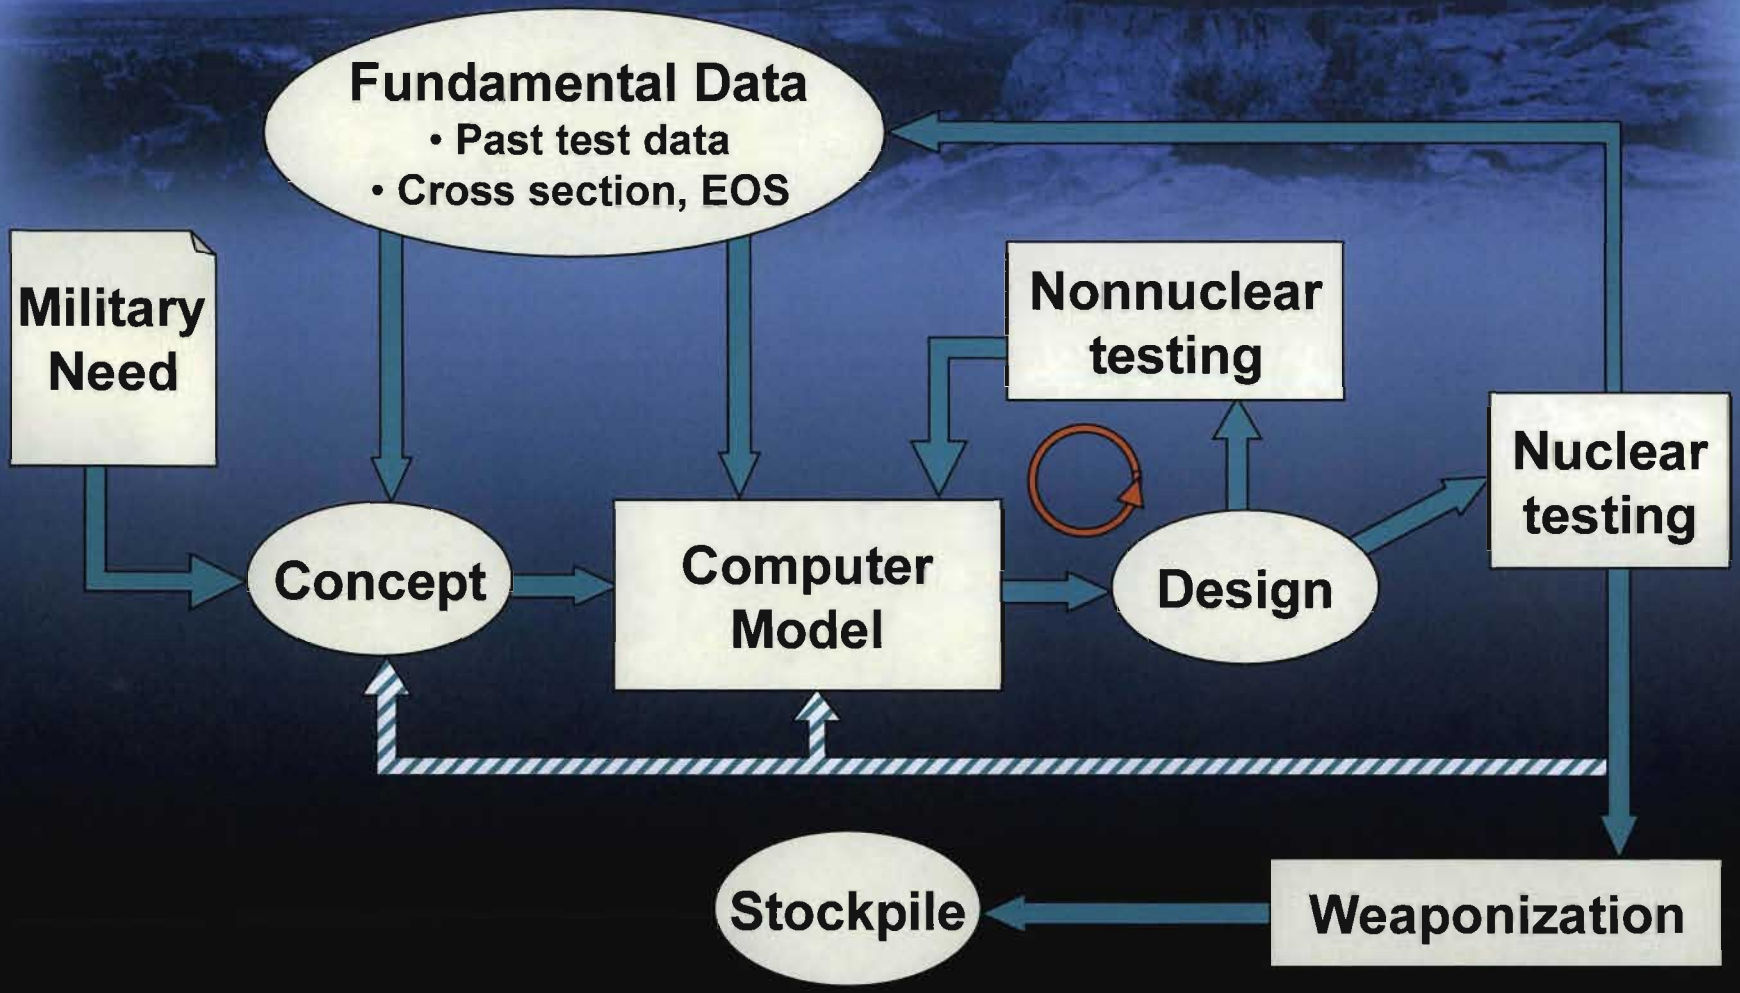
Castle/Bravo - tested on 2/28/54 at Bikini; Largest US detonation at 15 Mt

- Used lithium deuteride as a thermonuclear fuel

"Why buy a cow when powdered milk is so cheap?"

Harold Agnew, South Pacific (~1952-1954)

Largest Weapon Detonation



- Soviet test at Novaja Zemlya on 30 October 1961
- Fired at: ~58 Mt
- Design yield: 100 Mt

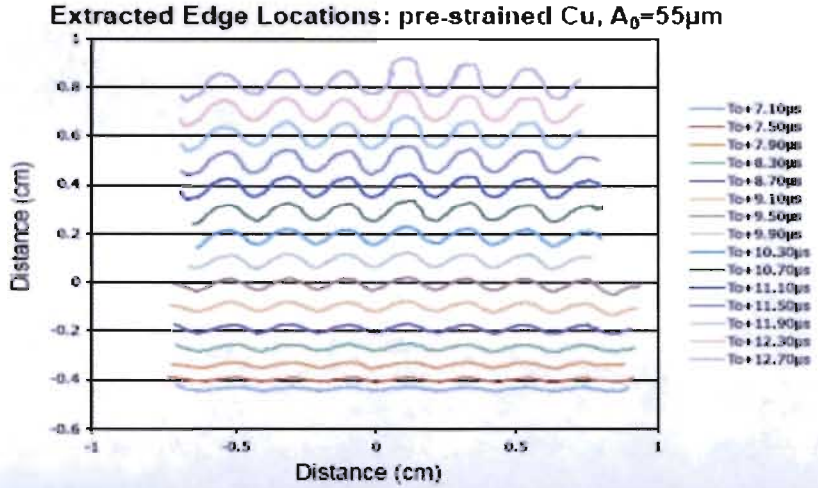
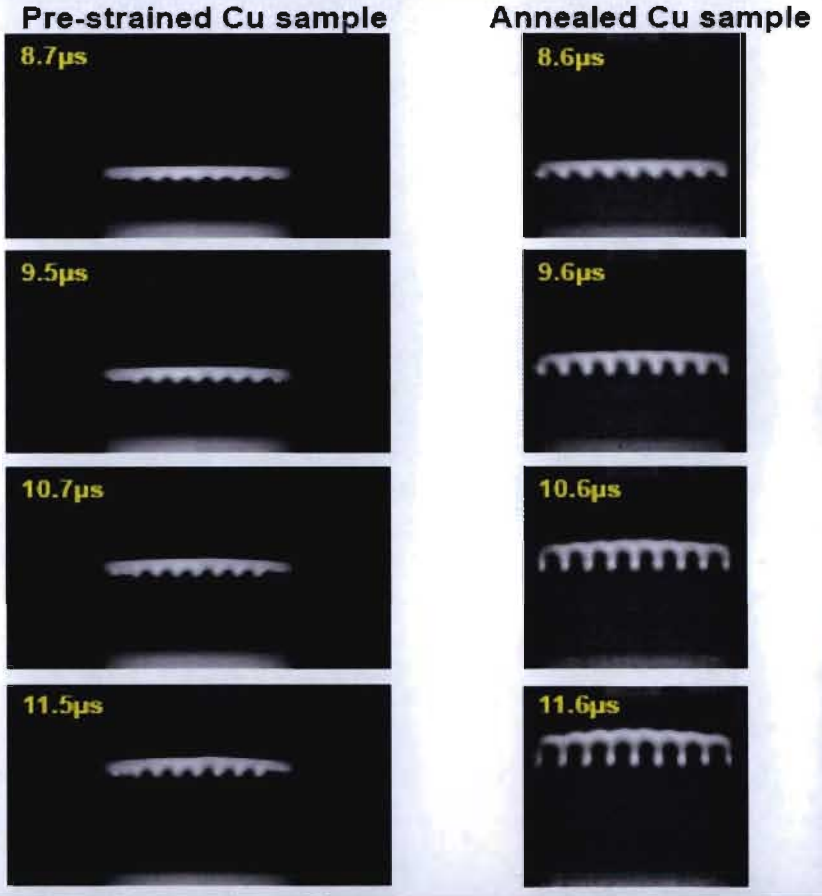
DARHT provides experimental data on the health of the deterrent



- World class X-ray radiography for hydrodynamic tests to gather data to support stockpile
- Axis 1 single image, operational since 1999
- Axis 2 up to four images
- World's first dual axis experiment successfully executed December 2009
- Experiments fully contained to reduce environmental impacts and increase shot rate



DARHT Containment System

pRad studies of perturbation growth rates as a function of time demonstrate a strong influence of materials processing

- **Comparison between fully annealed and cold worked copper samples.**
  - 55μm sinusoidal initial perturbation imposed on each sample.
  - Identical sample acceleration.
- **Significant reduction in growth rate is observed for cold worked Cu samples.**

Computer Codes

- *Computational Models* – sets of equations describing various weapons phenomenology and numerical solution techniques
  - » Radiation/Hydrodynamics
  - » Neutronics
  - » Thermonuclear burn
- *Physical Data* – unique for each material
  - » Neutron cross sections
  - » Equation of state
  - » Opacities
- *Nuclear test data* – needed to overcome our lack of full physics understanding (phenomenology and data)

Computers, Codes, and Nuclear Testing

- Manhattan Project work relied heavily on experimental and analytical programs – hand computing and electromechanical machines used
  - » produced workable unsophisticated designs (heavy, inefficient use of nuclear material)
  - » nuclear test of gun-assembled weapon not performed prior to dropping Little Boy
  - » if enough enriched uranium is available, gun designs are relatively easy

Computers, Codes, and Nuclear Testing (Cont.)

- Supercomputers and complex codes are used to make weapons lighter, smaller, safer, more efficient
  - » Classified nuclear test data essential to process (still lack understanding of full physics)
  - » US stockpile was designed with "supercomputers" equivalent to today's desktop PCs

Computers, Codes, and Nuclear Testing (Cont.)

- Advanced weapon states will continue to pursue larger computers to further understand weapon physics and operation
- Understanding stockpile aging issues without nuclear testing will require massive computational resources; success is not assured
- Supercomputers are of little value to beginning proliferants lacking nuclear test data

Nuclear Weapon Design is Unique

- Range of operating conditions within a nuclear weapon is greater than in anything else, manmade or natural, existing on earth
- Processes are very complicated and occur in extremely harsh environments
  - » extreme temperatures (>100 million degrees)
  - » high material velocities (>1 million miles/hour)
  - » very high pressures (>10 million atmospheres)
  - » small time scales (measured in billionths of a second)

Nuclear Weapon Design is Unique (Cont.)

- Forces are so large that the strongest metals compress and flow like fluids.
- Designing a machine that by its very nature destroys itself in a fraction of a second (and everything within a kilometer or more over the next several seconds) obviously complicates the process of understanding its reliability and of refining the design.
- Some parts of the device will be vaporized in an explosion while other parts only a few centimeters away must remain intact and function under the harsh environmental conditions described.

Annual Assessment– A statutory requirement and the highest priority of the Lab Director

- Detailed reports are prepared by lab staff on each warhead
- Lab Director briefed in detail by staff
- Lab Director issues letter to Secretaries of Defense & Energy and Chair of the NWC
- Lab Director briefs the Secretary of Energy
- STRATCOM prepares separate report and briefs the Secretary of Defense
- Secretaries of Defense & Energy brief the President
- President advises Congress

Key Questions for a Capability-Based Deterrent

- How agile do we need to be?
  - 3 – 5 – 10 years?
- How do we assess this?
  - historic weapon development times?
  - expert assessment?
  - negotiated via arms control?
- What about military readiness?
  - Dual use delivery platforms?
  - Dedicated platforms?
- How will capability be perceived by –
  - Allies? Adversaries? The rest of the world?
  - Must linkage to stockpile goals and a CTBT be explicit?
  - Will transparency play an important role?
  - Do we design transparency into weapons? The complex?

FOREWORD

While this document has been published as a Headquarters, U. S. Atomic Energy Commission publication, it has as its genesis two 1954 Los Alamos Scientific Laboratory reports identified as LAMS-1632 and LAMS-1633, titled "Weapons Activities of LASL." These publications are well known and used extensively by those interested in nuclear weapons as basic handbooks on the principles of nuclear weapons development and technology. Dr. Samuel Glasstone has revised and consolidated the above reports incorporating information furnished by the Los Alamos Scientific Laboratory, Lawrence Radiation Laboratory–Livermore, The Sandia Corporation, and the Defense Atomic Support Agency.

This document has been prepared solely for reference purposes on the principles of atomic weapons development and should not be considered as a technical guide for designing nuclear weapons.

Since this issue contains highly sensitive atomic weapons information of significance to our national defense and security, all viewers are enjoined to insure its proper security protection at all times.

ACKNOWLEDGMENT

In preparing this report, I have received invaluable assistance from members of the Lawrence Radiation Laboratory (Livermore), Los Alamos Scientific Laboratory, Defense Atomic Support Agency (Headquarters and Field Command), the Sandia Corporation, and the AEC Division of Military Application. Unfortunately, it is not possible to list the names of all those individuals who contributed either by providing information or by reviewing the draft manuscript or both. However, I wish to acknowledge my great indebtedness to them, for without their help this report could not have been produced. My special thanks are due to Lawrence S. Germain for his effective coordination of the contributions from LRL, Livermore.

UNCLASSIFIED

rate.* Most of the neutrons produced in fission actually have higher energies, but they lose energy rapidly in (inelastic) collisions, so that they are brought below the threshold of about 1 Mev for significant fission of uranium-238. Consequently, the maintenance of a chain reaction in uranium-238 is impossible. Nevertheless, fission of this isotope by fast neutrons does take place and the energy released can make a significant contribution to the total energy produced in nuclear weapons.

1.9 Of the three fissile species, only uranium-235 is found in nature; the other two are produced by artificial nuclear reactions (§1.53). Furthermore, only two, namely, uranium-235 and plutonium-239, are being used in weapons. Although uranium-233 has fission characteristics which would appear to make it of interest for use in certain types of artillery shells of small caliber, the strong gamma-ray activity of associated products introduces serious fabrication and handling problems.

1.10 The fission process may be regarded as yielding three types of products: (a) lighter nuclei, called fission fragments, (b) neutrons, referred to as fission neutrons, and (c) energy. Thus, taking uranium-235 as typical, the fission act may be represented by

$$\text{Uranium-235} + n \rightarrow \text{Fission fragments} + 2 \text{ to } 3\ n + \text{energy}$$

where n indicates a neutron. These products will be considered in turn. It may be mentioned that the general discussion of the fission process given below is applicable to all three fissile substances. Such differences in behavior as do exist arise from differences in the average number of neutrons produced when fission occurs and in the relative probabilities (or cross sections) of fission and nonfission reactions for neutrons of a given energy.

Fission Products

1.11 Uranium-235 (and other) nuclei split up in about 40 different ways, although some of these modes of fission are more probable than others. This means that roughly 80 different nuclides (fission fragments) are formed in fission in various proportions. Nearly all, if not all, of the fission-fragment nuclei are radioactive, emitting beta particles and frequently also gamma rays. On the average, each fission fragment undergoes three stages of beta decay before attaining stability, so that there are ultimately formed over 200 different nuclear species, most of which are radioactive. The mixture of fission fragments and their decay products is referred to by the general name of fission products. As just indicated, it is a very complex system containing many radioisotopes, the half-lives ranging from a small fraction of a second to a million years. It is the fission product mixture which contributes nearly all of the radioactivity of the fallout produced by a nuclear explosion.

Fission Neutrons

1.12 The number of neutrons released when a nucleus undergoes fission varies somewhat with the particular mode of fission, but the average number of fission neutrons is well defined. The value depends on the energy of the neutrons which cause fission, and increases to some extent with increasing neutron energy. The results of estimates based on experimental measurements are given in Table 1.1 of the average number (ν) of neutrons produced per fission caused by (a) slow neutrons, i.e., neutrons of essentially zero energy, (b) neutrons of about 0.5 Mev energy, which is roughly the average energy of the neutrons which maintain the chain in a simple fission weapon, and (c) neutrons of 14-Mev energy which contribute greatly to the fission energy of boosted (§1.49) and many two-stage (§7.38) devices.

1.13 The neutrons emitted in fission fall into two categories, namely, prompt neutrons and delayed neutrons. The former are all released within something like 10^{-14} sec of the fis-

*A distinction is sometimes made between the "fissile" nuclei, such as uranium-235, etc., in which fission can be produced by a neutron regardless of its energy, and the "fissionable" nuclei, such as uranium-238 and thorium-232, which require neutrons of high energy to cause fission.

UNCLASSIFIED

sion process, but the latter continue to be emitted for a few minutes. For uranium-235 fission, the prompt neutrons constitute 99.35 percent of the total fission neutrons and for plutonium-239 they represent nearly 99.8 percent. Because the time scale in nuclear explosions is very short, delayed neutrons play essentially no part in the fission chain reaction. In reactors for the controlled release of nuclear energy, however, these neutrons are of great significance.

Table 1.1—Neutrons Released per Fission

Nuclide	Neutron Energy		
	~0 Mev	0.5 Mev	14 Mev
Uranium-235	2.43	2.49	4.1
Plutonium-239	2.80	2.85	4.9
Uranium-233	2.45	2.51	4.2

Fission Energy

1.14 The rough estimate made earlier indicated that about 200 Mev of energy are produced per nucleus undergoing fission. More precise calculations, based on nuclear masses, and experimental measurements have shown that this is a good approximation for both uranium-235 and plutonium-239. The atomic mass in grams, i.e., 235 grams of uranium-235, contains 6.02×10^{23} nuclei, and the complete fission of this amount of uranium-235 would yield $6.02 \times 10^{23} \times 200 = 1.20 \times 10^{25}$ Mev or 1.93×10^{19} erg, since 1 Mev is equal to 1.60×10^{-6} erg. Making use of the fact that 1 calorie is equivalent to 4.18×10^{7} ergs, it can be readily shown that complete fission of all the nuclei in 1 kilogram of fissile material would result in a total energy release of 2.0×10^{13} calories.

1.15 Only part of the energy of fission is immediately available in a nuclear explosion, since most of the radioactive decay energy of the fission products is released over a long period of time. It is usually accepted that about 90 percent of the fission energy contributes to the explosion, so that in a weapon the fission of 1 kilogram of material would produce explosive energy of about 1.8×10^{13} calories. The energy liberated in the explosion of 1 ton of TNT is taken to be 10^{9} calories, and so 1 kilogram of fissile (or fissionable) material is equivalent in explosive power to 18,000 tons, i.e., 18 kilotons (or 18 kt), of TNT.* From these results it is readily found that complete fission of 0.056 kg (or 56 grams) or of 1.45×10^{23} nuclei of fissile material produces the equivalent of 1 kt of TNT of explosive energy. In other words, the energy per fission is 7.03×10^{-24} kt TNT equivalent. In stating the energy yields (or, in brief, the yields) of nuclear weapons, the basic unit, for very low yields, is the ton, with the kiloton (or 1,000 tons), i.e., 1 kt, and the megaton (or 1,000,000 tons), i.e., 1 Mt, of TNT equivalent being used for higher yields.

THE FISSION CHAIN REACTION

Condition for Chain Reaction: Critical Size

1.16 The condition for a self-sustaining fission chain reaction is that, on the average, the neutrons released in one act of fission shall cause (at least) one subsequent fission. Since the average number of neutrons produced in an act of fission is greater than two (see Table 1.1), it would appear, at first sight, that a chain reaction in uranium-235 or plutonium-239 would be inevitable. However, this is not so, because an appreciable proportion of the neutrons pro-

*In some calculations, the equivalent of 1 kg of uranium-235 is assumed to be 17 kt whereas for plutonium-239 it is 19 kt. The value 18 kt per kg is a good average for most fission weapons.

UNCLASSIFIED

thus determined by the availability of the prompt neutrons, without regard to those which are delayed. This situation is often described as prompt critical. Since more than 99 percent of fission neutrons are prompt, the neglect of the delayed neutrons has little effect on the value of ν. In other words, the data in Table 1.1 may be taken as being approximately applicable to weapons. Critical masses determined by experiment (§1.29) include the contribution of delayed neutrons, so that the prompt critical mass is very slightly larger than the measured value. Again, the difference is not significant, although corrections can be applied if necessary.

Factors Affecting Critical Mass

1.22 The critical size (or mass) of a given fissile material depends on a number of factors, as mentioned earlier. For example, the shape (or geometry) of the system has an influence on criticality because of the variation in the volume-to-area ratio. As seen in §1.17, this ratio determines the fraction of neutrons lost by leakage from the system. The optimum condition of minimum critical mass is obtained for a sphere; this has the largest ratio of volume to area, so that the fraction of neutrons produced which escape from the system is less than for any other shape of the same mass. Thus, the critical mass of a sphere is less than for any other geometrical form of the given material.

DOE b(3)

1.23 As far as the composition of the material is concerned, it is evident that the presence of impurities will increase the critical mass of the fissile species. Apart from the fact that the impurity may cause a loss of neutrons by parasitic capture, it adds area to the system, which increases the probability of neutron escape, without the compensating production of neutrons by fission in the increased volume. Similar considerations apply to the situation in which a given fissile substance, e.g., plutonium-239, exists in two forms with different densities. The less dense form (delta-plutonium metal) has a higher critical mass than the more dense form (alpha-plutonium) because of the larger surface area for a given mass. The rate of neutron production by fission depends on the mass, i.e., the number of fissile nuclei, but the rate of loss by escape is greater for the delta-plutonium since the area is larger for the same mass.

1.24 The value of ν also affects the critical size. The larger the magnitude of ν, the smaller will be the critical size (or mass) under the same general conditions. If more neutrons are formed per fission, it will be possible to tolerate a somewhat larger loss and yet attain criticality. This is apparent from the fact that the critical condition is that $k = \nu - 1 = 1$, so that an increase in 1 can be compensated by an increase in ν. It is because its ν is appreciably larger, that the critical size of plutonium-239 is less than that of uranium-235, under equivalent conditions. Since the densities of plutonium and uranium are not greatly different, the same relationship applies to the respective critical masses (see Table 1.2).

Table 1.2—Critical Masses of Spheres

Fissile Material	Density (g/cm^3)	Critical mass (kg)	
		Bare	Reflected
Uranium-235 (93.2 wt.%)	18.8	52.2	
Plutonium-239 (α)*	19.6	10.4	
Plutonium-239 (δ)†	15.8	16.5	

DOE b(3)

*Contains 4.5 wt.% plutonium-240.

†Contains 4.5 wt.% plutonium-240 and 1.0 wt.% gallium δ-phase stabilizer.

1.25 For a specified shape and composition, the size of a critical system can be decreased by surrounding it with a material which scatters some of the escaping neutrons back

UNCLASSIFIED

into the fissile core. By reducing the fraction of neutrons which escape completely, a smaller size (or mass) can become critical. Such a scattering material, on account of its function, is sometimes referred to as a neutron reflector.

1.26 In nuclear weapons, the fissile material is surrounded by a tamper or, more specifically, an inertial tamper, the mass of which delays expansion of the exploding material and permits a higher energy yield to be obtained from the system undergoing fission, as will be seen later. This inertial tamper also serves as a neutron reflector or neutronic tamper. In some cases, however, the neutronic aspect is more important than the inertial character of the tamper.

1.27 As is to be expected, increasing the thickness of the tamper decreases the escape of neutrons and thus makes possible a smaller critical mass of the core of fissile material. However, it has been shown by calculations and verified experimentally that when the neutronic tamper thickness reaches a certain value, there is little more to be gained by a further increase of thickness (Fig. 1.2). Thus, when the thickness is about two neutron scattering mean

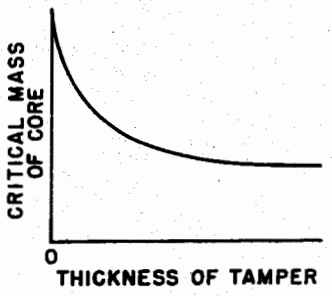

Figure 1.2

free paths, the effectiveness in decreasing the critical mass is within a few percent of that for an infinitely thick tamper.* In natural uranium, which is sometimes used as a tamper, the scattering mean free path of fast (1 Mev) neutrons is about 4 cm, i.e., 1.6 in., in metal of normal density. The value is proportionately less in compressed uranium of higher density. In weapons of low mass, beryllium is a common tamper material; the scattering mean free path is somewhat longer than in uranium because of the lower density.

1.28 Another important factor which affects the critical size is the energy (or speed) of the neutrons causing fission. For several reasons, some of which will be explained later, nuclear weapons are designed so that the fission chain is maintained by fast neutrons, with energies in the range of approximately 0.1 to 2 Mev. In the subsequent treatment it will be assumed, therefore, that fast-neutron fission makes the main contribution to the chain reaction.

Determination of Critical Mass

1.29 Critical masses can now be calculated with a fair degree of accuracy, provided all the conditions are known exactly. It is desirable, however, to check these values by experimental measurements. Because of the danger involved in handling critical assemblies, the general procedure is to extrapolate from observations made on a number of subcritical systems of increasing mass.

1.30 It was seen in §1.20 that the introduction of S neutrons into a fissile material results in the presence of kS neutrons in the first generation, k^2S in the second, and so on. If a

*The scattering mean free path is the average crow-flight distance a neutron travels before undergoing a scattering collision with a nucleus in the given tamper material.

UNCLASSIFIED

neutrons for initiating fission chains. In addition, the high-energy (14 Mev) neutrons liberated in the D-T reaction are used in many fission weapons to achieve what is known as "boosting." Neutrons from the D-T reaction are introduced at a later stage of the fission chain in order to maintain and enhance the progress of the fission reactions. There is a considerable increase in the energy released because of the greatly improved efficiency in utilization of the fissile material. The energy contributed by the D-T fusion reaction is quite small in comparison with that from fission.

PRODUCTION OF WEAPONS MATERIALS

Uranium-235

1.50 The two important fissile materials, namely, uranium-235 and plutonium-239, are both produced from natural uranium but by entirely different procedures. Ordinary uranium contains about 0.7 percent of uranium-235, together with about 99.3 percent of uranium-238 and a trace (0.006 percent) of uranium-234. The proportion of uranium-235 is increased by a process involving diffusion or, more correctly, effusion through porous barriers of the vapor of uranium hexafluoride (UF_6) made from natural uranium. The hexafluoride of the lighter isotope diffuses more rapidly than does that of the heavier species, and by the use of several thousand diffusion stages enrichments of over 90 percent are obtained, i.e., the material produced contains over 90 percent of uranium-235. The most common product for weapons use consists of about 93.5 weight percent uranium-235, the remainder being mainly uranium-238 and a small proportion of uranium-234. This product is commonly known as "oralloy,"* the two initial letters standing for Oak Ridge, where the material was first made in quantity.

[redacted] DOE 6(3)

1.51 The highly enriched uranium hexafluoride obtained from the gaseous diffusion plant is converted into the tetrafluoride (UF_4) by reduction with hydrogen (mixed with some fluorine). The tetrafluoride, which is a solid with a high melting point (close to 1000°C), is mixed with calcium and heated in a closed steel vessel lined internally with a refractory material. The calcium reduces the uranium tetrafluoride to uranium metal which is separated from the slag of calcium fluoride. Volatile impurities are removed by heating the liquid metal in a vacuum and the resulting product is of a high degree of purity.

1.52 The residual material from the isotope separation (gaseous diffusion) plant consists of uranium hexafluoride which has been depleted in uranium-235. In other words, it contains more than the normal 99.3 percent of uranium-238. This is converted into uranium metal by a procedure similar to that described above. It is referred to as depleted uranium or, in the weapons program, as D-38. At one time it was called Q-metal, but this name is not now in common use.

Plutonium-239

1.53 The element plutonium does not occur in nature, except in insignificant traces. Consequently, the plutonium-239 used in weapons is obtained artificially by a series of nuclear reactions resulting from exposure of uranium-238 to slow neutrons in a nuclear reactor. A nuclear reactor is a device in which a fission chain reaction is taking place in a controlled manner, as against the deliberately uncontrolled chain reaction in a weapon. If a material of low mass number, called a moderator, is present, in addition to fissile material, the fission neutrons are slowed down. Such a nuclear reactor is thus a good source of slow neutrons.

---

*The "alloy" part of the name originated from the designation Tube Alloys Limited applied to the British wartime atomic energy project. Natural uranium metal was thus called "tuballoy," a term still in common use, and then oralloy was adopted for the uranium-235 enriched material.

[redacted]

UNCLASSIFIED

1.54 Uranium-238 nuclei capture slow neutrons quite readily to form a higher isotope, uranium-239, with the emission of gamma radiation; thus, the (n,γ) reaction

$$_{92}U^{238} + {}_0n^1 \rightarrow {}_{92}U^{239} + \gamma$$

occurs, where the subscripts give the atomic numbers and the superscripts the mass numbers in each case; the neutron ($_0n^1$) has a charge (atomic number) of zero and a mass of unity. The uranium-239 produced by neutron capture is radioactive, with a half-life of 23 min, emitting a beta particle. Representing the latter by $_{-1}\beta^0$, since it carries a unit negative charge and has essentially no mass, the radioactive decay process may be written as

$$_{92}U^{239} \rightarrow {}_{-1}\beta^0 + {}_{93}Np^{239}$$

the product being an isotope of mass number 239 of an element of atomic number 93. This element, called neptunium (Np), is virtually nonexistent in nature.

DOE 6(3)

[redacted]

1.55 Neptunium-239 is also radioactive with a half-life of 2.3 days; it emits a beta particle according to the reaction

$$_{93}Np^{239} \rightarrow {}_{-1}\beta^0 + {}_{94}Pu^{239}$$

so that the product has a mass number of 239 and an atomic number of 94. The name plutonium, symbol Pu, has been given to the element with this atomic number. The isotope plutonium-239 is an alpha-particle emitter with a fairly long half life—about 24,000 years—so that it is relatively stable. It may be mentioned that the decay product of plutonium-239 is the fissile uranium-235, which has a half-life of about 9×10^8 years. Hence, as far as fission is concerned, plutonium-239 could be stored for thousands of years with only minor deterioration. The little deterioration which does occur arises mainly from the fact that the average number of neutrons, ν, produced by fission of uranium-235 is somewhat less than that from plutonium-239 (§1.12).

1.56 For the production of plutonium-239, natural uranium metal is used as the fuel material in a nuclear reactor with graphite (Hanford) or heavy water (Savannah River) as the moderator. The uranium-235 in the fuel sustains the fission chain reaction and produces neutrons, some of which are captured by the uranium-238 with the consequent formation of plutonium-239, as described above. After being in the reactor for an appropriate time, the "spent" fuel is removed, dissolved in nitric acid, and the plutonium is extracted from the solution by the use of certain organic solvents. It is then re-extracted into a water medium to give an aqueous solution of the nitrate, from which the plutonium is precipitated either as the peroxide or the oxalate. The solid compound is separated and heated with a mixture of hydrogen fluoride gas and oxygen to obtain plutonium tetrafluoride (PuF_4). The latter is finally reduced to plutonium metal with calcium (plus iodine).

1.57 Metallic plutonium exists in six different allotropic forms between room temperature and the melting point (640°C). The temperature ranges over which the various forms (or phases) are stable are shown in Table 1.3. It is seen that alpha-plutonium, referred to in §§1.23 and 1.34, which has a density of 19.6 g/cm^3, is stable at ordinary temperatures. The high density is advantageous from certain weapon standpoints, since it permits attainment of criticality in a smaller mass than is possible with other forms of plutonium (cf. Table 1.2). On the other hand, alpha-plutonium is brittle and difficult to fabricate. Furthermore, the presence of certain impurities retards the attainment of the alpha-phase equilibrium, so that fabricated parts exhibit dimensional instability. However, if these impurities are avoided, the dimensional instability problem does not arise.

1.58 Although delta-plutonium is normally stable in the temperature range of 319 to 451°C, the addition of 1 weight percent of gallium to plutonium stabilizes the delta phase at or-

[redacted]

UNCLASSIFIED

dinary temperatures. The plutonium used in most stockpile weapons is in the stabilized delta form. The material is much less brittle and easier to fabricate than alpha-plutonium: in fact delta-plutonium is said to resemble aluminum in this respect whereas the alpha-phase is more like cast iron. Delta-plutonium was used in the earliest implosion weapons because its low density permitted the use of a larger mass of subcritical fissile material (Table 1.2), thereby making possible an increase in the total energy yield. This aspect of weapons design is, however, no longer significant.

Table 1.3 — Properties of Solid Phases of Plutonium

Phase	Stability range	Density (g/cm^3)
Alpha (α)	Up to 120°C	19.6 (25°C)
Beta (β)	120 to 206°C	17.8 (150°C)
Gamma (γ)	206 to 319°C	17.2 (210°C)
Delta (δ)	319 to 451°C	15.9 (320°C)
Delta prime (δ')	451 to 476°C	16.0 (465°C)
Epsilon (ϵ)	476 to 640°C (m.p.)	16.5 (510°C)

Plutonium-240

1.59 As the plutonium-239 accumulates in the reactor in which it is produced, it also captures neutrons, the rate of capture being proportional to the neutron density (or flux) in the reactor and to the concentration of plutonium-239 nuclei. The reaction which takes place is

$$_{94}Pu^{239} + {}_0n^1 \rightarrow {}_{94}Pu^{240} + \gamma$$

the product being plutonium-240, an alpha emitter of about 6600 years half-life. The two isotopes of plutonium are not separated from one another in the chemical process used for the extraction of this element from the reactor fuel. Hence, plutonium-239 is always associated with a certain proportion of plutonium-240, the amount of the latter increasing, with both the exposure time and neutron density in the reactor, up to a limiting value of about 35 percent.

1.60 In a simple (unboosted) implosion type weapon, it is desirable that the plutonium-240 content be as small as possible for two reasons: (a) the high spontaneous fission rate of plutonium-240 causes a large neutron background (§1.37) which can result in the initiation of a fission chain before the optimum time, and (b) the fission of plutonium-240 requires mostly neutrons of high energy and, in addition, the ν value is smaller than for plutonium-239 so that it acts, to some extent, as an inert diluent.* Consequently, if plutonium-240 is present, the mass of plutonium-239 required for criticality is larger than would be the case for pure material (§1.23). [redacted] DOE b(3) It should be noted that to obtain a product with a small proportion of plutonium-240, the uranium fuel elements can be permitted to remain in the reactor for only a short time before they are removed and processed for the extraction of plutonium. As a result, the smaller the plutonium-240 content, the higher the cost of the material produced.

1.61 In evaluating the cost of the plutonium in a weapon, it must be recognized that the higher the plutonium-240 content the smaller the cost per unit mass of plutonium-239, but the larger the mass required for criticality. The actual cost per crit, which is the important cri-

*Fission of plutonium-240 exhibits an appreciable resonance for neutrons of about 1-ev energy. Otherwise, the cross sections are low except at high neutron energies.

[redacted] UNCLASSIFIED

terion, is thus determined by two opposing factors. The weapon cost first decreases and then increases as the proportion of plutonium-240 is increased. However, cost is not the only factor to be taken into account in the choice of weapon material. An important consideration, known as "one-point safety" (§5.13), is favored in some (but not all) circumstances by the use of material containing higher proportions of plutonium-240. [redacted] DOE b(3) This is regarded as the best compromise at the present time, although it may be subject to change with circumstances.

1.62 For a production reactor of a given type, the plutonium-240 content of the material produced depends on the neutron density (or reactor power) and the exposure time. Consequently, the quality of plutonium was at one time described in terms of megawatt-days of exposure in the reactor per ton of uranium fuel, i.e., in MWD/T units. This unit is not very precise because the reactor power is not uniform throughout its volume, so that the plutonium-240 content corresponding to a given MWD/T value will vary with the location of the fuel in the reactor. It also depends upon the characteristics of the production reactor, so that it is different for the Hanford (graphite moderated) and Savannah River (heavy-water moderated) reactor products. An alternative method for expressing quality is the number of grams of plutonium per ton of fuel removed for processing, generally indicated by g/T; the higher the g/T value the greater the plutonium-240 content. Because 1 MWD of reactor energy produces roughly 1 gram of plutonium, the values are approximately equal numerically in g/T and MWD/T units.

1.63 The two foregoing methods of indicating the quality of plutonium have now been replaced by the actual statement of the weight percent of plutonium-240. Some of the older fission weapons required plutonium of low plutonium-240 content ("clean" plutonium); the purest material generally used contained about 1.5 percent of plutonium-240 (about 220 MWD/T). [redacted] DOE b(3)

1.64 Another way of expressing the amount of plutonium-240 is based on direct measurement of the rate of neutron emission from the material. These neutrons arise mainly from the spontaneous fission of plutonium-240. The result is expressed as the number of neutrons emitted per gram per second, abbreviated to ngs. A rough "rule of thumb" is that the ngs value is 10.5 times the percentage of plutonium-240. The characteristics of three Hanford production materials with different plutonium-240 contents are given in Table 1.4.

Table 1.4—Characteristics of Hanford Plutonium

Plutonium-240 (percent)	MWD/T	Neutrons/gram-sec (ngs)
7.1	800	75
5.6	600	58
3.85	400	40

*Continued exposure in a reactor results in the conversion of some plutonium-240 into fissile plutonium-241 as a result of neutron capture. Thus, beyond a certain point the usefulness of dirty plutonium as a weapons material may increase.

UNCLASSIFIED

[redacted]

Production of Neutrons

1.65 In a fission weapon, the chain reaction is initiated by the introduction of neutrons into a critical or supercritical system. Consequently, the general methods for producing neutrons in weapons will be reviewed here. One of the simplest procedures for obtaining neutrons is by the action of alpha particles on certain light elements, notably beryllium; processes of this kind are referred to as (α,n) reactions. Recalling that the alpha particle is actually a helium nucleus, the reaction is represented by

$$_2He^4 + _4Be^9 \rightarrow _6C^{12} + _0n^1$$

1.66 A convenient source of alpha particles, which was used extensively at one time in fission weapons, is the radioelement polonium-210. This isotope has certain advantages, associated with corresponding drawbacks. It does not emit gamma rays, so that there is no neutron production by the (γ,n) reaction which might otherwise occur even when the polonium-210 and beryllium are separated in such a manner as to prevent access of alpha particles to the latter. Moreover, the polonium-210 is easy to produce by exposure of ordinary bismuth to neutrons in a nuclear reactor, when the (n,γ) reaction

$$_{83}Bi^{209} + _0n^1 \rightarrow _{83}Bi^{210} + \gamma$$

takes place. The bismuth-210 is a beta emitter with a half-life of 5 days, so that it soon decays to form polonium-210; thus,

$$_{83}Bi^{210} \rightarrow _{-1}\beta^0 + _{84}Po^{210}$$

However, the production of polonium-210 in this manner means that fewer neutrons are available for the conversion of uranium-238 into plutonium-239.

1.67 The moderately short half-life of polonium-210—138.4 days—means that it emits alpha particles rapidly and a small quantity can thus provide a strong neutron source in conjunction with beryllium. But the short half-life is also a serious disadvantage, because the activity falls off relatively rapidly. In one year, the alpha activity, and hence the rate of neutron production, will have decreased to 10 percent and in two years to 1 percent of its initial value.

CHAPTER 2

THE FISSION PROCESS IN WEAPONS

INCREASE OF NEUTRON POPULATION

The Multiplication Rate: Alpha

2.1 No matter how it originates, an explosion is associated with the very rapid liberation of a large amount of energy within a restricted space. If the energy is to be produced by fission, then an essential condition for explosion is a very high neutron density, since the rate of fission, and hence the rate of energy release, is proportional to the number of neutrons per unit volume. It is of interest, therefore, to examine the factors which lead to a high neutron density, since these will form a basis for fission weapon design.

2.2 In accordance with the definition of the effective multiplication factor, k, given in §1.19, it follows that for every n neutrons present at the beginning of a generation there will be nk neutrons at the beginning of the next generation, so that the gain of neutrons is $n(k-1)$ per generation. The rate of gain, dn/dt, may then be obtained upon dividing the actual gain by the average time, τ, between successive fission generations; hence,

$$\frac{dn}{dt} = \frac{n(k-1)}{\tau} \tag{2.1}$$

Equation (2.1) will be strictly correct only if delayed neutrons play no part in maintaining the fission chain. As already stated (§1.13), this condition is applicable, to a good approximation, to nuclear fission weapons.

2.3 The quantity $k-1$, which is the excess number of available neutrons per fission, may be represented by x, i.e.,

$$x \equiv k-1 \tag{2.2}$$

and then equation (2.1) becomes

$$\frac{dn}{dt} = \frac{x}{\tau} n \tag{2.3}$$

The time rate of increase (or decrease) in neutron population can be expressed in the general form

$$\frac{dn}{dt} = \alpha n \tag{2.4}$$

UNCLASSIFIED

where α is the specific rate constant for the process which is responsible for the change in the number of neutrons. In nuclear weapons work this constant is called the multiplication rate or merely "alpha." Comparison of equations (2.3) and (2.4) shows that for a fission chain reaction

$$\alpha = \frac{x}{\tau} \tag{2.5}$$

2.4 The foregoing results are applicable regardless of whether x, and hence α, is positive, zero, or negative. For a subcritical system, $k < 1$ (§1.20), i.e., $k - 1$ is negative; in these circumstances x is negative and so also is α. It follows from equation (2.4) that dn/dt is then negative and the number of neutrons in the system will decrease with time. Consequently, in agreement with previous conclusions, the fission chain in a subcritical system will eventually die out because of the steady decrease in the neutron population. When the system is just critical, $k = 1$, and x and α are both zero; the number of neutrons will thus remain constant. Finally, for a supercritical system, $k > 1$, and x and α are positive; there will then be a steady increase in the neutron population. Since dn/dt is proportional to n, by equation (2.4), it is evident that in a supercritical system, the number of neutrons will grow at increasingly faster rates as n increases.

2.5 Another aspect of the significance of α becomes apparent when equation (2.4) is written in the form

$$\frac{dn}{n} = \alpha \, dt$$

If α is assumed to remain constant, this expression can be readily integrated between the time limits of zero, when the number of neutrons present is n_0, and t, when the number is n. The result is

$$n = n_0 e^{\alpha t} \tag{2.6}$$

where, as usual, e is the base of natural logarithms. This expression, like those given above, is applicable regardless of whether α is positive, zero, or negative. If α is known, equation (2.6) can be used to calculate the neutron population at any time t relative to the value at any arbitrary zero time. It can also be seen from equation (2.6) that $1/\alpha$ is the time period during which the number of neutrons changes by a factor e; consequently, $1/\alpha$ is often referred to as the e-folding time, i.e., the time in which there is an e-fold change in the neutron population.

Determination of Alpha

2.6 The value of α is a highly important quantity in weapons design, as will shortly be apparent. Attempts are made to estimate it theoretically from the neutronic and hydrodynamic characteristics of the system, but there are many uncertainties involved and experimental measurements are desirable. In weapons tests, the determination of alpha is one of the most important diagnostic requirements. The methods used under these circumstances are described in Chapter 8. The present treatment will be restricted to procedures which can be used in the design phase without an actual test of the weapon.

2.7 Since a supercritical (or even a critical) mass cannot be handled safely under ordinary conditions, experimental measurements of α are made with a mass that is slightly subcritical. Into this assembly is injected a burst of neutrons and these neutrons initiate a large number of chains. However, since the system is subcritical, α will be negative and so the number of neutrons will decrease after the initial increase. By determining a quantity proportional to the neutron population as a function of time, with neutron counters located outside the assembly, it is possible to determine α by means of equation (2.6). The α obtained from the decrease in neutron population in the early stages is the so-called prompt value, required for weapons studies in which the delayed neutrons play no part.

UNCLASSIFIED

2.8 Another method is to introduce a single neutron at intervals into a slightly subcritical system. One (effective) neutron starts a fission chain which soon dies out; then another neutron starts a second chain which dies out, and so on for the duration of the experiment. Thus, instead of being subjected to the neutrons from a large number of chains almost simultaneously, the counters are exposed over an appreciable period to neutrons from a large number of chains one at a time. The method is thus statistical in character. The neutron counting is carried out by means of a multichannel time-delay circuit. The first channel is activated by entry of a neutron; then, after a pre-determined interval, a second channel is activated for a short time; after a further interval, a third channel is activated, and so on for intervals ranging from 0.25 μsec to a total of a few milliseconds. From the accumulated counts for the various channels, the time rate of decay of the prompt neutrons after fission can be determined and α calculated.

2.9 The values of α obtained as described above apply to the particular subcritical system used. In order to estimate what α would be in a supercritical (weapon) assembly of the same materials, an extrapolation procedure can be employed. By means of a number of measurements with different assemblies, α can be determined as a function of the number of (prompt) crits present. The values could then be extrapolated to give α for the number of crits expected at the time of initiation of the weapon. Such a procedure is highly uncertain since it involves extrapolation from a series of assemblies which are slightly subcritical to one which is highly supercritical.

Conditions for Nuclear Explosion

2.10 It was pointed out in §2.1 that the essential condition for a nuclear fission explosion is a very high neutron density. Equation (2.6) shows that if a large density n is to be attained within a short time, α must be large. In general, the magnitude of α determines the efficiency of a nuclear explosion, and it is of interest to consider how α may be made as large as possible.

2.11 According to equation (1.4), k is equal to $\nu - l$, where ν is the average number of neutrons produced in each act of fission and l is the number lost by escape and in other ways upon utilizing this result, together with equations (2.2) and (2.5) it follows that

$$\alpha = \frac{x}{\tau} = \frac{\nu - l - 1}{\tau} \tag{2.7}$$

so that to increase α it is necessary that $\nu - l - 1$ be large and τ be small. The value of ν is a specific property of the fissile material for fission by neutrons of a given energy. Since ν increases with neutron energy, it would appear to be advantageous from this standpoint if most of the fissions in a weapon were caused by fast neutrons. The relative neutron loss, l, can be decreased by making the system highly supercritical, e.g., by assembly or compression. If the volume increases, the loss of neutrons per fission increases and α will decrease accordingly. The importance of this effect of volume change will be seen later (§2.23).

2.12 A highly significant contribution to the magnitude of α is made by the fission generation time, τ. This is approximately equal to λ, the fission mean free path of the neutrons in the core material, divided by the (average) speed, v, of the neutrons causing fission, i.e.,

$$\tau \approx \frac{\lambda}{v} \tag{2.8}$$

so that in a fission weapon it is desirable that the ratio λ/v be as small as possible. It should be noted that the fission mean free path in equation (2.8) is not the same as the mean free path for all interactions used in §1.43. The λ employed here is the average (crow-flight) distance a neutron travels before it is captured in a fission reaction.

UNCLASSIFIED

2.13 The fission mean free path is equal to $1/N\sigma_f$, where N is the number of fissile nuclei per cm^3 and σ_f is the fission cross section.* Hence, from equation (2.8),

$$\tau \approx \frac{1}{N\sigma_f v} \tag{2.9}$$

so that the generation time is inversely proportional to the produce $\sigma_f v$. The value of σ_f decreases as v increases but the product is 2×10^9 (in 10^{-24} cm^3/sec units) for fast neutrons of 1-Mev energy compared with 10^8 for slow neutrons. Hence, the fission generation time is appreciably shorter for fast than for slow neutrons. Actually, the situation is worse for slow neutrons than would appear from a comparison of the values of $\sigma_f v$ because the effective generation time for these neutrons includes the slowing-down time and this is considerably longer than $\sigma_f v$ alone would indicate.

2.14 From the information already given, it is possible to make a rough, order-of-magnitude estimate of α. As seen from Table 1.1, ν is about 2.5 to 3; the loss, l, of neutrons per fission may be taken as 0.5 to 1, and so, by equation (2.2), x is close to unity for a highly supercritical system. For uncompressed uranium-235 or plutonium-239, the number, N, of nuclei per cm^3 is roughly 0.5×10^{23} and, as seen above, $\sigma_f v$ for fast-neutron fission is $2 \times 10^9 \times 10^{-24}$ cm^3/sec. It follows, therefore, from equation (2.7) and (2.9) that

$$\alpha \approx (0.5 \times 10^{23})(2 \times 10^{-15}) \approx 10^8 \text{ sec}^{-1}$$

Thus, for fast-neutron fission, α is about 10^8 sec^{-1} in a supercritical system and τ, the generation time, is roughly 10^{-8} sec (or 1 shake). It is the common practice to express values of α in reciprocal shakes, i.e., 10^8 sec^{-1} units, so that in the rough calculation made above α is approximately 1 $shake^{-1}$. Experimental measurements, both in the laboratory and at weapons tests, show that α is indeed of this order of magnitude.†

2.15 It is evident that in order to achieve an efficient nuclear explosion, fission should be brought about by fast neutrons, as far as possible. For such neutrons, the factors ν and τ, and to some extent l, favor a high value of α and, hence, a rapid increase in the neutron population. Except in certain special cases, appreciable amounts of elements of low mass number, which slow down neutrons, are consequently kept out of the core of a fission weapon.

2.16 According to equation (2.9), the fission generation time for neutrons of a given energy (or velocity) is inversely proportional to the number, N, of fissile nuclei per cm^3. It follows, therefore, that τ is inversely proportional to η, the core compression ratio; thus

$$\tau \propto \frac{1}{\eta} \tag{2.10}$$

Consequently, the generation time can be decreased, and the value of α increased, by compression of the core material.

2.17 In addition to the effect on τ, compression also causes a marked decrease in l, for the reason given in §1.40. This also contributes to an increase in α, as follows from equation (2.7). It is seen, therefore, that compression of the core will cause an increase in α because of the decrease in both τ and l.

Explosion Time

2.18 According to the arguments in §2.14, x is approximately equal to unity and so, by equation (2.5), $1/\alpha$ is roughly equal to τ, the generation time. It is thus possible to write equation (2.6) in the approximate form

---

*For the present purpose it is sufficient to regard the cross section as the effective area in sq cm of a nucleus for a particular reaction (or reactions). Cross sections vary with the neutron energy and the fission cross sections for uranium-235 and plutonium-239 have been measured over a large energy range.

†Some workers prefer to express α in reciprocal microseconds.

UNCLASSIFIED

material, expansion of the core should be delayed. This important function is fulfilled by the inertial tamper. In boosted weapons, the introduction of neutrons from an extraneous (D-T) source results in a considerable increase in the fission rate before the system expands appreciably. The inertial tamper is then less important than in an unboosted device.

2.24 [redacted] DOE 6(3)

In some weapons, however, there will be many neutrons present at the time of initiation. If, for example, there are 100 neutrons, i.e., 10^2 or $e^{4.6}$, there will be the equivalent of nearly 5 "generations" of neutrons at the start of the chain. [redacted] DOE 6(3)

EFFICIENCY OF FISSION WEAPONS

Definition of Efficiency

2.25 The efficiency, ϕ, of any weapon may be defined as the ratio of the energy actually developed when it explodes, i.e., the energy yield, to the total energy available; thus,

$$\phi = \frac{\text{Energy yield}}{\text{Energy available}} \tag{2.13}$$

In other words, the efficiency is the fraction of the total energy available which is actually released in the explosion. In the case of a fission weapon, this is equal to the ratio of the quantity of fissile material which actually suffers fission to the total amount present in the weapon. The efficiency of a weapon is generally expressed as a percentage, and so it is equal to ϕ, as defined by equation (2.13), multiplied by 100. There are several factors which determine the efficiency and some of these will be discussed below.

2.26 It is of interest to mention, in passing, that the efficiency of the earliest implosion weapons wa[redacted] DOE 6(3) (§1.36). This accounts for the fact that devices of the latter type have occupied a secondary place in the development of fission weapons, except for special purposes.

Calculation of Efficiency: Machine Methods

2.27 At the present time, the efficiency or, more correctly, the energy yield of a weapon is determined by machine calculations based on "codes" which have been developed to represent the behavior of the fission chain system. [redacted] DOE 6(3) from initiation up to this time, the material is essentially stationary or is still being compressed and only a small proportion of the total energy has been liberated. The treatment takes into account the neutronic behavior, the hydrodynamics, and heat flow; the motion of a series of concentric shells (or "mass points") is followed until the rate of energy release by fission has fallen almost to zero. The total yield includes the energy released after the system has expanded and become subcritical. Although self-sustaining chain propagation is no longer possible, convergent-chain interaction of the many neutrons and fissile nuclei still present will result in considerable energy production. This may amount to some 30 percent or more of the total yield.

The Bethe-Feynman Formula

2.28 Prior to the development of computing machine procedures, and before data were available from test explosions for comparison and normalization purposes, fission weapon

[redacted] [redacted] UNCLASSIFIED

efficiencies were estimated by the method of Bethe and Feynman. The basic formula is admittedly approximate, since it involves several simplifying assumptions. However, its derivation is useful in the respect that it provides a model of the explosion of a fission weapon and indicates, qualitatively at least, some of the factors which affect the efficiency of the explosion. The treatment given below is applicable to pure fission systems and not after boosting occurs.

2.29 As a result of the energy liberated in fission, very large pressures ($\sim 10^9$ atm) are developed in the core, and the core-tamper interface consequently receives a large outward acceleration. This causes highly compressed tamper material to pile up just ahead of the expanding interface, in an effect referred to as the "snowplow" phenomenon, because of the similarity to the piling up of snow in front of a snowplow. The inertia of the compressed tamper delays expansion of the core, so that a considerable pressure gradient builds up from the center of the core to its outer surface.

2.30 Furthermore, because of the delayed expansion, it may be supposed that the volume of the compressed (supercritical) core remains essentially constant during the first [redacted] so generations following initiation of the fission chain, i.e., up to explosion time. After this interval, almost the whole of the energy is released within an extremely short period, during which time the supercritical core expands rapidly until it becomes subcritical. Although there is an appreciable release of energy even while the system is subcritical, as mentioned in §2.27, it will be postulated that energy production ceases when the dimensions are just critical. It will be assumed, further, that no energy escapes during the short period of expansion from maximum supercriticality to the point where the system becomes subcritical.

2.31 Let R be the radius of a spherical core at the point of maximum supercriticality; then, in accordance with the postulate made above, this will remain unchanged until explosion time. Subsequently, the energy density of the system becomes so large that mechanical effects begin and the core starts to expand. Suppose that when the core has expanded by a fraction δ, so that the radius is $R(1 + \delta)$, the system is just critical (Fig. 2.1); beyond this point it will be subcritical. The self-sustaining fission chain will then end and, in accordance with the approximation postulated above, there will be no further release of energy.

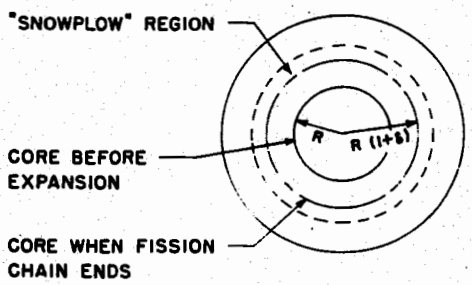

Figure 2.1

2.32 Consider a thin shell of material in the core, of volume dV and thickness dR; the cross sectional area of the shell is then dV/dR. If dP is the pressure difference on the two sides of this shell, caused by the liberated fission energy, the net outward force, dF, to which the shell is subjected, i.e., pressure × area, is then

$$dF = dP \frac{dV}{dR} = \frac{dP}{dR} dV \tag{2.14}$$

where dP/dR is the pressure gradient in the given shell. As a reasonable approximation, it may be supposed that the pressure gradient is essentially constant across the core radius, so that

UNCLASSIFIED

$$\frac{dP}{dR} \approx \frac{P}{R} \tag{2.15}$$

where P is the total difference in pressure from the center of the core to the outer surface before expansion occurs. Hence, from equations (2.14) and (2.15),

$$dF \approx \frac{P}{R} dV \tag{2.16}$$

2.33 The time required for the core to expand from radius R to $R(1 + \delta)$, i.e., a distance of $R\delta$, is about 7 generations, as seen in §2.21. However, as a rough approximation, this may be taken as $1/\alpha$, where α is the multiplication rate just prior to explosion time. The mean outward acceleration of the core material, and of the shell dV, may consequently be expressed as $R\delta\alpha^2$. The mass of the shell is ρdV, where ρ is the core density; hence, by Newton's second law of motion, i.e., force = mass × acceleration, the force dF acting on the shell is given by

$$dF \approx \rho dV \times R\delta\alpha^2$$

Upon comparing this result with equation (2.16), it is seen that

$$P \approx \rho R^2\alpha^2\delta \tag{2.17}$$

2.34 At the existing temperature the core will be gaseous and if, as postulated, the loss of energy from the system during the initial expansion is negligible, it may be considered as a gas undergoing an adiabatic process. The total energy of such a gas, which may be taken to be equal to the energy of the core, is then

$$E = \frac{PV}{\gamma - 1} \tag{2.18}$$

where γ is the ratio of the specific heats of the gas. Using equation (2.17) for P and writing M/ρ for the volume of the core, M being the mass, equation (2.18) becomes

$$E \approx \frac{MR^2\alpha^2\delta}{\gamma - 1} \tag{2.19}$$

2.35 If ϵ is the energy released in the complete fission of unit mass of core material, then the total energy available in the core is $M\epsilon$, and the efficiency, according to equation (2.13), is $E/M\epsilon$, where E is given by equation (2.19); consequently,

$$\phi = \frac{E}{M\epsilon} \approx \frac{R^2\alpha^2\delta}{(\gamma - 1)\epsilon} \tag{2.20}$$

It should be pointed out that in the foregoing derivation no allowance has been made for depletion of the core material as fission proceeds. For low efficiencies, to which most of the other approximations made are applicable, the depletion is not significant and can be neglected. Moreover, no allowance has been made for the inertial effect of the tamper on the efficiency. For the present purpose, which is to obtain a qualitative guide to some of the factors determining the efficiency, this can also be ignored. Hence, replacing the quantity $1/(\gamma - 1)\epsilon$ by a constant, K, equation (2.20) can be written as

$$\phi \approx KR^2\alpha^2\delta \tag{2.21}$$

UNCLASSIFIED

which is a simplified version of the Bethe-Feynman formula. The efficiency of a fission weapon is seen to depend on the factors R, α, and δ.

2.36 Since the efficiency of a fission weapon may be expected to increase as R^2, it would be advantageous for the core to be large at the time of the initiation of the fission chain. One way in which this can be achieved in practice, e.g., in a gun-type weapon, is to bring together subcritical masses which are designed to contain a large total mass of fissile material. Thus, for a given compression or, especially, for no compression, the efficiency would be expected to be greater the larger the mass of the assembled core.

2.37 In general, the most important factor in determining the efficiency of a fission weapon is α; as seen in §2.16, this increases in proportion to the compression. The efficiency, according to equation (2.21), will thus be related, approximately at least, to η^2 (or to $\eta^{1.7}$ if the effect of tamper compression is taken into account). In addition, although of lesser significance, the effect of compression on δ must be taken into account; the more highly compressed the core material at the time of initiation (or at explosion time), the farther will be the distance the core surface must travel during the expansion phase before the supercritical system becomes subcritical. Increased compression should thus result in a marked gain in the efficiency of a fission weapon. It is this fact which is largely responsible for the much higher efficiencies of implosion systems than of gun-type devices.

[redacted] DOE 6(3)

2.38 The effect of increasing compression in a simple (unboosted) implosion system is indicated by the data in Table 2.1 which are based partly on experimental observations and

Table 2.1— EFFECT OF COMPRESSION ON EFFICIENCY

Average Compression		Efficiency
Core	Tamper	(Percent)
[redacted]		

DOE 6(3)

partly on calculation [redacted] DOE 6(3)

The attainment of high compression has been an important objective in fission weapon design. In the earliest (solid-core) devices the improvement in efficiency was the main purpose. In more recent (hollow-core boosted) weapons, however, the principal objective is to make possible the design of compact systems in which both the high explosive (§1.42) and the fissile material have low masses. The number of crits at maximum compression is not large, so that α is relatively small before boosting. The initial efficiency of the fission chain is, therefore, also small but the total yield is greatly increased by the boosting.

INITIATION TIME AND PREINITIATION

Unboosted Implosion Weapons

2.39 The time at which the fission chain is initiated is of importance in determining the efficiency of a weapon [redacted] DOE 6(3)

[redacted] By this time the fissile core would be highly supercritical [redacted] DOE 6(3)

UNCLASSIFIED

[redacted] DOE b(3)

2.40 The avoidance of preinitiation was therefore an important aspect of the design of simple fission weapons. The neutron sources which served as initiators were constructed so as to produce a burst of neutrons as close as possible to the optimum time, and the neutron background from the fissile material was maintained within reasonable bounds. In all-plutonium cores, relatively clean (20 ngs) material was used and dirtier plutonium was employed only in composite cores which contained oralloy in addition, with the latter in excess. Such a utilization of fissile material was desirable in any event, for reasons given in §3.21 et seq.

2.41 The behavior of the solid core in an unboosted implosion weapon is somewhat as follows. [redacted] DOE b(3)

[redacted] At first critical, α is zero and it increases steadily as compression of the core proceeds. Just before maximum compression, when α is approaching its maximum value, neutrons are injected into the highly supercritical system. The divergent fission chain is initiated and energy is released. [redacted] DOE b(3)

[redacted] DOE b(3)

This condition is referred to as "second critical" (Fig. 2.2). Both the neutron density and the rate of the fission reaction are now at a maximum. Beyond second critical, α becomes negative and the neutron density decreases, in accordance with equation (2.6). Although a self-sustaining chain is no longer possible, considerable amounts of energy are produced by the convergent fission chains in the subcritical system.

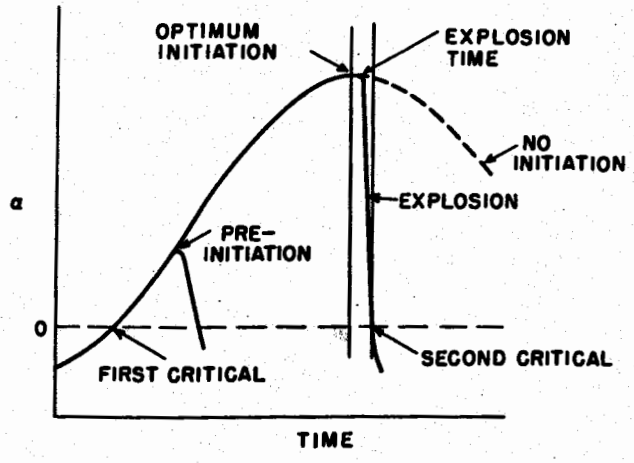

Figure 2.2

Boosted Implosion Systems

2.42 In modern boosted, implosion-type fission weapons, the situation is quite different from that described above. The cores are hollow, subcritical shells which contain the deuterium-tritium boosting gas. [redacted] DOE b(3)

[redacted] UNCLASSIFIED

[redacted] DOE 6(3)

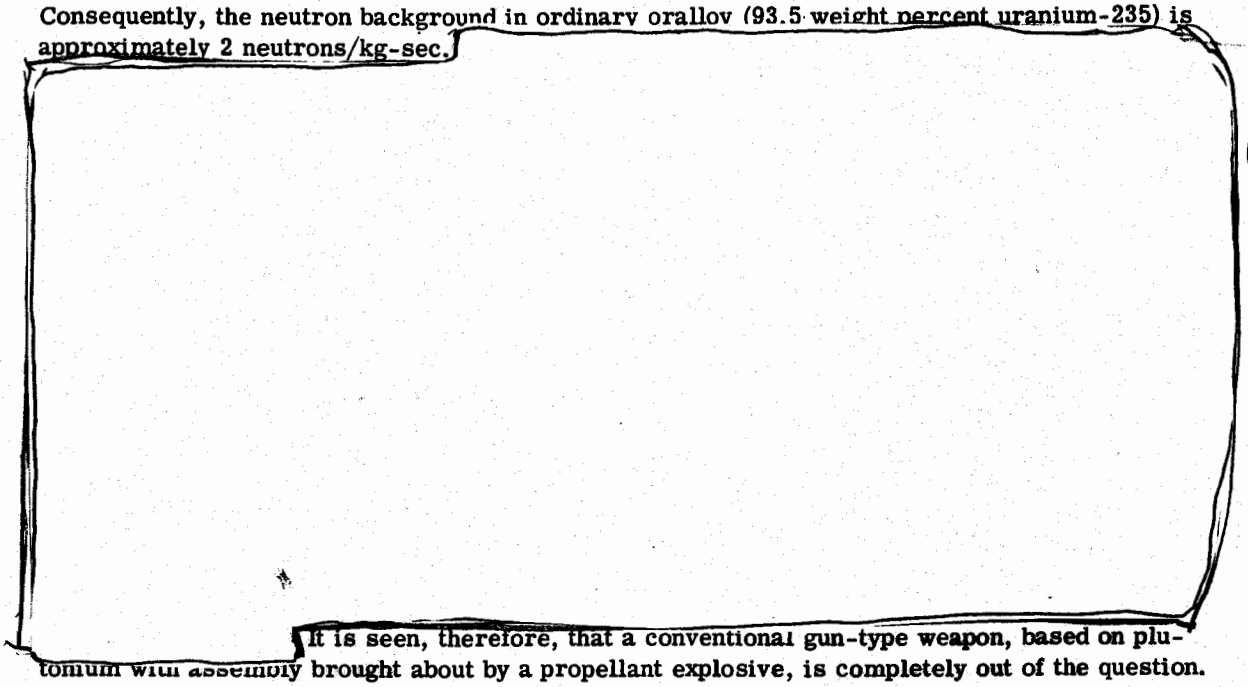
Gun-Type Weapons

2.45 In a gun-type weapon, the lack of compression makes it desirable for initiation to take place at or close to the time when assembly [redacted] DOE 6(3) Consequently, although plutonium-239 with an appreciable proportion of plutonium-240 could be used in implosion systems, even of the solid-core, unboosted type, it is unsuitable for gun-assembly devices, as the calculations given below will show.

2.46 Apart from the possible presence of a "flood" of neutrons, e.g., as the result of the explosion of another nuclear weapon in the vicinity of a given weapon, the chief sources of background neutrons, which could cause preinitiation in a gun-assembly weapon, are spontaneous fission and (α,n) reactions with light elements. In uranium-235 (oralloy) the rate of spontaneous fission is relatively small but (α,n) reactions with light-element impurities could produce an appreciable neutron background. [redacted] DOE 6(3)

2.47 Let P_1 be the probability that a background neutron will be available in the fissile material during the period that it is supercritical, i.e., in the preinitiation period, and let P_2 be the probability that this neutron will be able to start a fission chain. The preinitiation probability, P, is then given by

$$P = 1 - e^{P_1 P_2}$$
$$\approx P_1 P_2 \qquad (2.22)$$



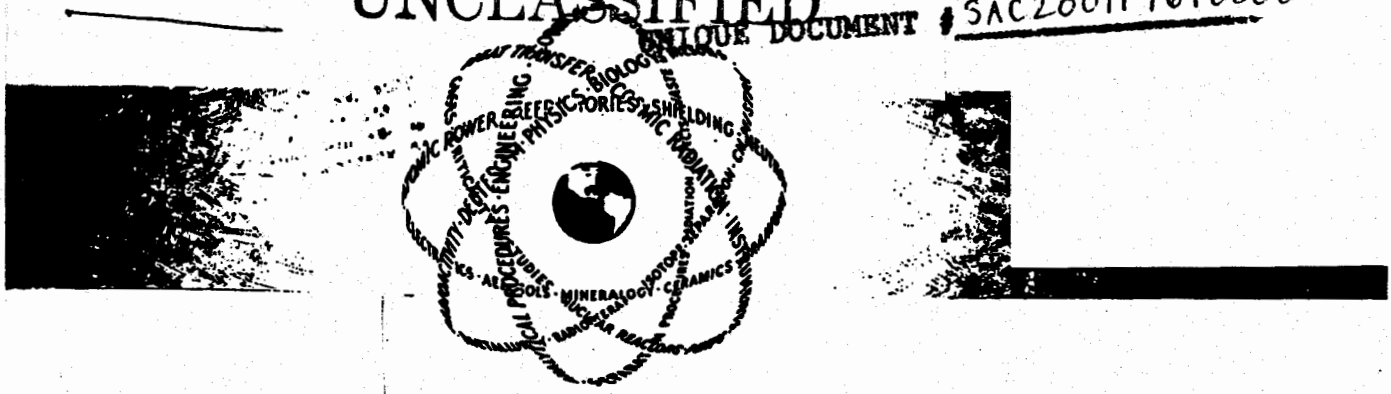
the approximate form being applicable when P_1P_2 is small, as it is in cases of interest. Actually P_2 is a function of time and both P_1 and P_2 depend, to some extent, on the position of the neutron and on other factors. For the present purpose, however, which is to draw general conclusions only, specific values will be assigned to P_1 and P_2. A background neutron entering a fissile assembly may escape altogether without being absorbed, or it may be captured in a nonfission reaction, or it may initiate a fission chain. Although the probabilities of these three processes are by no means equal, it is sufficient to postulate here that P_2 has a constant average value of 0.3 over the preinitiation period. Hence, for the purpose of making rough estimates, equation (2.22) may be written as

$$P \approx 0.3\, P_1 \qquad (2.23)$$

[redacted] DOE 6(3)

[redacted] UNCLASSIFIED

2.48 As a result of spontaneous fission, uranium-235 emits, on the average about 0.85 neutron per kilogram per sec, whereas uranium-238 produces roughly 17 neutrons/kg-sec. Consequently, the neutron background in ordinary orallov (93.5 weight percent uranium-235) is approximately 2 neutrons/kg-sec.



DOE 6(3)

It is seen, therefore, that a conventional gun-type weapon, based on plutonium with assembly brought about by a propellant explosive, is completely out of the question. It was the realization of this fact, when plutonium became available, that led to the development of implosion systems (§1.39).

ACKNOWLEDGMENT

In preparing this report, I have received invaluable assistance from members of the Lawrence Radiation Laboratory (Livermore), Los Alamos Scientific Laboratory, Defense Atomic Support Agency (Headquarters and Field Command), the Sandia Corporation, and the AEC Division of Military Application. Unfortunately, it is not possible to list the names of all those individuals who contributed either by providing information or by reviewing the draft manuscript or both. However, I wish to acknowledge my great indebtedness to them, for without their help this report could not have been produced. My special thanks are due to Lawrence S. Germain for his effective coordination of the contributions from LRL, Livermore.

UNCLASSIFIED

1.33 The procedure described above can be used to determine critical masses for both tamped (reflected) or untamped assemblies. It can also be applied to actual mockups of fission weapons. Some of the components, e.g., fissile substances, are the same as would be used in the weapon, whereas others, e.g., high explosive, would be simulated by other materials with similar neutronic properties.

1.34 Under precisely specified conditions, and for a given core material, there is a definite mass that is just critical; this is called a "crit." The critical masses of spheres of metallic uranium-235 (93.2 weight percent enrichment) and of the alpha- and delta-phases of plutonium-239 for fast-neutron fission are given in Table 1.2. Values are quoted for bare, i.e., untamped spheres, as well as for spheres with tampers of [redacted] beryllium, respectively. The effect of the neutronic tamper in reducing the critical mass is very striking. It will be noted, too, in accordance with remarks made earlier, that the critical mass of delta-plutonium is larger than that of the alpha form, whereas both are smaller than the critical mass of uranium-235.

DOE b(3)

FISSION WEAPONS

Gun Method of Assembly

1.35 As long as a mass of fissile material is less than the critical value for the existing conditions, that is to say, provided the system is subcritical, there is no danger of a divergent, or even a stationary, chain reaction. But, if energy is to be released in a nuclear explosion, the system must be made critical and, in fact, highly supercritical, as will be seen shortly. There are two general ways utilized in weapons whereby a subcritical system of fissile material is rapidly converted into one that is supercritical.

1.36 The first may be referred to as the gun method of assembly. Two portions of material of subcritical size are brought together very rapidly, so that the combined mass is supercritical. If a burst of neutrons is then introduced, a divergent fission chain is initiated and a rapid release of energy occurs in a very short time. This is the principle used in the so-called "gun-type" weapons: one [redacted] The name gun-type originates from the fact that in devices of this kind the two pieces of fissile material, [redacted] are located near opposite ends of a gun barrel.*

DOE b(3)

1.37 Although the gun assembly method for attaining criticality is satisfactory when uranium-235 is the fissile material, it has a serious drawback when plutonium-239 is used. This arises from the presence of the higher isotope, plutonium-240. Because of the way it is produced (§1.53), plutonium-239 is invariably associated with a certain proportion—generally from about 2 to 7 percent—of the higher isotope, plutonium-240. The latter happens to have a high probability for undergoing spontaneous fission, i.e., without the intervention of neutrons. The spontaneous fission rate of plutonium-240 is, in fact, about 440 fissions per second per gram. Since nearly three neutrons are liberated per fission, this means that 1 gram of plutonium-240 emits well over 1000 neutrons per second. [redacted]

DOE b(3)

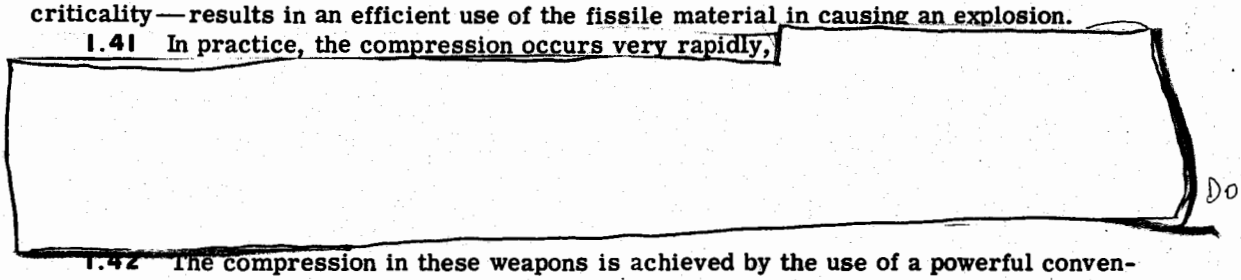
1.38 An efficient use of the fissile material in a simple gun-type weapon requires that the chain reaction be initiated by neutrons only when the assembly has attained its maximum criticality. [redacted] the considerable neutron background, arising from the presence of plutonium-240, may result in initiation of a self-sustaining chain reaction as soon as the assembly becomes just critical. If this occurs, there

E b(3)

*It is purely a coincidence that in most nuclear artillery shells the gun type of assembly is used. [redacted] There is, however, another type of artillery shell which does not employ gun assembly (§4.37).

DOE b(3)

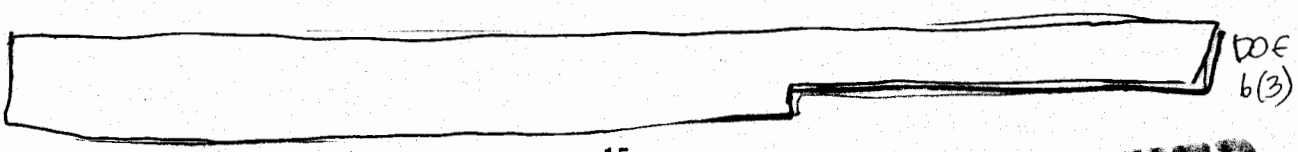
[redacted] UNCLASSIFIED



will be little or no explosion, since the neutron density will not increase rapidly and energy, resulting from fission, will not be produced fast enough; the reasons for such behavior will be apparent later. On the other hand, if uranium-235 is used in a gun-type weapon, the neutron background is very small and there is little probability of premature initiation, or "preinitiation," as it is called, immediately upon the system becoming critical. When maximum supercriticality is attained, neutrons are introduced deliberately from a suitable source to initiate the fission chain reaction. In this way, the optimum efficiency can be realized in the use of the fissile material.

Compression Method (Implosion Weapon)

1.39 Because of the probability of preinitiation, and low efficiency, of a gun-assembly weapon using plutonium-239, an alternative method for attaining criticality (or supercriticality) was developed, based on the compression of the subcritical fissile mass. This procedure turned out to be so successful and gave so much better efficiency that the gun-type of assembly has been utilized only in a relatively few weapons for special purposes, e.g., in artillery-fired shells and in rugged, impact-resistant bombs designed to penetrate some distance into the ground before exploding. Apart from these particular cases, the compression method is invariably used to attain supercriticality in fission weapons.



1.40 The principle of the method is that if a mass of fissile material is compressed, the rate of production of neutrons by fission in the subcritical state is essentially unchanged, since it depends mainly on the number of nuclei present. Actually, there will be some increase in the neutron production in convergent chains. On the other hand, the number of neutrons lost by escape is decreased as a result of compression because of the smaller surface area of the given mass. Consequently, a quantity of material which is subcritical in the normal state can become supercritical when compressed. The introduction of neutrons to initiate the fission chain at (or close to) the time of maximum compression—and, hence, of maximum supercriticality—results in an efficient use of the fissile material in causing an explosion.

1.41 In practice, the compression occurs very rapidly,

1.42 The compression in these weapons is achieved by the use of a powerful conventional (chemical) high explosive which surrounds the core of fissile material. By the use of explosive charges of special design much of the energy of the explosion is directed inward, thereby causing the material in the interior to be compressed in a spherically symmetric manner. It is for this reason that the term "implosion" is applied to weapons of this type.

1.43 An approximate derivation of the relationship between the degree of compression and the critical mass of fissile material is the following. In accordance with the definition given in §1.27, footnote, the total mean free path of a neutron is the average (crow-flight) distance it travels before it interacts in any way with a nucleus. The proportion of neutrons which do not interact but escape from the system may be expected to be determined by the ratio of the dimensions, e.g., the radius of a sphere, to the mean free path. It may be concluded, therefore, that for a given fissile (core) material, under specified conditions, the critical radius should be approximately proportional to the neutron mean free path; thus, if R_c is the critical radius and λ is the mean free path in the material,

UNCLASSIFIED

$$R_c \propto \lambda \tag{1.6}$$

1.44 The greater the probability of the interaction of a neutron with a nucleus, the smaller will be the distance the neutron travels before interacting. Hence, the neutron mean free path is related inversely to its interaction probability. This probability is proportional to the number of fissile nuclei per unit volume, and hence to the density; if ρ is the density of the core material, then

$$\lambda \propto \frac{1}{\rho} \tag{1.7}$$

It follows therefore from equations (1.6) and (1.7) that

$$R_c \propto \frac{1}{\rho} \tag{1.8}$$

1.45 The critical mass, M_c, is equal to the product of the critical volume, which is $\frac{4}{3}\pi R_c^3$, and the density of the fissile material; hence,

$$M_c = \frac{4}{3}\pi R_c^3 \rho$$

Upon substituting equation (1.8) for R_c, it is seen that

$$M_c \propto \frac{1}{\rho^2} \tag{1.9}$$

The density of the material is dependent upon the degree of compression; thus, if η is the compression ratio, i.e., the ratio of the volume before to that after compression, then

$$\rho \propto \eta$$

and substitution in equation (1.9) leads to the result

$$M_c \propto \frac{1}{\eta^2} \tag{1.10}$$

The critical mass of a given fissile material, under specified conditions, is thus inversely proportional to the square of the compression ratio. The proportionality constant is readily derived by writing M_{c0} for the critical mass of the uncompressed material, i.e., when $\eta = 1$. It follows then from equation (1.10) that

$$M_c = \frac{M_{c0}}{\eta^2} \tag{1.11}$$

1.46 An alternative way of stating this result is in terms of the number of crits (or critical masses), C, present in the compressed core. If M is the actual mass of fissile material, the number of crits in the compressed state is defined by

$$C = \frac{M}{M_c}$$

UNCLASSIFIED

Combination with equation (1.11) then yields

$$C = \frac{M\eta^2}{M_{c0}} = C_0\eta^2 \qquad (1.12)$$

where M/M_{c0} has been replaced by C_0, the number of crits before compression.

DOE 6(3)

The introduction of neutrons into this highly supercritical system resulting from compression will cause a very rapidly divergent fission chain reaction to develop. In these circumstances there is very efficient use of the fissile material for the release of energy. It is the high degree of supercriticality (and increased efficiency) attainable by compression that constitutes the great advantage of implosion-type weapons over those of the gun type.

1.47 Strictly speaking, the relationship of the number of crits to the square of the compression holds only for a bare core. For a tamped core, a more correct form of equation (1.12) is

$$C = C_0\eta_c^{1.2}\eta_t^{0.8}$$

where η_c is the compression of the core and η_t is that of the tamper. Since the tamper is generally compressed less than the core, a good approximation for weapons is to write

$$C = C_0\eta_c^{1.7}$$

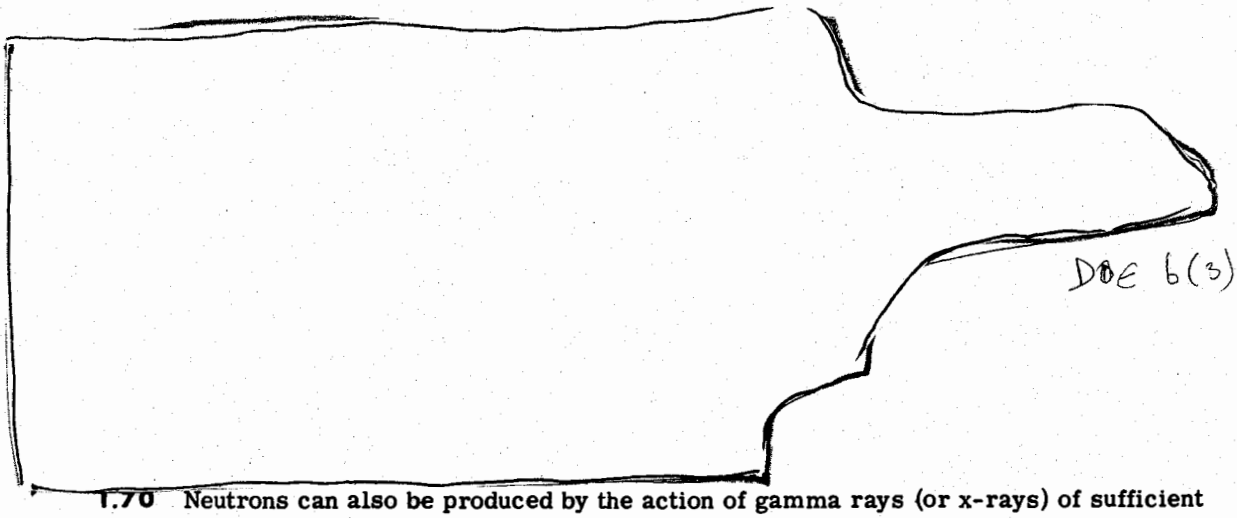
The effect of compression is still substantial, although not as large as is implied by equation (1.12).

Fusion Reactions in Fission Weapons

1.48 It was stated in §1.2 that the large-scale release of energy in weapons is possible by making use of fusion reactions in which two very light nuclei combine (or fuse) together to form particles of greater mass. However, apart from the application of nuclear fusion reactions as a source of energy, described in Chapter 7, certain fusion processes are important in the design of fission weapons for another reason. The significance of these reactions does not lie in the energy released but in the neutrons which are produced. Three fusion reactions, involving the less common isotopes of hydrogen, namely, deuterium (D^2) and tritium (T^3), are of interest in this connection. Two of these reactions are between pairs of deuterium nuclei (deuterons) only, i.e.,

$$_1D^2 + {}_1D^2 \rightarrow {}_0n^1 + {}_2He^3$$

and



$$_1D^2 + {}_1D^2 \rightarrow {}_1H^1 + {}_1T^3$$

which take place at about the same rate, and the third is a much more rapid interaction between a deuteron and a tritium nucleus (triton), i.e.,

$$_1D^2 + {}_1T^3 \rightarrow {}_0n^1 + {}_2He^4$$

1.49 It is seen that when two deuterons interact, a neutron is formed in one case and a triton in the other; the triton then readily reacts with a deuteron to produce another neutron. Both deuteron-deuteron (D-D) and deuteron-triton (D-T) reactions are employed to provide

UNCLASSIFIED

1.70 Neutrons can also be produced by the action of gamma rays (or x-rays) of sufficient energy on various nuclei; these processes are referred to as photoneutron or (γ,n) reactions. Since the average binding energy of a nucleon in a nucleus is about 8 Mev in many cases (Fig. 1.1), a photon of this energy will eject a neutron from most nuclei. This fact was utilized in an experimental device for initiating the fission chain in nuclear weapons (§5.34).

1.71 In the great majority of weapons of recent design the neutrons required for initiation are produced by the fusion reactions described in §1.48. The procedures involve either the D-D or D-T reactions at high temperatures (thermonuclear reactions) or the interaction of accelerated tritons with a deuterium target (electronuclear reactions). The methods used for achieving these processes in weapons are described in Chapter 5.

Production of Deuterium and Tritium

1.72 Deuterium oxide (heavy water) is present to the extent of about one molecule in 6500, i.e., 0.015 mole percent, in ordinary water. In spite of this very small proportion, concentration of the deuterium in water is not too difficult, and heavy water of about 99.75 percent purity, i.e., 99.75 mole percent D_2O, is now produced on a large scale.

1.73 Three main processes are used to separate the two hydrogen isotopes in water; these are (a) isotopic (or chemical) exchange, (b) distillation, and (c) electrolysis. Several isotope exchange processes have been considered but the most satisfactory appears to be one involving reaction between hydrogen sulfide gas and liquid water. The exchange reaction results in a relatively higher proportion of deuterium in the liquid phase than in the gas. By utilizing a countercurrent flow of gas and liquid in several stages, in a system operating at two different temperatures, considerable enrichment in deuterium can be achieved in the liquid.

1.74 The distillation method for separating the isotopes of hydrogen depends on the fact that heavy water (D_2O) has a slightly higher boiling point, i.e., slightly lower vapor pressure, than light water (H_2O). Consequently, a partial separation can be achieved by fractional distillation, preferably under reduced pressure.

1.75 When an acid or alkaline aqueous solution is electrolyzed, the hydrogen gas liberated at the cathode contains relatively more of the lighter isotope (H_2) than does the residual water. By repeated electrolysis in stages, heavy water of a high degree of purity can be obtained.

1.76 Each of the three foregoing procedures has certain advantages under appropriate conditions. Hence, in the production of heavy water in quantity, ordinary water is first partially enriched in deuterium by the isotopic exchange process with hydrogen sulfide. The deuterium is further concentrated by fractional distillation of the enriched water under reduced pressure, and then it is brought up to 99.75 percent purity by electrolysis. Deuterium gas can be released from heavy water by any of the familiar chemical processes used to prepare hydrogen gas. It can then be very simply converted into any compound that may be required, e.g., uranium deuteride (UD_3) or lithium deuteride (LiD), for weapons applications.

UNCLASSIFIED

1.77 The third isotope of hydrogen, i.e., tritium, is a radioactive beta emitter, with a half-life of 12·26 years. It is found in natural waters to an insignificant extent only and the cost of extraction would be prohibitive. Consequently, tritium is produced by nuclear reactions resulting from the exposure of lithium (as a suitable compound) to neutrons in a reactor. The less abundant lithium-6 isotope, present to the extent of 7 atomic percent in natural lithium, readily captures slow neutrons and undergoes the (n,α) reaction

$$_3Li^6 + _0n^1 \rightarrow _2He^4 + _1T^3$$

with the formation of tritium. The more common isotope, lithium-7, reacts with fast neutrons to some extent and this process also leads to the production of tritium; thus,

$$_3Li^7 + _0n^1 \rightarrow _2He^4 + _1T^3 + _0n^1$$

1.78 After irradiation by neutrons for a length of time, the lithium compound is removed from the reactor and the gases, consisting mainly of tritium and helium, with other hydrogen isotopes as impurities, are separated from the residual solid. Purification is achieved by a gaseous diffusion process. Compounds of tritium can be prepared from the gas by reactions similar to those employed for deuterium and ordinary (light) hydrogen.

FOREWORD

While this revision of WASH-1037 and the original issuance have been published as Headquarters, U. S. Atomic Energy Commission documents, they have as their genesis two 1954 Los Alamos Scientific Laboratory reports, LA 1632 and LA 1633, both entitled "Weapons Activities of LASL." We are indebted to LASL for these early reports. Although the previous LA and WASH reports received extensive use as basic handbooks on the principles of nuclear weapons development and technology, they were not to be considered as technical guides for designing weapons. Similarly, this revision of WASH-1037 is not to serve as such a guide.

In the preparation of this document, Dr. Samuel Glasstone has reviewed, coordinated, and edited data provided by members of the Los Alamos Scientific Laboratory, the Lawrence Livermore Laboratory, the Sandia Laboratories, and the Defense Nuclear Agency. The exceptional cooperation of these organizations and the outstanding work of Dr. Glasstone have permitted the Atomic Energy Commission to publish this revision to WASH-1037. Further, we wish to recognize the very significant contributions of Dr. Leslie M. Redman in the preparation of this issuance.

This publication contains highly sensitive nuclear weapon design information of significance to our national defense and security. Viewers are enjoined to ensure its proper security protection at all times.

PREFACE

The overall design of a nuclear weapon is a complex operation involving a cooperative effort among mathematicians, scientists, and engineers in several areas of specialization. In spite of the complexity of these weapons, their design and operation are based on certain fundamental physical principles. One of the purposes of this report is to provide a description of these principles in fairly elementary terms. The mathematical aspects of weapon design have been omitted or oversimplified, since the emphasis here is placed on the physical phenomena rather than on the mathematical techniques used in treating them.

Another objective is to describe how the ideas used in weapons design have changed over the years. The earliest atomic bombs weighed some 8000 pounds and gave an explosive energy yield in the vicinity of 20 kilotons TNT equivalent. [redacted] DOE 6(3)

A semihistorical approach is used to show how such improvements in efficiency have been attained and indications are given of new directions in which further developments appear possible. It will be apparent that advances in weapons design have been continuous in the past and may be expected to be so in the future.

In preparing this report, we have received invaluable assistance from members of the Los Alamos Scientific Laboratory, Lawrence Livermore Laboratory, Sandia Laboratories (Albuquerque and Livermore), the Defense Nuclear Agency (Headquarters and Field Command), and the AEC Division of Military Application. To all the people who helped us by supplying information and/or providing constructive reviews of the draft material, we wish to express our great indebtedness.

energy. The results of estimates based on experimental measurements are given in Table 1.1 of the average

Table 1.1 NEUTRONS RELEASED PER FISSION

Nuclide	Neutron Energy		
	~0 MeV	0.5 MeV	14 MeV
Uranium-235	2.43	2.49	4.1
Plutonium-239	2.80	2.85	4.9
Uranium-233	2.45	2.51	4.2

number, ν, of neutrons produced per fission caused by (*a*) slow neutrons, i.e., neutrons of essentially zero energy, (*b*) neutrons of about 0.5-MeV energy, which is roughly the average energy of the neutrons which maintain the chain in a simple fission weapon, and (*c*) neutrons of 14-MeV energy which contribute greatly to the fission energy of boosted and many two-stage devices (Chapters 6 and 7).

1.13 The neutrons emitted in fission fall into two categories, namely, prompt neutrons and delayed neutrons. The former are all released within something like 10^{-14} sec of the fission process, but the latter continue to be emitted for a few minutes. For uranium-235 fission, the prompt neutrons constitute 99.35 percent of the total fission neutrons and for plutonium-239 they represent about 99.75 percent. Because the time scale in nuclear explosions is very short, delayed neutrons play essentially no part in the fission chain reaction. In reactors for the controlled release of nuclear energy, however, these neutrons are of great significance.

Fission Energy

1.14 The rough estimate made earlier indicated that about 200 MeV of energy are produced per nucleus undergoing fission. More precise calculations, based on nuclear masses, and experimental measurements have shown that this is a good approximation for both uranium-235 and plutonium-239. The atomic mass in grams, i.e., 235 grams of uranium-235, contains 6.02×10^{23} nuclei, and the complete fission of this amount of uranium-235 would yield $6.02 \times 10^{23} \times 200 = 1.20 \times 10^{26}$ MeV or 1.93×10^{20} erg, since 1 MeV is equal to 1.60×10^{-6} erg. Making use of the fact that 1 calorie is equivalent to 4.18×10^{7} ergs, it can be readily shown that complete fission of all the nuclei in 1 kilogram of fissile material would result in a total energy release of 2.0×10^{13} calories.

1.15 Only part of the energy of fission is immediately available in a nuclear explosion, since most of the radioactive decay energy of the fission products is released over a long period of time. It is usually accepted that about 90 percent of the fission energy contributes to the explosion, so that in a weapon the fission of 1 kilogram of material would produce explosive energy of about 1.8×10^{13} calories. The energy liberated in the explosion of 1 ton of TNT is taken to be 10^{9} calories (or 4.18×10^{16} ergs), and so 1 kilogram of fissile (or fissionable) material is equivalent in explosive power to 18,000 tons, i.e., 18 kilotons (or 18 kt) of TNT. From these results it is readily found that complete fission of 0.056 kg (or 56 g) or of 1.45×10^{23} nuclei of fissile material produces the equivalent of 1 kt of TNT of explosive energy. In other words, the energy per fission is about 7.0×10^{-24} kt TNT equivalent.* In stating the energy yields (or, in brief, the yields) of nuclear weapons, the basic unit, for very low yields, is the ton, with the kiloton (or 1,000 tons), i.e., 1 kt, and the megaton (or 1,000,000 tons), i.e., 1 Mt, of TNT equivalent being used for higher yields.

THE FISSION CHAIN REACTION

Condition for Chain Reaction: Critical Size

1.16 The condition for a self-sustaining fission chain reaction is that, on the average, the neutrons released in one act of fission shall cause (at least) one subsequent fission. Since the average number of neutrons produced in an act of fission is greater than two (see Table 1.1), it would appear, at first sight, that a chain reaction in uranium-235 or plutonium-239 would be inevitable. However, this is not so, because an appreciable proportion of the neutrons produced are lost in various ways. In a nuclear fission weapon, for example, an important source of loss is by leakage (or escape) of neutrons from the reacting material. Thus, many neutrons avoid being captured by a fissile nucleus by escaping from the system entirely. Some neutrons are also lost by parasitic capture, i.e., by capture in nonfission reactions of various kinds, either by the fissile species itself or by other nuclides which may be present.

*The energy per fission of uranium-235 is currently taken as 6.793×10^{-24} kt, i.e., 17.4 kt/kg; for plutonium-239 the values are 7.030×10^{-24} kt per fission and 17.7 kt/kg, respectively.

UNCLASSIFIED

1.17 The fraction of neutrons escaping from a system in which fission is occurring can be decreased by increasing the mass, i.e., by increasing the size at constant density of fissile material.* Since neutrons are produced by fission throughout the whole volume, whereas loss by escape takes place only from the exterior surface, it is evident that the escape probability will decrease as the volume-to-area ratio of the system is increased. This can be achieved, for a given geometry (shape), by increasing the dimensions of the fissile material at constant density.

1.18 In a very small mass of fissile material a self-sustaining chain reaction will not be possible under normal circumstances because of the large proportion of neutrons that escape. But as the size is increased (at constant density), the fraction of fission neutrons lost will decrease and ultimately a point is reached when one neutron will be available to carry on the fission chain for every neutron causing fission. The system is then said to be critical, and a self-sustaining chain reaction is just possible. If a system is smaller than the critical size (or mass), it is referred to as subcritical, and if larger, it is supercritical. In the latter case there are more neutrons available for fission at the end of any generation than were captured in fission reactions at the beginning of that generation. It will be seen shortly that the critical size (or mass) is dependent on the nature of the fissile material, its shape, and several other factors. For a given set of conditions, however, the critical size (or mass) has a definite value which can be determined by experiment or can sometimes be calculated.

Convergent, Stationary, and Divergent Chains

1.19 If ν is the average number of neutrons produced in each act of fission, for the existing neutron energy distribution (or neutron spectrum), and l is the number lost by escape and in other ways, e.g., by nonfission capture, then $\nu - l$ is the number of neutrons which can cause further fission; let this be represented by k, called the effective multiplication factor, i.e.,

$$k = \nu - l. \tag{1.4}$$

Thus, for every neutron causing fission in one generation, k neutrons will cause fission in the next generation. Alternatively, k may be defined as the ratio of the number of neutrons in any one generation to the number in the preceding generation. Hence, in accordance with the statements made above, k is less than unity for a subcritical system; in a critical system $k = 1$; and in a supercritical system k is greater than unity.

1.20 Suppose S neutrons are introduced into a mass of fissile material and cause fissions to occur; then kS neutrons will be present in the next generation, k^2S in the third, and so on. Since, for a subcritical system, $k < 1$, it is evident that as g, the number of generations, increases, k^gS will approach zero. In other words, the number of neutrons present will gradually decrease from one generation to the next, because more neutrons are lost in various ways than are being produced by fission. There is, consequently, a convergent or decaying chain which gradually dies out. For a system of critical size, $k = 1$ and then k^gS is always equal to S. The number of neutrons thus remains constant from generation to generation; this is referred to as a stationary chain. Finally, if $k > 1$, as is the case for a supercritical system, k^gS increases steadily. The fission chain is then said to be a divergent or expanding chain.

1.21 In the foregoing discussion no distinction has been made between the prompt and delayed fission neutrons. As stated earlier, however, it is essentially the prompt neutrons only which are significant in fission weapons. The effective critical size (or mass) of a weapon is thus determined by the availability of the prompt neutrons, without regard to those which are delayed. This situation is often described as prompt critical. Since more than 99 percent of fission neutrons are prompt, the neglect of the delayed neutrons has little effect on the value of ν. In other words, the data in Table 1.1 may be taken as being approximately applicable to weapons. Critical masses determined by experiment (§1.29) include the contribution of delayed neutrons, so that the prompt critical mass applicable to weapons is very slightly larger than the value measured in the laboratory. Again, the difference is small, although corrections can be applied if necessary.

Factors Affecting Critical Mass

1.22 The critical size (or mass) of a given fissile material depends on a number of factors, as mentioned earlier. For example, the shape (or geometry) of the system has an influence on criticality because of the variation in the ratio of volume to surface area. As seen in §1.17, this ratio determines the fraction of neutrons lost by leakage from the system. The optimum condition of minimum critical mass is obtained for a

*The reason for specifying constant density of fissile material will be apparent later (§1.40).

UNCLASSIFIED

sphere; this has the largest ratio of volume to area, so that the fraction of neutrons produced which escape from the system is less than for any other shape of the same mass. Thus, the critical mass of a sphere is less than for any other geometrical form of the given material.

[redacted]

DOE 6(3)

1.23 As far as the composition of the material is concerned, it is evident that the presence of impurities will increase the critical mass of the fissile species. Apart from the fact that the impurity may cause a loss of neutrons by parasitic capture, it adds area to the system, which increases the probability of neutron escape, without the compensating production of neutrons by fission in the increased volume. Similar considerations apply to the situation in which a given fissile substance, e.g., plutonium-239, exists in two or more allotropic forms with different densities. The less dense delta form of plutonium metal has a higher critical mass than the more dense alpha form because of the larger surface area for a given mass. The rate of neutron production by fission depends on the mass, i.e., the number of fissile nuclei, but the rate of loss by escape is greater for the delta-plutonium since the area is larger for the same mass.

1.24 The value of ν also affects the critical size. The larger the magnitude of ν, the smaller will be the critical size (or mass) under the same general conditions. If more neutrons are formed per fission, it will be possible to tolerate a somewhat larger loss and yet attain criticality. This is apparent from the fact that the critical condition is that $k = \nu - l = 1$, so that an increase in l can be compensated by an increase in ν. It is because both ν and the fast-neutron fission cross section of plutonium-239 are larger than for uranium-235 that the critical size of the former is less than that of the latter, under equivalent conditions. Since the densities of plutonium and uranium are not greatly different, the same relationship applies to the respective critical masses (see Table 1.2).

1.25 For a specified shape and composition, the size of a critical system can be decreased by surrounding it with a material which scatters some of the escaping neutrons back into the fissile core. By reducing the fraction of neutrons which escape completely, a smaller size (or mass) can become critical (§1.34). Such a scattering material, on account of its function, is sometimes referred to as a neutron reflector or as a neutron tamper.

1.26 In nuclear weapons, the fissile material is surrounded by a tamper or, more specifically, an inertial tamper, the mass of which delays expansion of the exploding material and permits a higher energy yield to be obtained from the system undergoing fission. This inertial tamper also serves as a neutron reflector or neutronic tamper. In some cases, however, the neutronic aspect is more important than the inertial character of the tamper.

1.27 As is to be expected, increasing the thickness of the tamper decreases the escape of neutrons and thus makes possible a smaller critical mass of the core of fissile material. However, it has been shown by calculations and verified experimentally that when the neutronic tamper thickness reaches a certain value, there is little more to be gained by a further increase of thickness (Fig. 1.2). Thus, when the thickness is about two neutron scattering mean free paths, the effectiveness in decreasing the critical mass is within a few percent of that for an infinitely thick tamper.* In natural uranium, which was at one time used as a

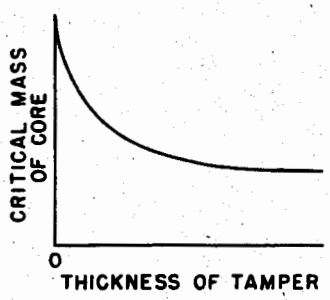

Figure 1.2

tamper, the scattering mean free path of fast (1 MeV) neutrons is about 4 cm, i.e., 1.6 in., in metal of normal density. The value is proportionately less in compressed uranium of higher density. In weapons of low mass, beryllium is a common tamper material; the scattering mean free path is somewhat longer than in uranium because of the lower density.

1.28 Another important factor which affects the critical size is the energy (or speed) of the neutrons causing fission. For several reasons, some of which will be explained later, nuclear weapons are designed so

*The scattering mean free path is the total distance a neutron travels before undergoing a scattering collision with a nucleus in the given tamper material.

[redacted] for fast-neutron fission are given in Table 1.2. Values are quoted for bare, i.e., untamped spheres, as well as for spheres with tampers of [redacted] The name gun-type originates from the fact that in devices of this kind the two pieces of fissile material [redacted] are located near opposite ends of a gun barrel.*

Table 1.2 CRITICAL MASSES OF SPHERES

Fissile Material	^{240}Pu (wt %)	Density (g/cm^3)	Critical mass (kg) Bare	[redacted] U	U	Be	Be
Uranium-235 (93.2 wt %)	-	18.8	52.5				
Plutonium-239 (α)	4.8	19.7	10.5				
Plutonium-239 (δ)*	4.8	15.8	16.6				
Plutonium-239 (δ)*	21	15.8	18.8				

*Contains ~1 wt % gallium

[redacted] beryllium, respectively. The effect of the neutronic tamper in reducing the critical mass is very striking. It will be noted, too, in accordance with remarks made earlier, that the critical mass of delta-plutonium is larger than that of the alpha form, whereas both are smaller than the critical mass of uranium-235.

FISSION WEAPONS

Gun Method of Assembly

1.35 As long as a mass of fissile material is less than the critical value for the existing conditions, that is to say, provided the system is subcritical, there is no danger of a divergent, or even a stationary, chain reaction. But, if energy is to be released in a nuclear explosion, the system must be made critical and, in fact, highly supercritical, as will be seen shortly. There are two general ways utilized in weapons whereby a subcritical system of fissile material is rapidly converted into one that is supercritical.

1.36 The first is generally referred to as the gun method of assembly. Two portions of material of subcritical size are brought together very rapidly, for reasons given below, so that the combined mass is supercritical. If a burst of neutrons is then introduced, a divergent fission chain is initiated and a rapid release of energy occurs in a very short time. This is the principle used in the so-called "gun-type" weapons: [redacted]

1.37 Although the gun assembly method for attaining criticality is satisfactory when uranium-235 is the fissile material, it has a serious drawback when plutonium-239 is used. This arises from the presence of the higher isotope, plutonium-240. Because of the way it is produced (§1.53), plutonium-239 is invariably associated with a certain proportion—generally from about 2 to 7 percent—of the higher isotope, plutonium-240. The latter happens to have a high probability for undergoing spontaneous fission, i.e., without the intervention of neutrons. The spontaneous fission rate of plutonium-240 is, in fact, about 440 fissions per second per gram. Since more than two neutrons are liberated per fission, on the average, this means that 1 gram of plutonium-240 emits over 1000 neutrons per second. [redacted]

1.38 An efficient use of the fissile material in a simple gun-type weapon requires that the chain reaction be initiated by neutrons only when the assembly has attained its maximum criticality. [redacted] the considerable neutron background, arising from the presence of plutonium-240, may result in initiation of a self-sustaining chain reaction as soon as the assembly becomes just critical. If this occurs, there will be little

*It is purely a coincidence that in most nuclear artillery shells the gun type of assembly is used [redacted] There is, however, another type of artillery shell which does not employ gun assembly (§4.23).

or no explosion, since the neutron density will not increase rapidly and energy, resulting from fission, will not be produced fast enough; the reasons for such behavior will be apparent later. On the other hand, uranium-235 has a small neutron background and therefore can be used in a gun-type weapon. If assembled rapidly enough, there is little probability of premature initiation, or "preinitiation," as it is called, immediately upon the system becoming critical. When maximum supercriticality is attained, neutrons are introduced deliberately from a suitable source to initiate the fission chain reaction. In this way, the optimum efficiency can be realized in the use of the fissile material.

Compression Method (Implosion Weapon)

1.39 Because of the probability of preinitiation, and low efficiency, of a gun-assembly weapon using plutonium-239, an alternative method for attaining criticality (or supercriticality) was developed, based on the compression of the subcritical fissile mass. This procedure turned out to be so successful and gave so much better efficiency that the gun type of assembly has been utilized only in a relatively few weapons for special purposes, e.g., in artillery-fired shells and in rugged, impact-resistant bombs designed to penetrate some distance into the ground before exploding. Apart from these particular cases, the compression method is invariably used to attain supercriticality in fission weapons.

1.40 The principle of the method is that if a mass of fissile material is compressed, the rate of production of neutrons by fission in the subcritical state is essentially unchanged, since it depends mainly on the number of nuclei present. Actually, there will be some increase in the neutron production in convergent chains. On the other hand, the number of neutrons lost by escape is decreased as a result of compression because of the smaller surface area of the given mass. Consequently, a quantity of material which is subcritical in the normal state can become supercritical when compressed. The introduction of neutrons to initiate the fission chain at (or close to) the time of maximum compression—and, hence, of maximum supercriticality—results in an efficient use of the fissile material in causing an explosion.

1.41 In practice, the compression occurs very rapidly.

[redacted]

DOE 6(3)

[redacted]

DOE 6(3)

1.42 The compression in these weapons is achieved by the use of a powerful conventional (chemical) high explosive which surrounds the core of fissile material. By the use of explosive charges of special design much of the energy of the explosion is directed inward, thereby causing the material in the interior to be compressed in a spherically symmetric manner. It is for this reason that the term "implosion" is applied to weapons of this type.

1.43 An approximate derivation of the relationship between the degree of compression and the critical mass of fissile material is the following.† The total mean free path of a neutron is the average distance it travels before it interacts in any way with a nucleus. The proportion of neutrons which do not interact but escape from the system may be expected to be determined by the ratio of the dimensions, e.g., the radius of a sphere, to the mean free path. It may be concluded, therefore, that for a given fissile (core) material, under specified conditions, the critical radius should be approximately proportional to the neutron mean free path; thus, if R_c is the critical radius and λ is the mean free path in the material,

$$R_c \propto \lambda. \tag{1.6}$$

1.44 The greater the probability of the interaction of a neutron with a nucleus, the smaller will be the distance the neutron travels before interacting. Hence, the neutron mean free path is related inversely to its interaction probability. This probability is proportional to the number of fissile nuclei per unit volume, and hence to the density; if ρ is the density of the core material, then

$$\lambda \propto \frac{1}{\rho}. \tag{1.7}$$

[redacted]

DOE 6(3)

†The purpose of the discussion in §1.43 through §1.47 is to provide a general basis for understanding the effect of compression on criticality. It is not intended to imply that the methods are currently used. At present, computer calculations, which can take many variables into consideration, are employed to derive criticality conditions. The term "crit" in §1.46 is now more or less obsolete in weapons calculations.

[redacted] UNCLASSIFIED

It follows therefore from equations (1.6) and (1.7) that

$$R_c \propto \frac{1}{\rho}. \tag{1.8}$$

1.45 The critical mass, M_c, is equal to the product of the critical volume, which is $\frac{4}{3}\pi R_c^3$, and the density of the fissile material; hence,

$$M_c = \frac{4}{3}\pi R_c^3 \rho.$$

Upon substituting equation (1.8) for R_c, it is seen that

$$M_c \propto \frac{1}{\rho^2}. \tag{1.9}$$

The density of the material is dependent upon the degree of compression; thus, if η is the compression ratio, i.e., the ratio of the volume before to that after compression, then

$$\rho \propto \eta,$$

and substitution in equation (1.9) leads to the result

$$M_c \propto \frac{1}{\eta^2}. \tag{1.10}$$

The critical mass of a given fissile material, under specified conditions, is thus inversely proportional to the square of the compression ratio. The proportionality constant is readily derived by writing M_{c0} for the critical mass of the uncompressed material, i.e., when $\eta = 1$. It follows then from equation (1.10) that

$$M_c = \frac{M_{c0}}{\eta^2}. \tag{1.11}$$

1.46 An alternative way of stating this result is in terms of the number of "crits" (or critical masses), C, present in the compressed core. If M is the actual mass of fissile material, the number of crits in the compressed state is defined by

$$C = \frac{M}{M_c}.$$

Combination with equation (1.11) then yields

$$C = \frac{M\eta^2}{M_{c0}} = C_0\eta^2, \tag{1.12}$$

where M/M_{c0} has been replaced by C_0, the number of crits before compression.

[redacted] DOE (3)

The introduction of neutrons into this highly supercritical system resulting from compression will cause a very rapidly divergent fission chain reaction to develop. In these circumstances there is very efficient use of the fissile material for the release of energy. It is the high degree of supercriticality (and increased efficiency) attainable by compression that constitutes the great advantage of implosion-type weapons over those of the gun type.

1.47 Strictly speaking, the relationship of the number of crits to the square of the compression holds only for a bare core. For a tamped core, a more correct form of equation (1.12) is

$$C = C_0\eta_c^{1.2}\eta_t^{0.8},$$

where η_c is the compression of the core and η_t is that of the tamper. Since the tamper is generally compressed less than the core, a good approximation for weapons is to write

$$C = C_0\eta_c^{1.7}.$$

The effect of compression is still substantial, although not as large as is implied by equation (1.12).

Fusion Reactions in Fission Weapons

1.48 It was stated in §1.02 that the large-scale release of energy in weapons is possible by making use of fusion reactions in which two very light nuclei combine (or fuse) together to form a nucleus of larger mass. However, apart from the application of nuclear fusion reactions as a source of energy, described in Chapter 7, certain fusion processes are important in the design of fission weapons for another reason. The significance of these reactions does not lie in the energy released but in the neutrons which are produced. Three fusion reactions, involving the less common isotopes of hydrogen, namely, deuterium ($^2_1$H or D) and tritium ($^3_1$H or T), are of interest in this connection. Two of these reactions are between pairs of deuterium nuclei (deuterons) only, i.e.,

$$^2_1\mathrm{H} + {}^2_1\mathrm{H} \rightarrow {}^1_0n + {}^3_2\mathrm{He} \text{ or } \mathrm{D} + \mathrm{D} \rightarrow n + {}^3\mathrm{He}$$

[redacted] UNCLASSIFIED

UNCLASSIFIED

and

$$^{2}_{1}H + ^{2}_{1}H \rightarrow ^{1}_{1}H + ^{3}_{1}H \text{ or } D + D \rightarrow H + T,$$

which take place at about the same rate, and the third is a much more rapid interaction between a deuteron and a tritium nucleus (triton), i.e.,

$$^{2}_{1}H + ^{3}_{1}H \rightarrow ^{1}_{0}n + ^{4}_{2}He \text{ or } D + T \rightarrow n + ^{4}He.$$

1.49 In a mixture of deuterium and tritium, the main reaction is between a deuteron and a triton which results in the formation of a neutron as one of the products. In deuterium alone, a neutron is also a product in one of the deuteron-deuteron (D-D) reactions. In the other D-D reaction, a triton is formed and this readily reacts with a deuteron to produce another neutron. Both deuteron-deuteron (D-D) and deuteron-triton (D-T) reactions are employed to provide neutrons for initiating fission chains. In addition, the high-energy (14 MeV) neutrons liberated in the D-T reaction are used in many fission weapons to achieve what is known as "boosting." Neutrons from the D-T reaction are introduced at a late stage of the fission chain in order to maintain and enhance the progress of the fission reactions. There is a considerable increase in the energy released because of the greatly improved efficiency in utilization of the fissile material. The energy contributed under the circumstances by the D-T fusion reaction is, however, quite small in comparison with that from fission.

PRODUCTION OF WEAPONS MATERIALS

Uranium-235

1.50 The two important fissile materials, namely, uranium-235 and plutonium-239, are both produced from natural uranium but by entirely different procedures. Ordinary uranium contains about 0.7 percent of uranium-235, together with about 99.3 percent of uranium-238 and a trace (0.006 percent) of uranium-234. The proportion of uranium-235 is increased by a process involving diffusion or, more correctly, effusion through porous barriers of the vapor of uranium hexafluoride (UF_6) made from natural uranium. The hexafluoride of the lighter isotope diffuses more rapidly than does that of the heavier species, and by the use of several thousand diffusion stages enrichments of over 90 percent are obtained, i.e., the material produced contains over 90 percent of uranium-235. The most common product for weapons use consists of about 93.2 weight percent uranium-235, the remainder being mainly uranium-238 and a small proportion of uranium-234. This product is commonly known as "oralloy," the two initial letters standing for Oak Ridge, where the material was first made in quantity.*

[redacted] DOE b(3)

1.51 The highly enriched uranium hexafluoride obtained from the gaseous diffusion plant is converted into the tetrafluoride (UF_4) by reduction with hydrogen (mixed with some fluorine). The tetrafluoride, which is a solid with a high melting point (close to 1000°C), is mixed with calcium and heated in a closed steel vessel lined internally with a refractory material. The calcium reduces the uranium tetrafluoride to uranium metal which is separated from the slag of calcium fluoride. Volatile impurities are removed by heating the liquid metal in a vacuum and the resulting product is of a high degree of purity.

1.52 The residual material from the isotope separation (gaseous diffusion) plant consists of uranium hexafluoride which has been depleted in uranium-235. In other words, it contains more than the normal 99.3 percent of uranium-238. This is converted into uranium metal by a procedure similar to that described above. It is referred to as depleted uranium or, in the weapons program, as D-38, because at one time it contained 0.38 percent uranium-235, although greater depletion has been regularly achieved. At one time it was called Q-metal, but this name is not now in common use.

Plutonium-239

1.53 The element plutonium does not occur in nature, except in insignificant traces. Consequently, the plutonium-239 used in weapons is obtained artificially by a series of nuclear reactions resulting from exposure of uranium-238 to slow neutrons in a nuclear reactor. A nuclear reactor is a device in which a fission chain reaction is taking place in a controlled manner, as against the deliberately uncontrolled chain reaction in a weapon. If a material of low mass number, called a

*The "alloy" part of the name originated from the designation Tube Alloys Limited applied to the British wartime atomic energy project. Natural uranium metal was thus called "tuballoy," a term still in common use, and then oralloy was adopted for the material highly enriched in uranium-235.

UNCLASSIFIED

UNCLASSIFIED

moderator, is present, in addition to fissile material, the fission neutrons are slowed down. Such a nuclear reactor is thus a good source of slow neutrons.

1.54 Uranium-238 nuclei capture slow neutrons quite readily to form a higher isotope, uranium-239, with the emission of gamma radiation; thus, the (n,γ) reaction

$$^{238}_{92}\mathrm{U} + ^{1}_{0}n \rightarrow ^{239}_{92}\mathrm{U} + \gamma$$

occurs, where the subscripts give the atomic numbers and the superscripts the mass numbers in each case; the neutron ($^{1}_{0}n$) has a charge (atomic number) of zero and a mass of unity. The uranium-239 produced by neutron capture is radioactive, with a half-life of 23 min, emitting a beta particle. Representing the latter by $^{0}_{-1}\beta$, since it carries a unit negative charge and has essentially no mass, the radioactive decay process may be written as

$$^{239}_{92}\mathrm{U} \rightarrow ^{0}_{-1}\beta + ^{239}_{93}\mathrm{Np},$$

the product being an isotope of mass number 239 of an element of atomic number 93. This element, called neptunium (Nn), is virtually nonexistent in nature.

DOE b(3)

[redacted]

1.55 Neptunium-239 is also radioactive with a half-life of 2.3 days; it emits a beta particle according to the reaction

$$^{239}_{93}\mathrm{Np} \rightarrow ^{0}_{-1}\beta + ^{239}_{94}\mathrm{Pu},$$

so that the product has a mass number of 239 and an atomic number of 94. The name plutonium, symbol Pu, has been given to the element with this atomic number. The isotope plutonium-239 is an alpha-particle emitter with a fairly long half-life—about 24,000 years—so that it is relatively stable. It may be mentioned that the decay product of plutonium-239 is the fissile uranium-235, which has a half-life of about 7×10^8 years. Hence, as far as fission is concerned, plutonium-239 could be stored for thousands of years with only minor deterioration. The little deterioration which does occur arises mainly from the fact that the average number of neutrons, ν, produced by fission of uranium-235 is somewhat less than that from plutonium-239 (§ 1.12).

1.56 For the production of plutonium-239, natural uranium metal is used as the fuel material in a nuclear reactor with graphite (Hanford) or heavy water (Savannah River) as the moderator. The uranium-235 in the fuel sustains the fission chain reaction and produces neutrons, some of which are captured by the uranium-238 with the consequent formation of plutonium-239, as described above. After being in the reactor for an appropriate time, the "spent" fuel is removed, dissolved in nitric acid, and the plutonium is extracted from the solution by the use of certain organic solvents. It is then reextracted into a water medium to give an aqueous solution of the nitrate, from which the plutonium is precipitated either as the peroxide or the oxalate. The solid compound is separated and heated with a mixture of hydrogen fluoride gas and oxygen to obtain plutonium tetrafluoride (PuF_4). The latter is finally reduced to plutonium metal with calcium (plus iodine).

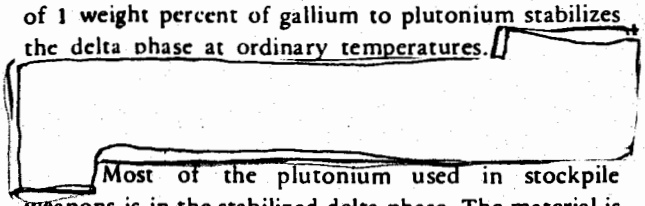
1.57 Metallic plutonium exists in six different allotropic forms between room temperature and the melting point (641°C). The temperature ranges over which the various forms (or phases) are stable are shown in Table 1.3. It is seen that alpha-plutonium, referred to in §§ 1.23 and 1.34, which has a density of about 19.8 g/cm³, is stable at ordinary temperatures. The high density is advantageous from certain weapon standpoints, since it permits attainment of criticality in a smaller mass than is possible with other forms of plutonium (cf. Table 1.2). On the other hand, alpha-plutonium is brittle and difficult to fabricate. Furthermore, the presence of certain impurities tends to stabilize the beta or delta phases to some extent,

Table 1.3 PROPERTIES OF SOLID PHASES OF PLUTONIUM

Phase	Stability range (°C)	Density (g/cm³)
Alpha (α)	Below 115	19.86 (25°C)
Beta (β)	115–~200	17.70 (190°)
Gamma (γ)	~200–310	17.14 (235°)
Delta (δ)	310–458	15.92 (320°)
Delta prime (δ')	458–480	16.0 (465°)
Epsilon (ϵ)	480–641 (m.p.)	16.51 (490°)

[redacted]

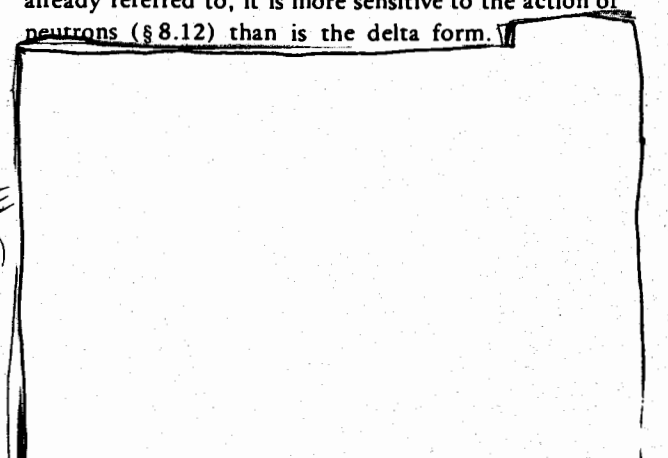
DOE b(3)



parts made of nominal alpha-plutonium are not dimensionally stable. However, if these impurities are avoided, the problem of dimensional instability does not arise at ambient temperatures.

1.58 Although delta-plutonium is normally stable in the temperature range of 310 to 458°C, the addition

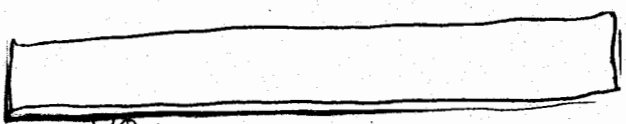
UNCLASSIFIED



[redacted] UNCLASSIFIED

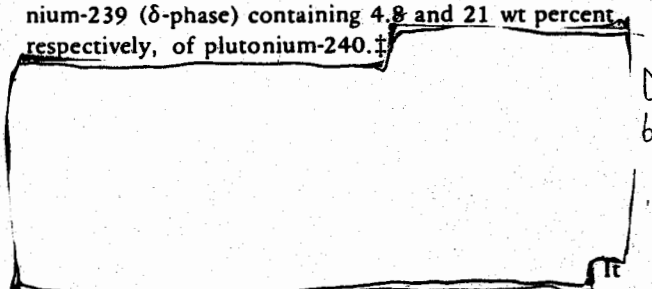
of 1 weight percent of gallium to plutonium stabilizes the delta phase at ordinary temperatures.

Most of the plutonium used in stockpile weapons is in the stabilized delta phase. The material is much less brittle and easier to fabricate than alpha-plutonium; in fact delta-plutonium is said to resemble copper in this respect whereas the alpha-phase is more like cast iron. Delta-plutonium was used in the earliest implosion weapons because it could be fabricated more readily. It offered the additional advantage that its low density permitted the use of a larger mass of subcritical fissile material (Table 1.2), thereby making possible an increase in the total energy yield. This latter aspect of weapons design is, however, no longer significant.



1.59 In order to minimize the critical mass and thus the overall weight of a weapon, it would be desirable to use plutonium of high density. Alpha plutonium has consequently been employed to some extent, but, in addition to the fabrication difficulty already referred to, it is more sensitive to the action of neutrons (§ 8.12) than is the delta form.

Plutonium-240 and -241



1.61 As the plutonium-239 accumulates in the reactor in which it is produced, it also captures neutrons, the rate of capture being proportional to the neutron density (or flux) in the reactor and to the concentration of plutonium-239 nuclei. The reaction which takes place is

$$^{239}_{94}\mathrm{Pu} + {}^{1}_{0}n \rightarrow {}^{240}_{94}\mathrm{Pu} + \gamma,$$

the product being plutonium-240, an alpha emitter of about 6600 years half-life. Because chemical processes are used for the extraction of plutonium from the spent reactor fuel, the two isotopes of this element are not separated from each other. Hence, plutonium-239 is always associated with a certain proportion of plutonium-240. Some of the latter is converted into plutonium-241 by neutron capture, but the amount of plutonium-240 (and plutonium-241) increases with both exposure time and the neutron density (or flux) in the reactor. In a production reactor, the practical limiting proportion of plutonium-240 is about 8 percent (~1 percent plutonium-241); it could go higher than this, as indeed it does in power reactors, but there would be a corresponding (and undesirable) loss of plutonium-239.

1.62 In a simple (unboosted) implosion type weapon, it is desirable that the plutonium-240 content be as small as possible for two reasons: (*a*) the high spontaneous fission rate of plutonium-240 causes a large neutron background (§ 1.37) which can result in the initiation of a fission chain before the optimum time, and (*b*) the fission of plutonium-240 requires neutrons of high energy and, in addition, the ν value is smaller than for plutonium-239 so that it acts, to some extent, as inert diluent.† Consequently, the presence of plutonium-240 increases the critical mass, as may be seen by comparing the values in Table 1.2 for plutonium-239 (δ-phase) containing 4.8 and 21 wt percent, respectively, of plutonium-240.‡

It should be noted that to obtain a product with a small proportion of plutonium-240, the uranium fuel elements can be permitted to remain in the reactor for only a short time before they are removed and processed for the extraction of plutonium. As a result, the smaller the plutonium-240 content, the higher the cost of the material produced.

†Fission of plutonium-240 exhibits an appreciable resonance for neutrons of about 1-eV energy. Otherwise, the cross sections are low except at high neutron energies, above about 0.5 MeV.

‡It is of interest that the critical mass of plutonium containing as much as 35 wt percent of plutonium-240 is still considerably less than that of uranium-235.

[redacted] UNCLASSIFIED

1.63 In evaluating the cost of the plutonium in a weapon, it must be recognized that the higher the plutonium-240 content the smaller the cost per unit mass of plutonium-239, but the larger the mass required for criticality. The actual cost per crit, which is the important criterion, is thus determined by two opposing factors. The weapon cost first decreases and then increases as the proportion of plutonium-240 is increased. However, cost is not the only factor to be taken into account in the choice of weapon material. Other considerations are the effect of plutonium-240 on boosting (Chapter 6) and on "one-point" safety (Chapter 9). Although in principle, fission weapons could be designed to use materials with a much higher content of plutonium-240 (§ 2.72), the plutonium in current use for weapons contains roughly 6 percent of plutonium-240 (see Table 1.5). This is regarded as the best compromise at the present time, although it may be subject to change with circumstances.

1.64 For a production reactor of a given type, the plutonium-240 content of the material produced depends on the neutron density (or reactor power) and the exposure time. Consequently, the quality of plutonium was at one time described in terms of megawatt-days of exposure in the reactor per ton of uranium fuel, i.e., in MWD/T units. This unit is not very precise because the power of a reactor is not uniform throughout its volume; the plutonium-240 content corresponding to a given MWD/T value will often vary with the location of the fuel in the reactor. It also depends upon the characteristics of the production reactor, so that it is different for the Hanford (graphite moderated) and Savannah River (heavy-water moderated) reactor products (see Table 1.4). An alternative method for expressing quality is the number of grams of plutonium per ton of fuel removed for processing, generally indicated by *g*/T; the higher the *g*/T value the greater the plutonium-240 content. Because 1 MWD of reactor energy produces roughly 1 gram of plutonium, the values are approximately equal numerically in *g*/T and MWD/T units.

Table 1.4 CHARACTERISTICS OF PRODUCTION PLUTONIUM

MWD/T			
Hanford	Savannah River	Plutonium-240 (percent)	Neutrons/gram-sec (n/g/s)
800	1375	7.1	75
600	1000	5.6	58
400	630	3.85	40

1.65 The two foregoing methods of indicating the quality of plutonium have now been replaced by the actual statement of the weight percent of plutonium-240. Some of the older fission weapons required plutonium of low plutonium-240 content ("clean" plutonium); the purest material generally used contained about 1.5 percent of plutonium-240.

[redacted]

DOE b(3)

1.66 Another way of expressing the amount of plutonium-240 is based on direct measurement of the rate of neutron emission from the material. These neutrons arise mainly from the spontaneous fission of plutonium-240. The result is expressed as the number of neutrons emitted per gram per second, abbreviated to n/g/s.* The n/g/s value is seen to be approximately 10.5 times the percentage of plutonium-240. The characteristics of three production materials from the Hanford and Savannah River plants with different plutonium-240 contents are given in Table 1.4.

1.67 Continued exposure in a nuclear reactor leads to the conversion of some plutonium-240 into plutonium-241 by neutron capture, as mentioned in § 1.61. Thus, "reactor grade" plutonium, produced in power reactors, may contain 10 percent or more of the latter isotope, together with about 15 percent of plutonium-240. The fission properties, i.e., cross sections and average number of neutrons per fission, of plutonium-241 are similar to those of plutonium-239, and it would consequently be equally effective for weapons purposes. Some consideration has thus been given to the possibility of utilizing reactor grade plutonium for weapons, especially since relatively large amounts of plutonium-240 can be tolerated, if necessary.

1.68 An interesting point in this connection arises from the radioactive beta-decay of plutonium-241 (half-life 13 years) to form americium-241.

[redacted]

DOE b(3)

*The incorrect abbreviation "ngs" is often used in the weapons literature.

DOE b(3)

If the plutonium were to be used in the alpha phase, however, the presence of a relatively large proportion of plutonium-241, which would decay to americium-241, could lead to a phase change to the delta form. The accompanying decrease in density would then result in dimensional instabilities. To test this point, a sample of alpha-plutonium containing 12.3 percent of plutonium-241 has been under observation since February 1964. A decrease in density from 19 to about 17.8 g/cm^3 occurred between 56 and 64 months, when the americium content was roughly 2.7 weight percent, but x-ray examination showed that the material still consisted entirely of the alpha phase. The significance of the results is uncertain and the observations are being continued.

Composition of Weapons Plutonium

1.69 In addition to plutonium-239 and -240, which are the main components, weapons-grade plutonium contains small quantities of isotopes of both higher and lower mass numbers. These are produced in a reactor by various neutron reactions either $(n,2n)$ or (n,γ). The average isotopic compositions of plutonium from Hanford and Savannah River plants reported in June 1968 are quoted in Table 1.5; these may be regarded as typical of current production.

Table 1.5 COMPOSITION OF WEAPONS-GRADE PLUTONIUM IN WEIGHT PERCENT

	Hanford	Savannah River
Plutonium-238	<0.05	<0.05
Plutonium-239	93.17	92.99
Plutonium-240	6.28	6.13
Plutonium-241	0.54	0.86
Plutonium-242	<0.05	<0.05

Possible Weapons Materials

1.70 Several fissile nuclides, with atomic number exceeding 94, are known, but they are of no practical value for weapons purposes because of their short half-lives. A region of stability has been predicted, theoretically, however, for very heavy species in the vicinity of those having "magic numbers" of both protons and neutrons, e.g., 114 protons and 184 neutrons, i.e., $^{298}_{114}$X, and 126 protons and 184 neutrons, i.e., $^{310}_{126}$X. Such nuclides might have half-lives up to 10^6 to 10^8 years, and would be expected to be capable of sustaining a fission chain with neutrons.

DOE b(3)

DOE b(3)

Production of Neutrons

1.73 In a fission weapon, the chain reaction is initiated by the introduction of neutrons into a critical or supercritical system. Consequently, the general methods for producing neutrons in weapons will be reviewed here. One of the simplest procedures for obtaining neutrons is by the action of alpha particles on certain light elements, notably beryllium; processes of this kind are referred to as (α,n) reactions. Recalling that the alpha particle is actually a helium nucleus, the reaction is represented by

$$^4_2\mathrm{He} + ^9_4\mathrm{Be} \rightarrow ^{12}_6\mathrm{C} + ^1_0n.$$

1.74 A convenient source of alpha particles, which was used extensively at one time in fission weapons, is

[redacted] UNCLASSIFIED

the radioelement polonium-210. This isotope has certain advantages, associated with corresponding drawbacks. It does not emit gamma rays, so that there is no neutron production by the (γ,n) reaction which might otherwise occur even when the polonium-210 and beryllium are separated in such a manner as to prevent access of alpha particles to the latter. Moreover, the polonium-210 is easy to produce by exposure of ordinary bismuth to neutrons in a nuclear reactor, when the (n,γ) reaction

$$^{209}_{83}\text{Bi} + ^{1}_{0}n \rightarrow ^{210}_{83}\text{Bi} + \gamma$$

takes place. The bismuth-210 is a beta emitter with a half-life of 5 days, so that it soon decays to form polonium-210; thus,

$$^{210}_{83}\text{Bi} \rightarrow ^{0}_{-1}\beta + ^{210}_{84}\text{Po}.$$

However, the production of polonium-210 in this manner means that fewer neutrons are available for the conversion of uranium-238 into plutonium-239.

1.75 As a result of the moderately short half-life of polonium-210—138.4 days—it emits alpha particles rapidly and a small quantity can thus provide a strong neutron source in conjunction with beryllium. But the short half-life is also a serious disadvantage, because the activity falls off relatively rapidly. In one year, the alpha activity, and hence the rate of neutron production, will have decreased to 18 percent and in two years to 2.6 percent of its initial value.

[redacted]

DOE 6(3)

[redacted]

DOE 6(3)

1.79 Neutrons can also be produced by the action of gamma rays (or x rays) of sufficient energy on various nuclei; these processes are referred to as photoneutron or (γ,n) reactions. Since the average binding energy of a nucleon in a nucleus is about 8 MeV in many cases (Fig. 1.1), a photon of this energy will eject a neutron from most nuclei. This fact was utilized in an experimental device for initiating the fission chain in nuclear weapons (§ 5.25).

[redacted]

DOE 6(3)

[redacted] UNCLASSIFIED

1.80 In the great majority of weapons of recent design the neutrons required for initiation are produced by the fusion reactions described in § 1.48. The procedures involve either the D-D or D-T reactions at high temperatures (thermonuclear reactions) or the interaction of accelerated tritons with a deuterium target (electronuclear reactions). The methods used for achieving these processes in weapons are described in Chapter 5.

Production of Deuterium and Tritium

1.81 Deuterium (in the form of the mixed oxide, HDO) is present to the extent of about one atom to 6500 atoms of hydrogen, i.e., 0.015 atom percent, in ordinary water. In spite of this very small proportion, concentration of the deuterium in water is not too difficult, and heavy water of about 99.75 percent purity, i.e., 99.75 mole percent D_2O, is now produced on a large scale.

1.82 Three main processes are used to separate the two hydrogen isotopes in water; these are (*a*) isotopic (or chemical) exchange, (*b*) distillation, and (*c*) electrolysis. Several isotope exchange processes have been considered but the most satisfactory appears to be one involving reaction between hydrogen sulfide gas and liquid water. The exchange reaction results in a relatively higher proportion of deuterium in the liquid phase than in the gas. By utilizing a countercurrent flow of gas and liquid in several stages, in a system operating at two different temperatures, considerable enrichment in deuterium can be achieved in the liquid.

1.83 The distillation method for separating the isotopes of hydrogen depends on the fact that heavy water (D_2O) has a slightly higher boiling point, i.e., slightly lower vapor pressure, than light water (H_2O). Consequently, a partial separation can be achieved by fractional distillation, preferably under reduced pressure.

1.84 When an acid or alkaline aqueous solution is electrolyzed, the hydrogen gas liberated at the cathode contains relatively more of the lighter isotope (H_2) than does the residual water. By repeated electrolysis in stages, heavy water of a high degree of purity can be obtained.

1.85 Each of the three foregoing procedures has certain advantages under appropriate conditions. Hence, in the production of heavy water in quantity, ordinary water is first partially enriched in deuterium by the isotopic exchange process with hydrogen sulfide. The deuterium is further concentrated by fractional distillation of the enriched water under reduced pressure, and then it is brought up to 99.75 percent purity by electrolysis. Deuterium gas can be released from heavy water by any of the familiar chemical processes used to prepare hydrogen gas. It can then be very simply converted into any compound that may be required, e.g., uranium deuteride (UD_3), lithium deuteride (LiD), etc., for weapons applications.

1.86 The third isotope of hydrogen, i.e., tritium, is a radioactive beta emitter, with a half-life of 12.33 years. It is found in natural waters to an insignificant extent only and the cost of extraction would be prohibitive. Consequently, tritium is produced by nuclear reactions resulting from the exposure of lithium (as a suitable compound) to neutrons in a reactor. The less abundant lithium-6 isotope, present to the extent of 7 atomic percent in natural lithium, readily captures slow neutrons and undergoes the (n,α) reaction

$$^{6}_{3}\mathrm{Li} + {}^{1}_{0}n \rightarrow {}^{4}_{2}\mathrm{He} + {}^{3}_{1}\mathrm{H}\ (\text{or T})$$

with the formation of tritium. The more common isotope, lithium-7, reacts with fast neutrons to some extent and this process also leads to the production of tritium; thus,

$$^{7}_{3}\mathrm{Li} + {}^{1}_{0}n \rightarrow {}^{4}_{2}\mathrm{He} + {}^{3}_{1}\mathrm{H}\ (\text{or T}) + {}^{1}_{0}n.$$

1.87 After irradiation by neutrons for a length of time, the lithium compound is removed from the reactor and the gases, consisting mainly of tritium and helium, with other hydrogen isotopes as impurities, are separated from the residual solid. Purification is achieved by a gaseous diffusion process. Compounds of tritium can be prepared from the gas by reactions similar to those employed for deuterium and ordinary (light) hydrogen.

Enrichment of Lithium

1.88 For the production of tritium, described above, it is not necessary to separate the lithium-6 from the more abundant lithium-7. Natural lithium is consequently used for this purpose. For certain applications, e.g., in some thermonuclear weapons, however, it is required that the lithium, which is employed as a hydride,* be enriched in the lighter isotope. Such material, with a lithium-6 enrichment of up to 90 percent, is produced by the counter current flow of

*Used generically, the term hydride refers to a binary compound containing any of the isotopes of hydrogen.

UNCLASSIFIED

lithium amalgam, Li(Hg), and an aqueous solution of lithium hydroxide, Li^+OH^-, in a cascade of packed columns. The amalgam is obtained by the electrolysis of lithium hydroxide solution using a mercury cathode.

1.89 The lighter isotope is concentrated in the amalgam by the exchange reaction

$$^7Li(Hg) + {}^6Li^+ \rightleftharpoons {}^7Li^+ + {}^6Li(Hg),$$

and is recovered by decomposing the amalgam with pure water in the presence of a graphite catalyst, i.e.,

$$^6Li(Hg) + H_2O = {}^6LiOH + Hg + \tfrac{1}{2}H_2.$$

A portion of the resulting (enriched) lithium hydroxide is drawn off as the product and the remainder is refluxed to the cascade. The recovered mercury is returned to the amalgam maker at the head of the cascade.

1.90 The hydroxide enriched in lithium-6 is neutralized with hydrochloric acid; the resulting aqueous solution of lithium chloride is concentrated by evaporation and the salt is allowed to crystallize. Lithium metal is then obtained by electrolysis of the molten lithium chloride. For the production of various lithium hydrides enriched in ^6Li, the metal is reacted at a suitable temperature with the appropriate isotope of hydrogen under pressure.

UNCLASSIFIED

Chapter 2

THE FISSION PROCESS IN WEAPONS

INCREASE OF NEUTRON POPULATION

The Multiplication Rate: Alpha

2.01 No matter how it originates, an explosion is associated with the very rapid liberation of a large amount of energy within a restricted space. If the energy is to be produced by fission, then an essential condition for explosion is a very high neutron density, since the rate of fission, and hence the rate of energy release, is proportional to the number of free neutrons per unit volume. It is of interest, therefore, to examine the factors which lead to a high neutron density, since these will form a basis for fission weapon design.

2.02 In accordance with the definition of the effective multiplication factor, k, given in § 1.19, it follows that for every n neutrons present at the beginning of a generation there will be nk neutrons at the beginning of the next generation, so that the gain of neutrons is $n(k-1)$ per generation. The rate of gain, dn/dt, may then be obtained upon dividing the actual gain by the average time, τ, between successive fission generations; hence,

$$\frac{dn}{dt} = \frac{n(k-1)}{\tau}. \tag{2.1}$$

Equation (2.1) will be strictly correct only if delayed neutrons play no part in maintaining the fission chain. As already stated (§ 1.13), this condition is applicable, to a good approximation, to nuclear fission weapons.

2.03 The quantity $k-1$, which is the excess number of available neutrons per fission, may be represented by x, i.e.,

$$x \equiv k-1, \tag{2.2}$$

and then equation (2.1) becomes

$$\frac{dn}{dt} = \frac{x}{\tau} n. \tag{2.3}$$

The time rate of increase (or decrease) in neutron population can be expressed in the general form

$$\frac{dn}{dt} = \alpha n, \tag{2.4}$$

where α is the specific rate constant for the process which is responsible for the change in the number of neutrons. In nuclear weapons work this constant is called the multiplication rate or merely "alpha." Comparison of equations (2.3) and (2.4) shows that for a fission chain reaction

$$\alpha = \frac{x}{\tau}. \tag{2.5}$$

Since τ is the time per fission generation and x is a number (per fission), the units of α are generations per unit time or generations/time.

2.04 The foregoing results are applicable regardless of whether x, and hence α, is positive, zero, or negative. For a subcritical system, $k < 1$ (§ 1.20), i.e., $k-1$ is negative; in these circumstances x is negative and so also is α. It follows from equation (2.4) that dn/dt is then negative and the number of neutrons in the system will decrease with time. Consequently, in agreement with previous conclusions, the fission chain in a subcritical system will eventually die out because of the steady decrease in the neutron population. When the system is just critical, $k = 1$, and x and α are both zero; the number of neutrons will thus remain constant. Finally, for a supercritical system, $k > 1$, and x and α are positive; there will then be a steady increase in the neutron population. Since dn/dt is proportional to n, by equation (2.4), it is evident that in a supercritical system, the number of neutrons will grow at increasingly faster rates as n increases.

2.05 Another aspect of the significance of α becomes apparent when equation (2.4) is written in the form

[redacted] UNCLASSIFIED

$$\frac{dn}{n} = \alpha\, dt.$$

If α is assumed to remain constant, an acceptable assumption for a simple fission device somewhat before explosion, this expression can be readily integrated between the time limits of zero, when the number of neutrons present is n_0, and t, when the number is n. The result is

$$n = n_0 e^{\alpha t}, \qquad (2.6)$$

where, as usual, e is the base of natural logarithms. This expression, like those given above, is applicable regardless of whether α is positive, zero, or negative. If α is known, equation (2.6) can be used to calculate the neutron population at any time t relative to the value at any arbitrary zero time. It can also be seen from equation (2.6) that $1/\alpha$ is the time period during which the number of neutrons changes by a factor e; consequently, $1/\alpha$ is often referred to as the e-folding time, i.e., the time in which there is an e-fold change in the neutron population.*

Measurement of Alpha

2.06 The value of α is a highly important quantity in weapons design, as will shortly be apparent. It is generally obtained from a computer calculation based on the neutronic and hydrodynamic characteristics of the system, but there are uncertainties involved and experimental measurements are desirable. In weapons tests, the alpha measurement is one of the most important diagnostic requirements. Calculations are then normalized to agree with the observed values for each type of implosion system.

2.07 The determination of α involves the measurement of the time variation of the neutron population in the exploding system during a period of a microsecond or less. It follows from equation (2.6) that if $\log n$ is plotted against time, the slope of the curve will give α. The quantity measured is not n, the actual neutron population, but some parameter which is proportional to it. Because the number of neutrons emitted per fission varies, the relationship between the total number of neutrons and the total fissions is statistical rather than exact. More important is the fact that, since some neutrons are lost by nonfission captures and by escape, not all the fission neutrons are available for causing fissions in the next generation. However, at any given instant, the fission rate is proportional to n at that instant, and so the time variation of any quantity proportional to the fission rate can be used to determine α. A convenient quantity of this kind which lends itself to ready measurement is the gamma-ray flux emitted from the exploding weapon.

2.08 One method for determining α is to place a number of gamma-ray scintillation detectors fairly close to the device to be exploded. These detectors are connected by coaxial cables to oscilloscopes located at some distance. When the explosion occurs the detectors will respond to the gamma-ray flux in their vicinity and will send appropriate signals to the oscilloscopes before being destroyed by the explosion. Instead of the gamma-ray flux, the neutrons escaping from the system have sometimes been used to determine α. The rate of escape may be regarded as being proportional to the neutron population in the weapon undergoing fission.

2.09 During the design phase of a weapon, α is computed theoretically and laboratory experiments, which do not involve nuclear explosions, are used to provide normalization points for the calculations. Since a supercritical (or even a critical) mass cannot be handled safely under ordinary conditions, experimental measurements of α are made with a mass that is slightly subcritical. In the Rossi method, a single neutron is introduced at intervals into a slightly subcritical system. One (effective) neutron starts a fission chain which soon dies out; then another neutron starts a second chain which dies out, and so on for the duration of the experiment. The counters are thus exposed over an appreciable period to neutrons from a large number of chains one at a time, and so the method is statistical in character. The neutron counting is carried out by means of a multichannel time-delay circuit. The first channel is activated by entry of a neutron; then, after a pre-determined interval, a second channel is activated for a short time; after a further interval, a third channel is activated, and so on for intervals ranging from 0.25 μsec to a total of a few milliseconds. From the accumulated counts for the various channels, the time rate of decay of the prompt neutrons after fission can be determined and α calculated from equation (2.6).

2.10 The values of α obtained as described above apply to the particular subcritical system used. In order to estimate what α would be in a supercritical

*It will be shown in §2.16 that x is about 1, so that $\alpha \approx 1/\tau$ by equation (2.5); hence, $1/\alpha$ is approximately equal to the generation time. The neutron population thus changes by about a factor of e (= 2.72) in each generation.

[redacted] UNCLASSIFIED

UNCLASSIFIED

(weapon) assembly of the same materials, an extrapolation procedure can be employed. By means of a number of measurements with different assemblies, α can be determined as a function of the number of (prompt) crits present. The values could then be extrapolated to give α for the number of crits expected at the time of initiation of the weapon. Such a procedure is highly uncertain since it involves extrapolation from a series of assemblies which are slightly subcritical to one which is highly supercritical. As previously noted, detailed machine calculations, normalized to experimental results, are currently used to estimate α values.

Conditions for Nuclear Explosion

2.11 It was pointed out in § 2.01 that the essential condition for a nuclear fission explosion is a very high density of free neutrons. Equation (2.6) shows that if a large density n is to be attained within a short time, α must be large. In general, the magnitude of α determines the efficiency of a nuclear explosion, and it is of interest to consider how α may be made as large as possible.

2.12 According to equation (1.4), k is equal to $\nu-l$, where ν is the average number of neutrons produced in each act of fission and l is the average number lost per fission by escape and in other ways. Upon utilizing this result, together with equations (2.2) and (2.5), it follows that

$$\alpha = \frac{x}{\tau} = \frac{\nu-l-1}{\tau}. \qquad (2.7)$$

In order to increase α it is consequently necessary that $\nu-l-1$ be large and τ be small. The value of ν is a specific property of the fissile material for fission by neutrons of a given energy. Since ν increases with neutron energy, it would appear to be advantageous from this standpoint if most of the fissions in a weapon were caused by fast neutrons. The relative neutron loss, l, can be decreased, e.g., by assembly or compression or by using a neutron tamper. If the volume increases, the loss of neutrons per fission increases and α will decrease accordingly.

2.13 A highly significant contribution to the magnitude of α is made by the fission generation time, τ. This is approximately equal to λ, the fission mean free path of the neutrons in the core material, divided by the (average) speed, v, of the neutrons causing fission, i.e.,

$$\tau \approx \frac{\lambda}{v}, \qquad (2.8)$$

so that in a fission weapon it is desirable that the ratio λ/v be as small as possible. It should be noted that the fission mean free path in equation (2.8) is not the same as the total mean free path for all interactions used in § 1.43. The λ employed here is the average distance a neutron travels before it is captured in a fission reaction.

2.14 The fission mean free path is equal to $1/N\sigma_f$, where N is the number of fissile nuclei per cm^3 and σ_f is the fission cross section.* Hence, from equation (2.8),

$$\tau \approx \frac{1}{N\sigma_f v}, \qquad (2.9)$$

and the generation time is inversely proportional to the product $\sigma_f v$. The value of σ_f decreases as v increases but the product is $\sim 2 \times 10^9$ (in 10^{-24} cm^3/sec units) for fast neutrons of 1-MeV energy compared with 10^8 for slow neutrons. Hence, the fission generation time is appreciably shorter for fast than for slow neutrons.

2.15 From the information already given, it is possible to make rough, order-of-magnitude estimates of τ and α. For uncompressed uranium-235 or plutonium-239, the number, N, of nuclei per cm^3 is approximately 0.5×10^{23} and, as stated above, $\sigma_f v$ for fast-neutron fission is $2 \times 10^9 \times 10^{-24} = 2 \times 10^{-15}$ cm^3/sec. Hence, from equation (2.9),

$$\tau \approx 1/(0.5 \times 10^{23})(2 \times 10^{-15}) \approx 10^{-8} \text{ sec.}$$

The generation time for fast neutrons in a fission weapon is thus roughly 10^{-8} sec, i.e., 1 shake, or 0.01 microsecond, i.e., 0.01 μsec.

2.16 As seen from Table 1.1, ν is about 2.5 to 3, and the loss, l, of neutrons per fission may be taken to be 0.5 to 1. Hence, by equation (2.2), the value of x is close to unity for a highly supercritical system. It follows, therefore, from equation (2.7) that

$$\alpha \approx \frac{1}{\tau} \approx 10^8 \text{ gen/sec (or } 10^8 \text{ gen sec}^{-1}\text{).}$$

*For the present purpose it is sufficient to regard the cross section as the effective area in sq cm of a nucleus for a particular reaction (or reactions). Cross sections vary with the neutron energy and the fission cross sections for uranium-235 and plutonium-239 have been measured over a large energy range.

UNCLASSIFIED

Thus, for fast-neutron fission α is approximately 10^8 gen/sec.

2.17 Values of α are commonly expressed either in generations per shake, i.e., gen/shake, or per microsecond, i.e., gen/μsec. The rough calculations made above indicate that, in a weapon, α is of the order of 1 generation per shake or 100 generations per μsec. Experimental measurements, both in the laboratory and at weapons tests, show that this is indeed the case.

2.18 It is evident that in order to achieve an efficient nuclear explosion, fission should be brought about by fast neutrons, as far as possible. For such neutrons, the factors ν and τ, and to some extent l, favor a high value of α and, hence, a rapid increase in the neutron population. It would appear desirable, therefore, to keep elements of low mass number, which slow down neutrons more effectively than heavier ones, out of the core, in particular, as well as the reflector of a fission weapon. At one time, special precautions were taken to do so, but in recent years the element beryllium, mass number 9, has been widely used as a reflector material in small weapons because of its satisfactory neutronic properties (see Table 1.2) and low mass.

2.19 According to equation (2.9), the fission generation time for neutrons of a given energy (or velocity) is inversely proportional to the number, N, of fissile nuclei per cm^3. It follows, therefore, that τ is inversely proportional to η, the core compression ratio; thus

$$\tau \propto \frac{1}{\eta}. \qquad (2.10)$$

Consequently, the generation time can be decreased, and the value of α increased proportionately, by compression of the core material.

2.20 In addition to the effect on τ, compression also causes a marked decrease in l for the reason given in § 1.40. This also contributes to an increase in α, as follows from equation (2.7). It is seen, therefore, that compression of the core will cause an increase in α because of the decrease in both τ and l.

Explosion Time

2.21 Suppose that a slightly subcritical mass of fissile material is compressed, as in an implosion device. The system will pass through a critical configuration, referred to as "first critical," and then become increasingly supercritical. After reaching a stage of optimum (or maximum) supercriticality, corresponding to optimum assembly or maximum compression, the system would subsequently become less and less supercritical. If a fission chain is initiated by the introduction of neutrons, the variation of α with time would be qualitatively as indicated in Fig. 2.1.

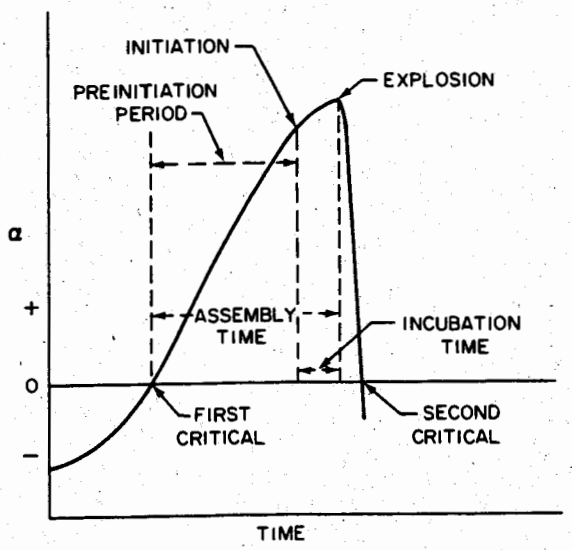


Figure 2.1

2.22 If a divergent chain reaction, leading to an explosion, is to be established in the system, at least one neutron must be present while the system is supercritical, i.e., after first critical. For maximum efficiency, the explosion should occur as close as possible to maximum supercriticality and the neutrons should be introduced at an appropriate earlier time. For the present general discussion, it will be assumed that the fission chain is initiated before optimum supercriticality, as is the usual situation for implosion systems.

2.23 Once the fission chain has been started, energy release will commence. The motion of the fissile material in the assembly process will not be affected significantly, however, until the energy generated by fission produces appreciable mechanical forces. After a certain time, the increase of temperature accompanying the release of the fission energy will generate expansion pressures high enough to stop the motion of the assembly, and subsequently disassembly will begin. The point at which assembly ceases and disassembly commences is known as the "explosion time." The interval between initiation of the fission chain by a neutron and explosion time is referred to as the

"incubation time" (Fig. 2.1). The time between first critical and explosion (or maximum supercriticality) is here called the "assembly time."*

2.24 Because of the rapid increase in the neutron population during the propagation of the fission chain reaction, the fission energy is released at a very high rate. The heat generated causes the temperature to increase and the fissile material expands (or disassembles) rapidly. Soon the volume becomes so large that the system becomes subcritical and the divergent chain reaction ceases. The point at which the material passes through the critical stage during expansion is called "second critical" (§ 2.59).

2.25 The number of fission generations corresponding to the explosion time for a spherical (imploded) core can be calculated in a semiquantitative way in the following manner.† If the reasonable assumption is made that the pressure in the assembly has a parabolic distribution, then the pressure P at a distance r from the center of the core of radius R is

$$P = P_0\left(1 - \frac{r^2}{R^2}\right), \tag{2.11}$$

where P_0 is the pressure at the center. If $\bar{P}$ is the average pressure in the core then, as shown in the appendix to this chapter,

$$\bar{P} = \frac{1}{5}\rho R a, \tag{2.12}$$

where ρ is the density of the core material and a is the acceleration at its surface.

2.26 If the change in velocity at the surface of the core at a time t after initiation of the chain reaction is represented by Δv, then

$$\Delta v = \int_0^t a\,dt. \tag{2.13}$$

Furthermore, with an exponentially increasing neutron population, as indicated by equation (2.6), the acceleration, as well as the energy density and the pressure, will vary as $e^{\alpha t}$; hence,

$$a = Ae^{\alpha t},$$

where A is a constant. If this result is substituted into equation (2.13), it is seen that

$$\Delta v = \frac{a}{\alpha}. \tag{2.14}$$

2.27 Suppose the unperturbed velocity of the core surface during assembly, i.e., before it is affected by the fission energy, is v_0; then the assembly motion will be halted when

$$\Delta v = v_0, \tag{2.15}$$

and this corresponds to explosion time. Consequently, from equations (2.14) and (2.15), at explosion time

$$a = v_0\alpha,$$

and from equation (2.12)

$$\bar{P} = \frac{1}{5}\rho R v_0 \alpha. \tag{2.16}$$

This is the average pressure in the core at explosion time.

2.28 The application of equation (2.16) may be illustrated by considering the hypothetical case of a core with a density, ρ, of 20 g/cm^3, and a radius, R, of 5 cm. The unperturbed rate of assembly, v_0, may be [redacted] DOE b(3)
and α is set at 1 gen/shake, i.e., 10^8 gen/sec. If these values are substituted into equation (2.16), it follows that at explosion time

[redacted] DOE b(3)

2.29 At explosion time, the core will be effectively a gas at very high pressure and it may be considered to

*In weapons test, a measured time interval is that between firing the HE system and the first appearance of gamma rays from the explosion; it is called the "HE transit time" or simply the "transit time."

†The purpose of this treatment is merely to provide a general understanding of the core behavior. In weapons design studies, more exact calculations are made with the aid of computers.

‡The unit 1 bar is equivalent to a pressure of 10^6 dynes/cm^2; the megabar, i.e., 10^6 bars, is then 10^{12} dynes/cm^2. The standard atmospheric pressure (760 mm of mercury) is 1.013 bars; thus a pressure of 1 atm is approximately 1 bar.

UNCLASSIFIED

have been compressed adiabatically. The energy, E, of the core will then be given by

$$E = \frac{PV}{\gamma - 1}. \qquad (2.17)$$

For an ideal gas, γ is $\frac{5}{3}$, but for the core it is probably nearer to $\frac{3}{2}$. Hence, using the value of $\bar{P}$ derived above, it is found that at explosion time the energy per unit volume is

DOE b(3) $\bar{E}_v =$ [redacted]

provided the loss of energy from the system prior to this time is not significant.

2.30 Since the density of the core has been taken to be 20 g/cm^3, the average energy per gram, $\bar{E}_g$, at explosion time in the hypothetical case under consideration is

DOE b(3) $\bar{E}_g =$ [redacted]

DOE b(3) [redacted]

2.31 The radius of the core is 5 cm and hence the volume, V, is $\frac{4}{3}\pi(5)^3 = 524$ cm^3. The total energy, E, released by explosion time, is, therefore,

DOE b(3). $E = \bar{E}_v V =$ [redacted]

which is equivalent (§ 1.15) to

DOE b(3) [redacted] ons TNT.

Consequently, an energy [redacted] ons of DOE b(3) TNT is released by explosion time in the case under consideration.

2.32 The amount of fission energy contributing to the explosion is equivalent to 7×10^{-24} kiloton (or 7×10^{-21} ton) per fission (§ 1.15). Hence, at explosion time the number of fissions that have occurred is

DOE b(3) Number of fissions = [redacted]

2.33 It was seen in § 2.16 that x is approximately equal to unity in a weapon and then α is roughly equivalent to $1/\tau$. Consequently, equation (2.6) may be written as

$$n \approx n_0 e^{t/\tau} = n_0 e^g,$$

where t/τ, represented by g, is the number of generations in which the neutron population increases from n_0 to n. If it is postulated that the fission chain is initiated by a single neutron, the number of neutrons present after g generations is

$$n \approx e^g.$$

As an approximation, it may be assumed that the number of fissions after g generations is equal to the neutron population, n, at that time. Hence, it follows that in the hypothetical example used above explosion time occurs [redacted] DOE b(3)

2.34 It will be evident from the foregoing treatment that the explosion time depends on such quantities as ρ, R, v_0, and α, and hence it will vary with the design of the fission weapon [redacted] DOE b(3)

2.35 In this derivation of explosion time it has been assumed that the fission chain is initiated by one neutron. The results would not be affected significantly if a few neutrons were present at initiation time. In some types of initiators, however, many neutrons are supplied to start fission chains. The number of generations at explosion time will then be less than obtained above [redacted] DOE b(3)

2.36 Another point that should be mentioned about these calculations is the assumption that the

UNCLASSIFIED

total number of fissions which have occurred by a particular time is equal to the neutron population at that time. This assumption represents a simplification of the actual situation. A more precise treatment, however, leads to results in agreement with those obtained above.

Rate of Energy Release

2.37 Since the explosion energy released per fission is equivalent to 7×10^{-21} ton of TNT and the total number of fissions at g generations may be set equal to e^g, assuming initiation by a single neutron, it follows that

$$\text{Energy released by } g \text{ generations} \approx 7 \times 10^{-21}\, e^g$$
$$= 7 \times 10^{-21} \times 10^{g/2.3} \text{ tons TNT.}$$

The energy releases after various numbers of generations have been calculated from this expression; some of these are quoted in Table 2.1.

Table 2.1 TOTAL ENERGY RELEASE

No. of generations	Energy release (TNT equivalent)
[redacted]	

DOE 6(3)

2.38 [redacted] It is evident from the results in Table 2.1 that nearly all the energy is released in the next 7 (or so) generations. The reason is, of course, that the energy increases by a factor of $e = 2.72$ in each generation or, $e^7 \approx 10^3$ in 7 generations.

DOE 6(3)

2.39 It is true, in general, that only a small proportion, usually something like 0.1 percent (1 part in 10^3) of the energy of a fission weapon is produced by explosion time; the remaining 99.9 percent is released during the next few generations. It is thus accepted that before explosion time, at [redacted] generations after initiation, the energy release is too small to have any appreciable effect on the motion of the assembly. Within this period, therefore, the core volume may be assumed to remain essentially constant.

DOE 6(3)

2.40 In a simple device with a short incubation period the core volume is more or less constant between initiation and explosion time; hence, α in a pure fission (but not boosted) device is also roughly constant. After explosion time, however, when the system expands, α decreases and the generation time increases. As a rough approximation, however, the generation time may be taken to be 1 shake. Hence, it is during a period of about 7 shakes, i.e., 0.07 μsec, that most of the energy of a fission device is produced. The release of a large amount of energy in such a very short interval of time, in a restricted volume, results in the attainment of very high temperatures—several tens of million degrees. Large pressures consequently develop in the core and rapid expansion, i.e., an explosion, occurs.

2.41 When the expansion is such that α has fallen to zero and the system passes through second critical, the self-sustaining fission chain will cease, although substantial amounts of fissile material may still be present. To attain a high efficiency, i.e., to consume as much as possible of the fissile species, expansion of the core should be delayed. This important function in pure fission weapons was filled by the inertial tamper. In boosted devices, however, the introduction of neutrons from an extraneous (D-T) source results in a considerable increase in the fission rate before the system expands significantly. The inertial tamper then appears to be less important than in an unboosted system.

EFFICIENCY OF FISSION WEAPONS

Definition of Efficiency

2.42 The efficiency, ϕ, of any weapon may be defined as the ratio of the energy actually developed when it explodes, i.e., the energy yield, to the total energy available; thus,

$$\phi = \frac{\text{Energy yield}}{\text{Energy available}}. \qquad (2.18)$$

In other words, the efficiency is the fraction of the total energy available which is actually released in the explosion. In the case of a fission weapon, this is equal to the ratio of the quantity of fissile material which actually suffers fission to the total amount present in the weapon. The efficiency of a weapon is generally expressed as a percentage, and so it is equal to ϕ, as defined by equation (2.18), multiplied by 100. There are several factors which determine the efficiency and some of these will be discussed below.

2.43 It is of interest to mention, in passing, that the efficiency of the earliest implosion weapons was [redacted] the gun-type systems (§ 1.56). This accounts for the fact that devices of the latter type have occupied a secondary place in the development of fission weapons, except for special purposes.

DOE b(3)

Calculation of Efficiency: Computer Methods

2.44 At the present time, the efficiency or, more correctly, the energy yield of a weapon is determined by computer calculations based on codes which have been developed to represent the behavior of the fission chain system. The calculations usually start at or immediately before explosion time, when significant mechanical effects may be assumed to begin. From initiation up to this time, the material is essentially stationary or is still being compressed and only a small proportion of the total energy has been liberated. The treatment takes into account the neutronic behavior, the hydrodynamics, and heat flow; the motion of a series of concentric shells (or "mass points") is followed until the rate of energy release by fission has fallen almost to zero. The total yield includes the energy released after the system has expanded and become subcritical. Although self-sustaining chain propagation is no longer possible, convergent-chain interaction of the many neutrons and fissile nuclei still present will result in considerable energy production. This may amount to some 30 percent or more of the total yield.

The Bethe–Feynman Formula

2.45 Prior to the development of computing machine procedures, and before data were available from test explosions for comparison and normalization purposes, fission weapon efficiencies were estimated by the method of Bethe and Feynman. The basic formula is admittedly approximate, since it involves several simplifying assumptions. However, its derivation is useful in the respect that it provides a model of the explosion of a fission weapon and indicates, qualitatively at least, some of the factors which affect the efficiency of the explosion. The treatment given below is applicable to pure fission systems and not after boosting occurs.

2.46 As a result of the energy liberated in fission, very large pressures (10–1000 megabars) are developed in the core, and the core-tamper interface consequently receives a large outward acceleration. This causes highly compressed tamper material to pile up just ahead of the expanding interface, in an effect referred to as the "snowplow" phenomenon, because of the similarity to the piling up of snow in front of a snowplow. The inertia of the compressed tamper delays expansion of the core, so that a considerable pressure gradient builds up from the center of the core to its outer surface.

2.47 Furthermore, because of the delayed expansion, it may be supposed that the volume of the compressed (supercritical) core remains essentially constant during the [redacted] or so generations following initiation of the fission chain, i.e., up to explosion time. After this interval, almost the whole of the energy is released within an extremely short period, during which time the supercritical core expands rapidly until it becomes subcritical. Although there is an appreciable release of energy even while the system is subcritical, as mentioned in § 2.44, it will be postulated that energy production ceases when the dimensions are just subcritical. It will be assumed, further, that no energy escapes during the short period of expansion from maximum supercriticality to the point where the system becomes subcritical.

DOE b(3)

2.48 Let R be the radius of a spherical core at the point of maximum supercriticality; then, in accordance with the postulate made above, this will remain unchanged until explosion time. Subsequently, the energy density of the system becomes so large that mechanical effects begin and the core starts to expand. Suppose that when the core has expanded by a fraction δ, so that the radius is $R(1 + \delta)$, the system is just critical (Fig. 2.2); beyond this point it will be subcritical. The self-sustaining fission chain will then end and, in accordance with the approximation postulated above, there will be no further release of energy.

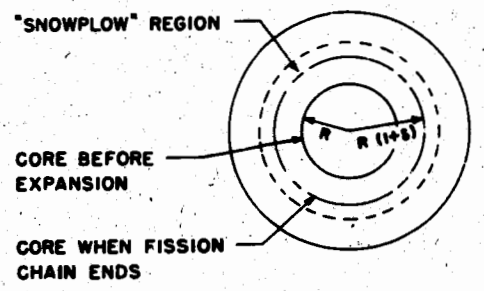

Figure 2.2

2.49 Consider a thin shell of material in the core, of volume dV and thickness dR; the cross sectional area of the shell is then dV/dR. If dP is the pressure difference on the two sides of this shell, caused by the liberated fission energy, the net outward force, dF, to

which the shell is subjected, i.e., pressure × area, is then

$$dF = dP\frac{dV}{dR} = \frac{dP}{dR}dV, \tag{2.19}$$

where dP/dR is the pressure gradient in the given shell. As a reasonable approximation, it may be supposed that the pressure gradient is essentially constant across the core radius, so that

$$\frac{dP}{dR} \approx \frac{P}{R}, \tag{2.20}$$

where P is the total difference in pressure from the center of the core to the outer surface before expansion occurs. Hence, from equations (2.19) and (2.20),

$$dF \approx \frac{P}{R}dV. \tag{2.21}$$

2.50 The time required for the core to expand from radius R to $R(1+\delta)$, i.e., a distance of $R\delta$, is about 7 generations, as seen in § 2.38. However, as a rough approximation, this may be taken as $1/\alpha$, where α is the multiplication rate just prior to explosion time. The mean outward acceleration of the core material, and of the shell dV, may consequently be expressed as $R\delta\alpha^2$. The mass of the shell is ρdV, where ρ is the core density; hence, by Newton's second law of motion, i.e., force = mass × acceleration, the force dF acting on the shell is given by

$$dF \approx \rho dV \times R\delta\alpha^2.$$

Upon comparing this result with equation (2.21), it is seen that

$$P \approx \rho R^2\alpha^2\delta. \tag{2.22}$$

2.51 As in the calculation of the explosion time, the total energy of the core, assuming there is negligible loss during the initial expansion, is expressed by equation (2.17), namely,

$$E = \frac{PV}{\gamma - 1}, \tag{2.23}$$

where γ is the ratio of the specific heats of the gas. Using equation (2.22) for P and writing M/ρ for the volume of the core, M being the mass, equation (2.23) becomes

$$E \approx \frac{MR^2\alpha^2\delta}{\gamma - 1}. \tag{2.24}$$

2.52 If ϵ is the energy released in the complete fission of unit mass of core material, then the total energy available in the core is $M\epsilon$, and the efficiency, according to equation (2.18), is $E/M\epsilon$, where E is given by equation (2.24); consequently,

$$\phi = \frac{E}{M\epsilon} \approx \frac{R^2\alpha^2\delta}{(\gamma - 1)\epsilon}. \tag{2.25}$$

It should be pointed out that in the foregoing derivation no allowance has been made for depletion of the core material as fission proceeds. For low efficiencies, to which most of the other approximations made are applicable, the depletion is not significant and can be neglected. Moreover, no allowance has been made for the inertial effect of the tamper on the efficiency. For the present purpose, which is to obtain a qualitative guide to some of the factors determining the efficiency, this can also be ignored. Hence, replacing the quantity $1/(\gamma - 1)\epsilon$ by a constant, K, equation (2.25) can be written as

$$\phi \approx KR^2\alpha^2\delta, \tag{2.26}$$

which is a version of the Bethe–Feynman formula that was developed for slightly supercritical systems. The efficiency of a fission weapon is seen to depend on the factors R, α, and δ.

2.53 Since the efficiency of a fission weapon may be expected to increase as R^2 (at constant density), it would be advantageous for the core to be large at the time of the initiation of the fission chain. One way in which this can be achieved in practice, e.g., in a gun-type weapon, is to bring together subcritical masses which are designed to contain a large total mass of fissile material. Thus, for a given compression or, especially, for no compression, the efficiency would be expected to be greater the larger the mass of the assembled core.

2.54 In general, the most important factor in determining the efficiency of a fission weapon is α, and the latter increases in proportion to the compression (§ 2.19). The efficiency, according to equation (2.26), will thus be related, approximately at least, to η^2 (or to $\eta^{1.7}$ if the effect of tamper compression is included (§ 1.47)). In addition, although of lesser significance, the effect of compression on δ must be taken into account; the more highly compressed the core material

UNCLASSIFIED

at the time of initiation (or at explosion time), the farther will be the distance the core surface must travel during the expansion phase before the supercritical system becomes subcritical. Increased compression should thus result in a marked gain in the efficiency of a fission weapon. It is this fact which is largely responsible for the much higher efficiencies of implosion systems than of gun-type devices.

DOE 6(3)

2.55 The effect of increasing compression in a simple (unboosted) implosion system is indicated by the data in Table 2.2 which are based partly on experimental observations and partly on calculation.

Table 2.2 EFFECT OF COMPRESSION ON EFFICIENCY

Average compression		Efficiency
Core	Tamper	(percent)

DOE 6(3)

DOE 6(3)

The attainment of high compression was an important objective in pure fission weapon design. In the earliest (solid-core) devices the improvement in efficiency was the main purpose. In more recent (hollow-core boosted) weapons, however, the principal objective is to make possible the design of compact systems in which both the high explosive (§ 1.42) and the fissile material have low masses. The number of crits at maximum compression is not large, so that α is relatively small before boosting. The initial efficiency of the fission chain is, therefore, also small but the total yield is greatly increased by the boosting.

INITIATION TIME AND PREINITIATION

Unboosted Implosion Weapons

2.56 It was indicated in Chapter 1 that preinitiation of a fission weapon, i.e., initiation of a chain reaction before the optimum time, could lead to a decrease in efficiency. The reason for this will be clear from the results derived in the preceding section. According to equation (2.26), the efficiency is proportional to α^2 and hence initiation at a time that will lead to explosion before α has attained its optimum value (see Fig. 2.3), i.e., preinitiation, would inevitably result in a loss of efficiency in a simple (unboosted) fission device.

2.57

DOE 6(3)

Fortuitously, major advances in the design of weapons with improved characteristics led at the same time to a decrease in preinitiation probability. Such advances included the use of composite cores containing both plutonium and oralloy, with smaller amounts of plutonium than in all-plutonium cores, and the development of small weapons with hollow cores.

2.58 The problems of preinitiation and its avoidance are conveniently considered in relation to the assembly and incubation times defined in § 2.23. In an unboosted, solid-core device, the system is initially subcritical and upon assembly it passes promptly through first ciritical and then becomes supercritical, as already described. The value of α is negative before first critical, it is zero at first critical, and becomes increasingly positive during assembly (Fig. 2.3). Prior to initiation, of course, there is no neutron multiplication and hence no actual α, but the curve in Fig. 2.3 shows the potential α at various times during assembly.

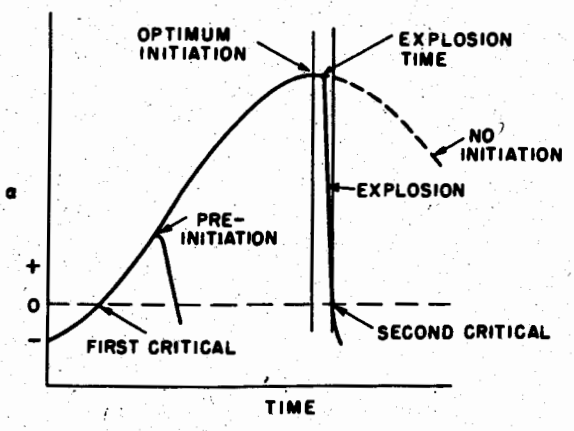

Figure 2.3

2.59 Just before optimum assembly, where α is approaching its maximum value, neutrons are injected into the highly supercritical system. The divergent

UNCLASSIFIED

fission chain is initiated and energy is released. Between initiation time and explosion time the volume is more or less constant and so also is α (§ 2.40). Rapid expansion, however, results in loss of neutrons at an increasing rate and causes the core to become less and less supercritical; hence α decreases rapidly after explosion time. When second critical is reached, both the neutron population and the rate of fission have their maximum values. Beyond second critical a self-sustaining chain reaction is no longer possible; nevertheless, considerable amounts of energy are produced by convergent chains in the subcritical system.

2.60 It is seen from Fig. 2.3 that for the particular type of simple fission weapon under consideration, the assembly time, i.e., between first critical and explosion, is long compared with the incubation time, i.e., between initiation and explosion time.

DOE 6(3)

Because of the longer assembly times, preinitiation is more probable in gun-type than in implosion systems. Some aspects of preinitiation in weapons of the former type are discussed later (§ 2.73).

Gun-Type Weapons

2.73 In a gun-type weapon, the lack of compression makes it desirable for initiation to take place at or close to the time when assembly [redacted]

DOE 6(3)

[redacted]

DOE 6(3)

Consequently, although plutonium-239 with an appreciable proportion of plutonium-240 could be used in implosion systems, even of the solid-core, unboosted type, it is unsuitable for use in conventional gun-assembly devices, as the calculations given below will show.

2.74 Apart from the possible presence of a "flood" of neutrons, e.g., as the result of the explosion of another nuclear weapon in the vicinity of a given weapon, the chief sources of background neutrons, which could cause preinitiation in a gun-assembly weapon, are spontaneous fission and (α,n) reactions with light elements. In uranium-235 (oralloy) the rate of spontaneous fission is relatively small, as will be seen shortly, but (α,n) reactions with light-element impurities could produce an appreciable neutron background. [redacted]

DOE 6(3)

2.75 Let P_1 be the probability that a background neutron will be available in the fissile material during the period that it is supercritical, i.e., in the preinitiation period, and let P_2 be the probability that this neutron will be able to start a fission chain. The preinitiation probability, P, is then given by

$$P = 1 - e^{P_1 P_2}$$

$$\approx P_1 P_2, \qquad (2.27)$$

the approximate form being applicable when $P_1 P_2$ is small, as it is in cases of interest. Actually P_2 is a function of time and both P_1 and P_2 depend, to some extent, on the position of the neutron and on other factors. For the present purpose, however, which is to draw general conclusions only, specific values will be assigned to P_1 and P_2. A background neutron entering a fissile assembly may escape altogether without being absorbed, or it may be captured in a nonfission

[redacted]

DOE 6(3)

[redacted] UNCLASSIFIED

reaction, or it may initiate a fission chain. Although the probabilities of these three processes are by no means equal, it is sufficient to postulate here that P_2 has a constant average value of 0.3 over the preinitiation period. Hence, for the purpose of making rough estimates, equation (2.27) may be written as

$$P \approx 0.3\, P_1. \qquad (2.28)$$

2.76 As a result of spontaneous fission, uranium-235 emits, on the average, about 0.70 neutron per kilogram per sec, whereas uranium-238 produces roughly 15 neutrons/kg-sec. Consequently, the neutron background in ordinary oralloy (93.2 weight percent uranium-235) is approximately 1.6 neutrons/kg-sec.

[redacted]

DOE 6(3)

2.77 According to the numbers quoted above, more than half of the background neutrons in ordinary (93.2 percent) oralloy arise from the uranium-238 present.

[redacted]

DOE 6(3)

2.78 Because of the high preinitiation probability, it is necessary to keep other background neutrons to a minimum in gun-assembly devices. It is for this reason

[redacted]

DOE 6(3)

t is seen, therefore, that a conventional gun-type weapon, based on plutonium with assembly brought about by a propellant explosive, is completely out of the question. It was the realization of this fact, when plutonium became available, that led to the development of implosion systems (§1.39), together with the expectation that the compression achieved by implosion would lead to greater efficiency.

2.80

APPENDIX

A2.01 The average pressure P in a spherical imploding core of radius R is defined by

$$\bar{P}V = \bar{P}(\tfrac{4}{3}\pi R^3) = \int_0^R P\,(4\pi r^2)dr, \qquad (2.29)$$

where P is the pressure at the distance r from the center; hence,

$$\bar{P} = \frac{3}{R^3}\int_0^R Pr^2\,dr.$$

It follows, therefore, from equation (2.11), for a parabolic pressure distribution, that

$$\bar{P} = \frac{3P_0}{R^3}\int_0^R \left(1 - \frac{r^2}{R^2}\right)r^2\,dr. \qquad (2.30)$$

The integral in equation (2.30) may be evaluated as follows:

$$\int_0^R \left(1 - \frac{r^2}{R^2}\right)r^2\,dr = \int_0^R \left(r^2 - \frac{r^4}{R^2}\right)dr$$
$$= \frac{R^3}{3} - \frac{R^5}{5R^2} = \frac{2}{15}R^3.$$

If this result is inserted into equation (2.30), it is seen that

$$\bar{P} = \frac{2}{5}P_0. \qquad (2.31)$$

A2.02 Because of the pressure gradient in the core, the material will be accelerated, and this acceleration, $a(r)$, at the radial distance r, is given by the expression

$$a(r) = -\frac{1}{\rho}\frac{dP}{dr},$$

where ρ is the density of the core material. If P is again expressed by equation (2.11), then

$$a(r) = -\frac{P_0}{\rho}\frac{d\left(1 - \frac{r^2}{R^2}\right)}{dr} = \frac{P_0}{\rho}\frac{2r}{R^2}.$$

Hence, the acceleration, a, at the surface of the core, where $r = R$, is

$$a = \frac{2P_0}{\rho R},$$

so that

$$P_0 = \frac{\rho R a}{2}.$$

Upon inserting this expression into equation (2.31), it follows that

$$\bar{P} = \frac{1}{5}\rho R a,$$

which is equation (2.12).

IRAQ – NUCLEAR WEAPONS

1. You asked for a second opinion on the issue of IRAQ's nuclear weapons capability and how quickly IRAQ might acquire a deployable nuclear capability. I have reviewed the DIS paper and spoken to DI52 and in short I agree with it as a "best guess" broad based scientific judgement although I will introduce a caveat.

2. It is very important to distinguish between hard intelligence and best scientific judgement. As I understand it the former is a little thin on the ground so we have to look at the latter. Let me start with the key ingredient for a nuclear weapon or device which is a source of fissile material (Plutonium or Highly Enriched Uranium (HEU)). The scientific judgement is clear – without such material you cannot make a nuclear weapon. The domestic source of HEU that IRAQ was trying to establish was destroyed after the Gulf War. It is hard to believe that IRAQ has covertly established a domestic source given the relatively large signatures of the necessary facilities and it would almost certainly take a few years from start up to acquire enough material. If fissile material were acquired from abroad then much time would be saved but I suspect the likelihood of this is low but it's purely an intelligence matter.

3. [redacted]

4. Finally, let us assume that against all the odds IRAQ acquires HEU and a viable [redacted] from a third party. The nuclear component would have to be fabricated and integrated with the explosives system and the firing electronics and incorporated in a bomb case. This will all take some time and the one year "guestimate" is reasonable. However my caveat is that the clock does not necessarily start ticking from the moment of fissile material acquisition. Much of the engineering integration including any conventional explosive trials can be conducted in advance. Indeed it is possible to practice casting fissile material components using simulant material (natural or depleted uranium are ideal surrogates for HEU). If all this has been done ahead of time then it might take only a few weeks to complete assembly once fissile material is obtained. The signatures of some of these precursor activities is quite low but it is on intelligence judgement as to the likelihood of detecting it.

POLICY DIRECTOR

No.

DECLASSIFIED

DECLASSIFIED

5. A more advanced design suitable for deployment on a missile would almost certainly involve more development work and explosive trials. I have no feel for timescale but 2-3 years is a good guess. Again most of this work can be done in advance of acquiring the fissile material.

FOREWORD BY THE PRIME MINISTER, THE RIGHT HONOURABLE TONY BLAIR MP

The document published today is based, in large part, on the work of the Joint Intelligence Committee (JIC). The JIC is at the heart of the British intelligence machinery. It is chaired by the Cabinet Office and made up of the heads of the UK's three Intelligence and Security Agencies, the Chief of Defence Intelligence, and senior officials from key government departments. For over 60 years the JIC has provided regular assessments to successive Prime Ministers and senior colleagues on a wide range of foreign policy and international security issues.

Its work, like the material it analyses, is largely secret. It is unprecedented for the Government to publish this kind of document. But in light of the debate about Iraq and Weapons of Mass Destruction (WMD), I wanted to share with the British public the reasons why I believe this issue to be a current and serious threat to the UK national interest.

In recent months, I have been increasingly alarmed by the evidence from inside Iraq that despite sanctions, despite the damage done to his capability in the past, despite the UN Security Council Resolutions expressly outlawing it, and despite his denials, Saddam Hussein is continuing to develop WMD, and with them the ability to inflict real damage upon the region, and the stability of the world.

Gathering intelligence inside Iraq is not easy. Saddam's is one of the most secretive and dictatorial regimes in the world. So I believe people will understand why the Agencies cannot be specific about the sources, which have formed the judgements in this document, and why we cannot publish everything we know. We cannot, of course, publish the detailed raw intelligence. I and other Ministers have been briefed in detail on the intelligence and are satisfied as to its authority. I also want to pay tribute to our Intelligence and Security Services for the often extraordinary work that they do.

What I believe the assessed intelligence has established beyond doubt is that Saddam has continued to produce chemical and biological weapons, that he continues in his efforts to develop nuclear weapons, and that he has been able to extend the range of his ballistic missile programme. I also believe that, as stated in the document, Saddam will now do his utmost to try to conceal his weapons from UN inspectors.

The picture presented to me by the JIC in recent months has become more not less worrying. It is clear that, despite sanctions, the policy of containment has not worked sufficiently well to prevent Saddam from developing these weapons.

I am in no doubt that the threat is serious and current, that he has made progress on WMD, and that he has to be stopped.

Saddam has used chemical weapons, not only against an enemy state, but against his own people. Intelligence reports make clear that he sees the building up of his WMD capability, and the belief overseas that he would use these weapons, as vital to his

strategic interests, and in particular his goal of regional domination. And the document discloses that his military planning allows for some of the WMD to be ready within 45 minutes of an order to use them.

I am quite clear that Saddam will go to extreme lengths, indeed has already done so, to hide these weapons and avoid giving them up.

In today's inter-dependent world, a major regional conflict does not stay confined to the region in question. Faced with someone who has shown himself capable of using WMD, I believe the international community has to stand up for itself and ensure its authority is upheld.

The threat posed to international peace and security, when WMD are in the hands of a brutal and aggressive regime like Saddam's, is real. Unless we face up to the threat, not only do we risk undermining the authority of the UN, whose resolutions he defies, but more importantly and in the longer term, we place at risk the lives and prosperity of our own people.

The case I make is that the UN Resolutions demanding he stops his WMD programme are being flouted; that since the inspectors left four years ago he has continued with this programme; that the inspectors must be allowed back in to do their job properly; and that if he refuses, or if he makes it impossible for them to do their job, as he has done in the past, the international community will have to act.

I believe that faced with the information available to me, the UK Government has been right to support the demands that this issue be confronted and dealt with. We must ensure that he does not get to use the weapons he has, or get hold of the weapons he wants.

EXECUTIVE SUMMARY

1. Under Saddam Hussein Iraq developed chemical and biological weapons, acquired missiles allowing it to attack neighbouring countries with these weapons and persistently tried to develop a nuclear bomb. Saddam has used chemical weapons, both against Iran and against his own people. Following the Gulf War, Iraq had to admit to all this. And in the ceasefire of 1991 Saddam agreed unconditionally to give up his weapons of mass destruction.

2. Much information about Iraq's weapons of mass destruction is already in the public domain from UN reports and from Iraqi defectors. This points clearly to Iraq's continuing possession, after 1991, of chemical and biological agents and weapons produced before the Gulf War. It shows that Iraq has refurbished sites formerly associated with the production of chemical and biological agents. And it indicates that Iraq remains able to manufacture these agents, and to use bombs, shells, artillery rockets and ballistic missiles to deliver them.

3. An independent and well-researched overview of this public evidence was provided by the International Institute for Strategic Studies (IISS) on 9 September. The IISS report also suggested that Iraq could assemble nuclear weapons within months of obtaining fissile material from foreign sources.

4. As well as the public evidence, however, significant additional information is available to the Government from secret intelligence sources, described in more detail in this paper. This intelligence cannot tell us about everything. However, it provides a fuller picture of Iraqi plans and capabilities. It shows that Saddam Hussein attaches great importance to possessing weapons of mass destruction which he regards as the basis for Iraq's regional power. It shows that he does not regard them only as weapons of last resort. He is ready to use them, including against his own population, and is determined to retain them, in breach of United Nations Security Council Resolutions (UNSCR).

5. Intelligence also shows that Iraq is preparing plans to conceal evidence of these weapons, including incriminating documents, from renewed inspections. And it confirms that despite sanctions and the policy of containment, Saddam has continued to make progress with his illicit weapons programmes.

6. As a result of the intelligence we judge that Iraq has:

   - continued to produce chemical and biological agents;
   - military plans for the use of chemical and biological weapons, including against its own Shia population. Some of these weapons are deployable within 45 minutes of an order to use them;
   - command and control arrangements in place to use chemical and biological weapons. Authority ultimately resides with Saddam Hussein. (There is intelligence that he may have delegated this authority to his son Qusai);

- developed mobile laboratories for military use, corroborating earlier reports about the mobile production of biological warfare agents;
- pursued illegal programmes to procure controlled materials of potential use in the production of chemical and biological weapons programmes;

- tried covertly to acquire technology and materials which could be used in the production of nuclear weapons;
- sought significant quantities of uranium from Africa, despite having no active civil nuclear power programme that could require it;
- recalled specialists to work on its nuclear programme;

- illegally retained up to 20 al-Hussein missiles, with a range of 650km, capable of carrying chemical or biological warheads;
- started deploying its al-Samoud liquid propellant missile, and has used the absence of weapons inspectors to work on extending its range to at least 200km, which is beyond the limit of 150km imposed by the United Nations;
- started producing the solid-propellant Ababil-100, and is making efforts to extend its range to at least 200km, which is beyond the limit of 150km imposed by the United Nations;
- constructed a new engine test stand for the development of missiles capable of reaching the UK Sovereign Base Areas in Cyprus and NATO members (Greece and Turkey), as well as all Iraq's Gulf neighbours and Israel;
- pursued illegal programmes to procure materials for use in its illegal development of long range missiles;

- learnt lessons from previous UN weapons inspections and has already begun to conceal sensitive equipment and documentation in advance of the return of inspectors.

7. These judgements reflect the views of the Joint Intelligence Committee (JIC). More details on the judgements and on the development of the JIC's assessments since 1998 are set out in Part 1 of this paper.

8. Iraq's weapons of mass destruction are in breach of international law. Under a series of UN Security Council Resolutions Iraq is obliged to destroy its holdings of these weapons under the supervision of UN inspectors. Part 2 of the paper sets out the key UN Security Council Resolutions. It also summarises the history of the UN inspection regime and Iraq's history of deception, intimidation and concealment in its dealings with the UN inspectors.

9. But the threat from Iraq does not depend solely on the capabilities we have described. It arises also because of the violent and aggressive nature of Saddam Hussein's regime. His record of internal repression and external aggression gives rise to unique concerns about the threat he poses. The paper briefly outlines in Part 3 Saddam's rise to power, the nature of his regime and his history of regional aggression. Saddam's human rights abuses are also catalogued, including his record of torture, mass arrests and summary executions.

10. The paper briefly sets out how Iraq is able to finance its weapons programme. Drawing on illicit earnings generated outside UN control, Iraq generated illegal income of some $3 billion in 2001.

PART 1

IRAQ'S CHEMICAL, BIOLOGICAL, NUCLEAR AND BALLISTIC MISSILE PROGRAMMES

CHAPTER 1: THE ROLE OF INTELLIGENCE

1. Since UN inspectors were withdrawn from Iraq in 1998, there has been little overt information on Iraq's chemical, biological, nuclear and ballistic missile programmes. Much of the publicly available information about Iraqi capabilities and intentions is dated. But we also have available a range of secret intelligence about these programmes and Saddam Hussein's intentions. This comes principally from the United Kingdom's intelligence and analysis agencies – the Secret Intelligence Service (SIS), the Government Communications Headquarters (GCHQ), the Security Service, and the Defence Intelligence Staff (DIS). We also have access to intelligence from close allies.

2. Intelligence rarely offers a complete account of activities which are designed to remain concealed. The nature of Saddam's regime makes Iraq a difficult target for the intelligence services. Intelligence, however, has provided important insights into Iraqi programmes and Iraqi military thinking. Taken together with what is already known from other sources, this intelligence builds our understanding of Iraq's capabilities and adds significantly to the analysis already in the public domain. But intelligence sources need to be protected, and this limits the detail that can be made available.

3. Iraq's capabilities have been regularly reviewed by the Joint Intelligence Committee (JIC), which has provided advice to the Prime Minister and his senior colleagues on the developing assessment, drawing on all available sources. Part 1 of this paper includes some of the most significant views reached by the JIC between 1999 and 2002.

Joint Intelligence Committee (JIC)

The JIC is a Cabinet Committee with a history dating back to 1936. The JIC brings together the Heads of the three Intelligence and Security Agencies (Secret Intelligence Service, Government Communications Headquarters and the Security Service), the Chief of Defence Intelligence, senior policy makers from the Foreign Office, the Ministry of Defence, the Home Office, the Treasury and the Department of Trade and Industry and representatives from other Government Departments and Agencies as appropriate. The JIC provides regular intelligence assessments to the Prime Minister, other Ministers and senior officials on a wide range of foreign policy and international security issues. It meets each week in the Cabinet Office.

CHAPTER 2

IRAQ'S PROGRAMMES: 1971–1998

1. Iraq has been involved in chemical and biological warfare research for over 30 years. Its **chemical warfare** research started in 1971 at a small, well guarded site at Rashad to the north east of Baghdad. Research was conducted there on a number of chemical agents including mustard gas, CS and tabun. Later, in 1974 a dedicated organisation called al-Hasan Ibn al-Haitham was established. In the late 1970s plans were made to build a large research and commercial-scale production facility in the desert some 70km north west of Baghdad under the cover of Project 922. This was to become Muthanna State Establishment, also known as al-Muthanna, and operated under the front name of Iraq's State Establishment for Pesticide Production. It became operational in 1982-83. It had five research and development sections, each tasked to pursue different programmes. In addition, the al-Muthanna site was the main chemical agent production facility, and it also took the lead in weaponising chemical and biological agents including all aspects of weapon development and testing, in association with the military. According to information, subsequently supplied by the Iraqis, the total production capacity in 1991 was 4,000 tonnes of agent per annum, but we assess it could have been higher. Al-Muthanna was supported by three separate storage and precursor production facilities known as Fallujah 1, 2 and 3 near Habbaniyah, north west of Baghdad, parts of which were not completed before they were heavily bombed in the 1991 Gulf War.

> **Effects of Chemical Weapons**
>
> **Mustard** is a liquid agent, which gives off a hazardous vapour, causing burns and blisters to exposed skin. When inhaled, mustard damages the respiratory tract; when ingested, it causes vomiting and diarrhoea. It attacks and damages the eyes, mucous membranes, lungs, skin, and blood-forming organs.
>
> **Tabun, sarin and VX** are all nerve agents of which VX is the most toxic. They all damage the nervous system, producing muscular spasms and paralysis. As little as 10 milligrammes of VX on the skin can cause rapid death.

2. Iraq started **biological warfare** research in the mid-1970s. After small-scale research, a purpose-built research and development facility was authorised at al-Salman, also known as Salman Pak. This is surrounded on three sides by the Tigris river and situated some 35km south of Baghdad. Although some progress was made in biological weapons research at this early stage, Iraq decided to concentrate on developing chemical agents and their delivery systems at al-Muthanna. With the outbreak of the Iran-Iraq War, in the early 1980s, the biological weapons programme was revived. The appointment of Dr Rihab Taha in 1985, to head a small biological weapons research team at al-Muthanna,

The effects of biological agents

Anthrax is a disease caused by the bacterium Bacillus Anthracis. Inhalation anthrax is the manifestation of the disease likely to be expected in biological warfare. The symptoms may vary, but can include fever and internal bleeding. The incubation period for anthrax is 1 to 7 days, with most cases occurring within 2 days of exposure.

Botulinum toxin is one of the most toxic substances known to man. The first symptoms of poisoning may appear as early as 1 hour post exposure or as late as 8 days after exposure, with the incubation period between 12 and 22 hours. Paralysis leads to death by suffocation.

Aflatoxins are fungal toxins, which are potent carcinogens. Most symptoms take a long time to show. Food products contaminated by aflatoxins can cause liver inflammation and cancer. They can also affect pregnant women, leading to stillborn babies and children born with mutations.

Ricin is derived from the castor bean and can cause multiple organ failure leading to death within one or two days of inhalation.

helped to develop the programme. At about the same time plans were made to develop the Salman Pak site into a secure biological warfare research facility. Dr Taha continued to work with her team at al-Muthanna until 1987 when it moved to Salman Pak, which was under the control of the Directorate of General Intelligence. Significant resources were provided for the programme, including the construction of a dedicated production facility (Project 324) at al-Hakam. Agent production began in 1988 and weaponisation testing and later filling of munitions was conducted in association with the staff at Muthanna State Establishment. From mid-1990, other civilian facilities were taken over and some adapted for use in the production and research and development of biological agents. These included:

- al-Dawrah Foot and Mouth Vaccine Institute which produced botulinum toxin and conducted virus research. There is some intelligence to suggest that work was also conducted on anthrax;
- al-Fudaliyah Agriculture and Water Research Centre where Iraq admitted it undertook aflatoxin production and genetic engineering;
- Amariyah Sera and Vaccine Institute which was used for the storage of biological agent seed stocks and was involved in genetic engineering.

3. By the time of the Gulf War Iraq was producing very large quantities of chemical and biological agents. From a series of Iraqi declarations to the UN during the 1990s we know that by 1991 they had produced at least:
   - 19,000 litres of botulinum toxin, 8,500 litres of anthrax, 2,200 litres of aflatoxin and were working on a number of other agents;

- 2,850 tonnes of mustard gas, 210 tonnes of tabun, 795 tonnes of sarin and cyclosarin, and 3.9 tonnes of VX.

4. Iraq's **nuclear programme** was established under the Iraqi Atomic Energy Commission in the 1950s. Under a nuclear co-operation agreement signed with the Soviet Union in 1959, a nuclear research centre, equipped with a research reactor, was built at Tuwaitha, the main Iraqi nuclear research centre. The research reactor worked up to 1991. The surge in Iraqi oil revenues in the early 1970s supported an expansion of the research programme. This was bolstered in the mid-1970s by the acquisition of two research reactors powered by highly enriched uranium fuel and equipment for fuel fabrication and handling. By the end of 1984 Iraq was self-sufficient in uranium ore. One of the reactors was destroyed in an Israeli air attack in June 1981 shortly before it was to become operational; the other was never completed.

5. By the mid-1980s the deterioration of Iraq's position in the war with Iran prompted renewed interest in the military use of nuclear technology. Additional resources were put into developing technologies to enrich uranium as fissile material (material that makes up the core of a nuclear weapon) for use in nuclear weapons. Enriched uranium was preferred because it could be more easily produced covertly than the alternative, plutonium. Iraq followed parallel programmes to produce highly enriched uranium (HEU), electromagnetic isotope separation (EMIS) and gas centrifuge enrichment. By 1991 one EMIS enrichment facility was nearing completion and another was under construction. However, Iraq never succeeded in its EMIS technology and the programme had been dropped by 1991. Iraq decided to concentrate on gas centrifuges as the means for producing the necessary fissile material. Centrifuge facilities were also under construction, but the centrifuge design was still being developed. In August 1990 Iraq instigated a crash programme to develop a single nuclear weapon within a year. This programme envisaged the rapid development of a small 50 machine gas centrifuge cascade to produce weapons-grade HEU using fuel from the Soviet research reactor, which was already substantially enriched, and unused fuel from the reactor bombed by the Israelis. By the time of the Gulf War, the crash programme had made little progress.

6. Iraq's declared aim was to produce a missile warhead with a 20-kiloton yield and weapons designs were produced for the simplest implosion weapons. These were similar to the device used at Nagasaki in 1945. Iraq was also working on more

Effect of a 20-kiloton nuclear detonation

A detonation of a 20-kiloton nuclear warhead over a city might flatten an area of approximately 3 square miles. Within 1.6 miles of detonation, blast damage and radiation would cause 80% casualties, three-quarters of which would be fatal. Between 1.6 and 3.1 miles from the detonation, there would still be 10% casualties.

advanced concepts. By 1991 the programme was supported by a large body of Iraqi nuclear expertise, programme documentation and databases and manufacturing infrastructure. The International Atomic Energy Agency (IAEA) reported that Iraq had:

- experimented with high explosives to produce implosive shock waves;
- invested significant effort to understand the various options for neutron initiators;
- made significant progress in developing capabilities for the production, casting and machining of uranium metal.

SCUD missiles

The short-range mobile SCUD ballistic missile was developed by the Soviet Union in the 1950s, drawing on the technology of the German V-2 developed in World War II.

For many years it was the mainstay of Soviet and Warsaw Pact tactical missile forces and it was also widely exported. Recipients of Soviet-manufactured SCUDs included Iraq, North Korea, Iran, and Libya, although not all were sold directly by the Soviet Union.

7. Prior to the Gulf War, Iraq had a well-developed **ballistic missile** industry. Many of the missiles fired in the Gulf War were an Iraqi modified version of the SCUD missile, the al-Hussein, with an extended range of 650km. Iraq had about 250 imported SCUD-type missiles prior to the Gulf War plus an unknown number of indigenously produced engines and components. Iraq was working on other stretched SCUD variants, such as the al-Abbas, which had a range of 900km. Iraq was also seeking to reverse-engineer the SCUD engine with a view to producing new missiles. Recent intelligence indicates that they may have succeeded at that time. In particular, Iraq had plans for a new SCUD-derived missile with a range of 1200km. Iraq also conducted a partial flight test of a multi-stage satellite launch vehicle based on SCUD technology, known as the al-Abid. Also during this period, Iraq was developing the Badr-2000, a 700-1000km range two-stage solid propellant missile (based on the Iraqi part of the 1980s CONDOR-2 programme run in co-operation with Argentina and Egypt). There were plans for 1200–1500km range solid propellant follow-on systems.

The use of chemical and biological weapons

8. Iraq had made frequent use of a variety of chemical weapons during the Iran-Iraq War. Many of the casualties are still in Iranian hospitals suffering from the long-term effects of numerous types of cancer and lung diseases. In 1988 Saddam also used mustard and nerve agents against Iraqi Kurds at Halabja in northern Iraq (see box on p15). Estimates vary, but according to Human Rights Watch up to 5,000 people were killed.

9. Iraq used significant quantities of mustard, tabun and sarin during the war with Iran resulting in over 20,000 Iranian casualties. A month after the attack on Halabja, Iraqi troops used over 100 tonnes of sarin against Iranian troops on the al-Fao peninsula. Over the next three months Iraqi troops used sarin and other nerve agents on Iranian troops causing extensive casualties.

The Attack on Halabja

On Friday 17th March 1988 the village of Halabja was bombarded by Iraqi warplanes. The raid was over in minutes. Saddam Hussein used chemical weapons against his own people. A Kurd described the effects of a chemical attack on another village:

"My brothers and my wife had blood and vomit running from their noses and their mouths. Their heads were tilted to one side. They were groaning. I couldn't do much, just clean up the blood and vomit from their mouths and try in every way to make them breathe again. I did artificial respiration on them and then I gave them two injections each. I also rubbed creams on my wife and two brothers."

(From "Crimes Against Humanity" Iraqi National Congress.)

Among the corpses at Halabja, children were found dead where they had been playing outside their homes. In places, streets were piled with corpses.

10. From Iraqi declarations to the UN after the Gulf War we know that by 1991 Iraq had produced a variety of delivery means for chemical and biological agents including over 16,000 free-fall bombs and over 110,000 artillery rockets and shells. Iraq also admitted to the UN Special Commission (UNSCOM) that it had 50 chemical and 25 biological warheads available for its ballistic missiles.

The use of ballistic missiles

11. Iraq fired over 500 SCUD-type missiles at Iran during the Iran-Iraq War at both civilian and military targets, and 93 SCUD-type missiles during the Gulf War. The latter were targeted at Israel and Coalition forces stationed in the Gulf region.

12. At the end of the Gulf War the international community was determined that Iraq's arsenal of chemical and biological weapons and ballistic missiles should be dismantled. The method chosen to achieve this was the establishment of UNSCOM to carry out intrusive inspections within Iraq and to eliminate its chemical and biological weapons and ballistic missiles with a range of over 150km. The IAEA was charged with the abolition of Iraq's nuclear weapons programme. Between 1991 and 1998 UNSCOM succeeded in identifying and destroying very large quantities of chemical weapons and ballistic missiles as well as associated production facilities. The IAEA also destroyed the infrastructure for Iraq's nuclear weapons programme and removed key nuclear materials. This was achieved despite a continuous and sophisticated programme of harassment, obstruction, deception and denial (see Part 2). Because of this UNSCOM concluded by 1998 that it was unable to fulfil its mandate. The inspectors were withdrawn in December 1998.

13. Based on the UNSCOM report to the UN Security Council in January 1999 and earlier UNSCOM reports, we assess that when the UN inspectors left Iraq they were unable to account for:

    - up to 360 tonnes of bulk chemical warfare agent, including 1.5 tonnes of VX nerve agent;
    - up to 3,000 tonnes of precursor chemicals, including approximately 300 tonnes which, in the Iraqi chemical warfare programme, were unique to the production of VX;
    - growth media procured for biological agent production (enough to produce over three times the 8,500 litres of anthrax spores Iraq admits to having manufactured);
    - over 30,000 special munitions for delivery of chemical and biological agents.

14. The departure of UNSCOM meant that the international community was unable to establish the truth behind these large discrepancies and greatly diminished its ability to monitor and assess Iraq's continuing attempts to reconstitute its programmes.

CHAPTER 3

THE CURRENT POSITION: 1998–2002

1. This chapter sets out what we know of Saddam Hussein's chemical, biological, nuclear and ballistic missile programmes, drawing on all the available evidence. While it takes account of the results from UN inspections and other publicly available information, it also draws heavily on the latest intelligence about Iraqi efforts to develop their programmes and capabilities since 1998. The **main conclusions** are that:

   - Iraq has a useable chemical and biological weapons capability, in breach of UNSCR 687, which has included recent production of chemical and biological agents;
   - Saddam continues to attach great importance to the possession of weapons of mass destruction and ballistic missiles which he regards as being the basis for Iraq's regional power. He is determined to retain these capabilities;
   - Iraq can deliver chemical and biological agents using an extensive range of artillery shells, free-fall bombs, sprayers and ballistic missiles;
   - Iraq continues to work on developing nuclear weapons, in breach of its obligations under the Non-Proliferation Treaty and in breach of UNSCR 687. Uranium has been sought from Africa that has no civil nuclear application in Iraq;
   - Iraq possesses extended-range versions of the SCUD ballistic missile in breach of UNSCR 687 which are capable of reaching Cyprus, Eastern Turkey, Tehran and Israel. It is also developing longer-range ballistic missiles;
   - Iraq's current military planning specifically envisages the use of chemical and biological weapons;
   - Iraq's military forces are able to use chemical and biological weapons, with command, control and logistical arrangements in place. The Iraqi military are able to deploy these weapons within 45 minutes of a decision to do so;
   - Iraq has learnt lessons from previous UN weapons inspections and is already taking steps to conceal and disperse sensitive equipment and documentation in advance of the return of inspectors;
   - Iraq's chemical, biological, nuclear and ballistic missiles programmes are well-funded.

CHEMICAL AND BIOLOGICAL WEAPONS

Joint Intelligence Committee (JIC) Assessment: 1999–2002

2. Since the withdrawal of the inspectors the JIC has monitored evidence, including from secret intelligence, of continuing work on Iraqi offensive chemical and biological warfare capabilities. In the first half of 2000 the JIC noted

intelligence on Iraqi attempts to procure dual-use chemicals and on the reconstruction of civil chemical production at sites formerly associated with the chemical warfare programme. Iraq had also been trying to procure dual-use materials and equipment which could be used for a biological warfare programme. Personnel known to have been connected to the biological warfare programme up to the Gulf War had been conducting research into pathogens. There was intelligence that Iraq was starting to produce biological warfare agents in mobile production facilities. Planning for the project had begun in 1995 under Dr Rihab Taha, known to have been a central player in the pre-Gulf War programme. The JIC concluded that Iraq had sufficient expertise, equipment and material to produce biological warfare agents within weeks using its legitimate bio-technology facilities.

3. In mid-2001 the JIC assessed that Iraq retained some chemical warfare agents, precursors, production equipment and weapons from before the Gulf War. These stocks would enable Iraq to produce significant quantities of mustard gas within weeks and of nerve agent within months. The JIC concluded that intelligence on Iraqi former chemical and biological warfare facilities, their limited reconstruction and civil production pointed to a continuing research and development programme. These chemical and biological capabilities represented the most immediate threat from Iraqi weapons of mass destruction. Since 1998 Iraqi development of mass destruction weaponry had been helped by the absence of inspectors and the increase in illegal border trade, which was providing hard currency.

4. In the last six months the JIC has confirmed its earlier judgements on Iraqi chemical and biological warfare capabilities and assessed that Iraq has the means to deliver chemical and biological weapons.

Recent intelligence

5. Subsequently, intelligence has become available from reliable sources which complements and adds to previous intelligence and confirms the JIC assessment that Iraq has chemical and biological weapons. The intelligence also shows that the Iraqi leadership has been discussing a number of issues related to these weapons. This intelligence covers:

   - **Confirmation that chemical and biological weapons play an important role in Iraqi military thinking:** intelligence shows that Saddam attaches great importance to the possession of chemical and biological weapons which he regards as being the basis for Iraqi regional power. He believes that respect for Iraq rests on its possession of these weapons and the missiles capable of delivering them. Intelligence indicates that Saddam is determined to retain this capability and recognises that Iraqi political weight would be diminished if Iraq's military power rested solely on its conventional military forces.

   - **Iraqi attempts to retain its existing banned weapons systems:** Iraq is already taking steps to prevent UN weapons inspectors finding evidence of

its chemical and biological weapons programme. Intelligence indicates that Saddam has learnt lessons from previous weapons inspections, has identified possible weak points in the inspections process and knows how to exploit them. Sensitive equipment and papers can easily be concealed and in some cases this is already happening. The possession of mobile biological agent production facilities will also aid concealment efforts. Saddam is determined not to lose the capabilities that he has been able to develop further in the four years since inspectors left.

- **Saddam's willingness to use chemical and biological weapons:** intelligence indicates that as part of Iraq's military planning Saddam is willing to use chemical and biological weapons, including against his own Shia population. Intelligence indicates that the Iraqi military are able to deploy chemical or biological weapons within 45 minutes of an order to do so.

Chemical and biological agents: surviving stocks

6. When confronted with questions about the unaccounted stocks, Iraq has claimed repeatedly that if it had retained any chemical agents from before the Gulf War they would have deteriorated sufficiently to render them harmless. But Iraq has admitted to UNSCOM to having the knowledge and capability to add stabiliser to nerve agent and other chemical warfare agents which would prevent such decomposition. In 1997 UNSCOM also examined some munitions which had been filled with mustard gas prior to 1991 and found that they remained very toxic and showed little sign of deterioration.

7. Iraq has claimed that all its biological agents and weapons have been destroyed. No convincing proof of any kind has been produced to support this claim. In particular, Iraq could not explain large discrepancies between the amount of growth media (nutrients required for the specialised growth of agent) it procured before 1991 and the amounts of agent it admits to having manufactured. The discrepancy is enough to produce more than three times the amount of anthrax allegedly manufactured.

Chemical agent: production capabilities

8. Intelligence shows that Iraq has continued to produce chemical agent. During the Gulf War a number of facilities which intelligence reporting indicated were directly or indirectly associated with Iraq's chemical weapons effort were attacked and damaged. Following the ceasefire UNSCOM destroyed or rendered harmless facilities and equipment used in Iraq's chemical weapons programme. Other equipment was released for civilian use either in industry or academic institutes, where it was tagged and regularly inspected and monitored, or else placed under camera monitoring, to ensure that it was not being misused. This monitoring ceased when UNSCOM withdrew from Iraq in 1998. However, capabilities remain and, although the main chemical weapon production facility at al-Muthanna was completely destroyed by UNSCOM and has not been

rebuilt, other plants formerly associated with the chemical warfare programme have been rebuilt. These include the chlorine and phenol plant at Fallujah 2 near Habbaniyah. In addition to their civilian uses, chlorine and phenol are used for precursor chemicals which contribute to the production of chemical agents.

9. Other dual-use facilities, which are capable of being used to support the production of chemical agent and precursors, have been rebuilt and re-equipped. New chemical facilities have been built, some with illegal foreign assistance, and are probably fully operational or ready for production. These include the Ibn Sina Company at Tarmiyah (see figure 1), which is a chemical research centre. It undertakes research, development and production of chemicals previously imported but not now available and which are needed for Iraq's civil industry. The Director General of the research centre is Hikmat Na'im al-Jalu who prior to the Gulf War worked in Iraq's nuclear weapons programme and after the war was responsible for preserving Iraq's chemical expertise.

FIGURE 1: THE IBN SINA COMPANY AT TARMIYAH

10. Parts of the al-Qa'qa' chemical complex damaged in the Gulf War have also been repaired and are operational. Of particular concern are elements of the phosgene production plant at al-Qa'qa'. These were severely damaged during the Gulf War, and dismantled under UNSCOM supervision, but have since been rebuilt. While phosgene does have industrial uses it can also be used by itself as a chemical agent or as a precursor for nerve agent.

11. Iraq has retained the expertise for chemical warfare research, agent production and weaponisation. Most of the personnel previously involved in the programme remain in country. While UNSCOM found a number of technical manuals (so called "cook books") for the production of chemical agents and critical precursors, Iraq's claim to have unilaterally destroyed the bulk of the documentation cannot be confirmed and is almost certainly untrue. Recent intelligence indicates that Iraq is still discussing methods of concealing such documentation in order to ensure that it is not discovered by any future UN inspections.

The Problem of Dual-Use Facilities

Almost all components and supplies used in weapons of mass destruction and ballistic missile programmes are dual-use. For example, any major petrochemical or biotech industry, as well as public health organisations, will have legitimate need for most materials and equipment required to manufacture chemical and biological weapons. Without UN weapons inspectors it is very difficult therefore to be sure about the true nature of many of Iraq's facilities.

For example, Iraq has built a large new chemical complex, Project Baiji, in the desert in north west Iraq at al-Sharqat (see figure 2). This site is a former uranium enrichment facility which was damaged during the Gulf War and rendered harmless under supervision of the IAEA. Part of the site has been rebuilt, with work starting in 1992, as a chemical production complex. Despite the site being far away from populated areas it is surrounded by a high wall with watch towers and guarded by armed guards. Intelligence reports indicate that it will produce nitric acid which can be used in explosives, missile fuel and in the purification of uranium.

FIGURE 2: AL-SHARQAT CHEMICAL PRODUCTION FACILITY

Biological agent: production capabilities

12. We know from intelligence that Iraq has continued to produce biological warfare agents. As with some chemical equipment, UNSCOM only destroyed equipment that could be directly linked to biological weapons production. Iraq also has its own engineering capability to design and construct biological agent associated fermenters, centrifuges, sprayer dryers and other equipment and is judged to be self-sufficient in the technology required to produce biological weapons. The

experienced personnel who were active in the programme have largely remained in the country. Some dual-use equipment has also been purchased, but without monitoring by UN inspectors Iraq could have diverted it to their biological weapons programme. This newly purchased equipment and other equipment previously subject to monitoring could be used in a resurgent biological warfare programme. Facilities of concern include:

- the Castor Oil Production Plant at Fallujah: this was damaged in UK/US air attacks in 1998 (Operation Desert Fox) but has been rebuilt. The residue from the castor bean pulp can be used in the production of the biological agent ricin;
- the al-Dawrah Foot and Mouth Disease Vaccine Institute: which was involved in biological agent production and research before the Gulf War;
- the Amariyah Sera and Vaccine Plant at Abu Ghraib: UNSCOM established that this facility was used to store biological agents, seed stocks and conduct biological warfare associated genetic research prior to the Gulf War. It has now expanded its storage capacity.

13. UNSCOM established that Iraq considered the use of mobile biological agent production facilities. In the past two years evidence from defectors has indicated the existence of such facilities. Recent intelligence confirms that the Iraqi military have developed mobile facilities. These would help Iraq conceal and protect biological agent production from military attack or UN inspection.

Chemical and biological agents: delivery means

14. Iraq has a variety of delivery means available for both chemical and biological agents. These include:

- free-fall bombs: Iraq acknowledged to UNSCOM the deployment to two sites of free-fall bombs filled with biological agent during 1990–91. These bombs were filled with anthrax, botulinum toxin and aflatoxin. Iraq also acknowledged possession of four types of aerial bomb with various chemical agent fills including sulphur mustard, tabun, sarin and cyclosarin;
- artillery shells and rockets: Iraq made extensive use of artillery munitions filled with chemical agents during the Iran-Iraq War. Mortars can also be used for chemical agent delivery. Iraq is known to have tested the use of shells and rockets filled with biological agents. Over 20,000 artillery munitions remain unaccounted for by UNSCOM;
- helicopter and aircraft borne sprayers: Iraq carried out studies into aerosol dissemination of biological agent using these platforms prior to 1991. UNSCOM was unable to account for many of these devices. It is probable that Iraq retains a capability for aerosol dispersal of both chemical and biological agent over a large area;
- al-Hussein ballistic missiles (range 650km): Iraq told UNSCOM that it filled 25 warheads with anthrax, botulinum toxin and aflatoxin. Iraq also

developed chemical agent warheads for al-Hussein. Iraq admitted to producing 50 chemical warheads for al-Hussein which were intended for the delivery of a mixture of sarin and cyclosarin. However, technical analysis of warhead remnants has shown traces of VX degradation product which indicate that some additional warheads were made and filled with VX;

- al-Samoud/Ababil-100 ballistic missiles (range 150km plus): it is unclear if chemical and biological warheads have been developed for these systems, but given the Iraqi experience on other missile systems, we judge that Iraq has the technical expertise for doing so;

- L-29 remotely piloted vehicle programme (see figure 3): we know from intelligence that Iraq has attempted to modify the L-29 jet trainer to allow it to be used as an Unmanned Aerial Vehicle (UAV) which is potentially capable of delivering chemical and biological agents over a large area.

FIGURE 3: THE L-29 JET TRAINER

Chemical and biological warfare: command and control

15. The authority to use chemical and biological weapons ultimately resides with Saddam but intelligence indicates that he may have also delegated this authority to his son Qusai. Special Security Organisation (SSO) and Special Republican Guard (SRG) units would be involved in the movement of any chemical and biological weapons to military units. The Iraqi military holds artillery and missile systems at Corps level throughout the Armed Forces and conducts regular training with them. The Directorate of Rocket Forces has operational control of strategic missile systems and some Multiple Launcher Rocket Systems.

Chemical and biological weapons: summary

16. Intelligence shows that Iraq has covert chemical and biological weapons programmes, in breach of UN Security Council Resolution 687 and has continued to produce chemical and biological agents. Iraq has:

    - chemical and biological agents and weapons available, both from pre-Gulf War stocks and more recent production;
    - the capability to produce the chemical agents mustard gas, tabun, sarin, cyclosarin, and VX capable of producing mass casualties;

- a biological agent production capability and can produce at least anthrax, botulinum toxin, aflatoxin and ricin. Iraq has also developed mobile facilities to produce biological agents;
- a variety of delivery means available;
- military forces, which maintain the capability to use these weapons with command, control and logistical arrangements in place.

NUCLEAR WEAPONS

Joint Intelligence Committee (JIC) Assessments: 1999–2001

17. Since 1999 the JIC has monitored Iraq's attempts to reconstitute its nuclear weapons programme. In mid-2001 the JIC assessed that Iraq had continued its nuclear research after 1998. The JIC drew attention to intelligence that Iraq had recalled its nuclear scientists to the programme in 1998. Since 1998 Iraq had been trying to procure items that could be for use in the construction of centrifuges for the enrichment of uranium.

Iraqi nuclear weapons expertise

18. Paragraphs 5 and 6 of Chapter 2 describe the Iraqi nuclear weapons programme prior to the Gulf War. It is clear from IAEA inspections and Iraq's own declarations that by 1991 considerable progress had been made in both developing methods to produce fissile material and in weapons design. The IAEA dismantled the physical infrastructure of the Iraqi nuclear weapons

Elements of a nuclear weapons programme: nuclear fission weapon

A typical nuclear fission weapon consists of:

- fissile material for the core which gives out huge amounts of explosive energy from nuclear reactions when made "super critical" through extreme compression. Fissile material is usually either highly enriched uranium (HEU) or weapons-grade plutonium:
  - HEU can be made in gas centrifuges (see separate box on p25);
  - plutonium is made by reprocessing fuel from a nuclear reactor;
- explosives which are needed to compress the nuclear core. These explosives also require a complex arrangement of detonators, explosive charges to produce an even and rapid compression of the core;
- sophisticated electronics to fire the explosives;
- a neutron initiator to provide initial burst of neutrons to start the nuclear reactions.

Weaponisation

Weaponisation is the conversion of these concepts into a reliable weapon. It includes:

- developing a weapon design through sophisticated science and complex calculations;
- engineering design to integrate with the delivery system;
- specialised equipment to cast and machine safely the nuclear core;
- dedicated facilities to assemble the warheads;
- facilities to rigorously test all individual components and designs;

The complexity is much greater for a weapon that can fit into a missile warhead than for a larger Nagasaki-type bomb.

programme, including the dedicated facilities and equipment for uranium separation and enrichment, and for weapon development and production, and removed the remaining highly enriched uranium. But Iraq retained, and retains, many of its experienced nuclear scientists and technicians who are specialised in the production of fissile material and weapons design. Intelligence indicates that Iraq also retains the accompanying programme documentation and data.

19. Intelligence shows that the present Iraqi programme is almost certainly seeking an indigenous ability to enrich uranium to the level needed for a nuclear weapon. It indicates that the approach is based on gas centrifuge uranium enrichment, one of the routes Iraq was following for producing fissile material before the Gulf War. But Iraq needs certain key equipment, including gas centrifuge components and components for the production of fissile material before a nuclear bomb could be developed.

Gas centrifuge uranium enrichment

Uranium in the form of uranium hexafluoride is separated into its different isotopes in rapidly spinning rotor tubes of special centrifuges. Many hundreds or thousands of centrifuges are connected in cascades to enrich uranium. If the lighter U235 isotope is enriched to more than 90% it can be used in the core of a nuclear weapon.

20. Following the departure of weapons inspectors in 1998 there has been an accumulation of intelligence indicating that Iraq is making concerted covert efforts to acquire dual-use technology and materials with nuclear applications. Iraq's known holdings of processed uranium are under IAEA supervision. But there is intelligence that Iraq has sought the supply of significant quantities of uranium from Africa. Iraq has no active civil nuclear power programme or nuclear power plants and therefore has no legitimate reason to acquire uranium.

Iraq's civil nuclear programme

- Iraq's long-standing civil nuclear power programme is limited to small scale research. Activities that could be used for military purposes are prohibited by UNSCR 687 and 715.
- Iraq has no nuclear power plants and therefore no requirement for uranium as fuel.
- Iraq has a number of nuclear research programmes in the fields of agriculture, biology, chemistry, materials and pharmaceuticals. None of these activities requires more than tiny amounts of uranium which Iraq could supply from its own resources.
- Iraq's research reactors are non-operational; two were bombed and one was never completed.

21. Intelligence shows that other important procurement activity since 1998 has included attempts to purchase:

    - vacuum pumps which could be used to create and maintain pressures in a gas centrifuge cascade needed to enrich uranium;
    - an entire magnet production line of the correct specification for use in the motors and top bearings of gas centrifuges. It appears that Iraq is attempting to acquire a capability to produce them on its own rather than rely on foreign procurement;
    - Anhydrous Hydrogen Fluoride (AHF) and fluorine gas. AHF is commonly used in the petrochemical industry and Iraq frequently imports significant amounts, but it is also used in the process of converting uranium into uranium hexafluoride for use in gas centrifuge cascades;
    - one large filament winding machine which could be used to manufacture carbon fibre gas centrifuge rotors;
    - a large balancing machine which could be used in initial centrifuge balancing work.

22. Iraq has also made repeated attempts covertly to acquire a very large quantity (60,000 or more) of specialised aluminium tubes. The specialised aluminium in question is subject to international export controls because of its potential application in the construction of gas centrifuges used to enrich uranium, although there is no definitive intelligence that it is destined for a nuclear programme.

Nuclear weapons: timelines

23. In early 2002, the JIC assessed that UN sanctions on Iraq were hindering the import of crucial goods for the production of fissile material. The JIC judged

that while sanctions remain effective Iraq would not be able to produce a nuclear weapon. If they were removed or prove ineffective, it would take Iraq at least five years to produce sufficient fissile material for a weapon indigenously. However, we know that Iraq retains expertise and design data relating to nuclear weapons. We therefore judge that if Iraq obtained fissile material and other essential components from foreign sources the timeline for production of a nuclear weapon would be shortened and Iraq could produce a nuclear weapon in between one and two years.

BALLISTIC MISSILES

Joint Intelligence Committee (JIC) Assessment: 1999–2002

24. In mid-2001 the JIC drew attention to what it described as a "step-change" in progress on the Iraqi missile programme over the previous two years. It was clear from intelligence that the range of Iraqi missiles which was permitted by the UN and supposedly limited to 150kms was being extended and that work was under way on larger engines for longer-range missiles.

25. In early 2002 the JIC concluded that Iraq had begun to develop missiles with a range of over 1,000kms. The JIC assessed that if sanctions remained effective the Iraqis would not be able to produce such a missile before 2007. Sanctions and the earlier work of the inspectors had caused significant problems for Iraqi missile development. In the previous six months Iraqi foreign procurement efforts for the missile programme had been bolder. The JIC also assessed that Iraq retained up to 20 al-Hussein missiles from before the Gulf War.

The Iraqi ballistic missile programme since 1998

26. Since the Gulf War, Iraq has been openly developing two short-range missiles up to a range of 150km, which are permitted under UN Security Council Resolution 687. The al-Samoud liquid propellant missile has been extensively tested and is being deployed to military units. Intelligence indicates that at least 50 have been produced. Intelligence also indicates that Iraq has worked on extending its range to at least 200km in breach of UN Security Resolution 687. Production of the solid propellant Ababil-100 (Figure 4) is also underway, probably as an unguided rocket at this stage. There are also plans to extend its range to at least 200km. Compared to liquid propellant missiles, those powered by solid

FIGURE 4: ABABIL-100

propellant offer greater ease of storage, handling and mobility. They are also quicker to take into and out of action and can stay at a high state of readiness for longer periods.

27. According to intelligence, Iraq has retained up to 20 al-Hussein missiles (Figure 5), in breach of UN Security Council Resolution 687. These missiles were either hidden from the UN as complete systems, or re-assembled using illegally retained engines and other components. We judge that the engineering expertise available would allow these missiles to be maintained effectively, although the fact that at least some require re-assembly makes it difficult to judge exactly how many could be available for use. They could be used with conventional, chemical or biological warheads and, with a range of up to 650km, are capable of reaching a number of countries in the region including Cyprus, Turkey, Saudi Arabia, Iran and Israel.

FIGURE 5: AL-HUSSEIN

28. Intelligence has confirmed that Iraq wants to extend the range of its missile systems to over 1000km, enabling it to threaten other regional neighbours. This work began in 1998, although efforts to regenerate the long-range ballistic missile programme probably began in 1995. Iraq's missile programmes employ hundreds of people. Satellite imagery (Figure 6) has shown a new engine test stand being constructed (A), which is larger than the current one used for al-Samoud (B), and that formerly used for testing SCUD engines (C) which was dismantled under UNSCOM supervision. This new stand will be capable of testing engines for medium range ballistic missiles (MRBMs) with ranges over 1000km, which are not permitted under UN Security Council Resolution 687. Such a facility would not be needed for systems that fall within the UN permitted range of 150km. The Iraqis have recently taken measures to conceal activities at this site. Iraq is also working to obtain improved guidance technology to increase missile accuracy.

FIGURE 6: AL-RAFAH/SHAHIYAT LIQUID PROPELLANT ENGINE STATIC TEST STAND

29. The success of UN restrictions means the development of new longer-range missiles is likely to be a slow process. These restrictions impact particularly on the:

- availability of foreign expertise;
- conduct of test flights to ranges above 150km;
- acquisition of guidance and control technology.

30. Saddam remains committed to developing longer-range missiles. Even if sanctions remain effective, Iraq might achieve a missile capability of over 1000km within 5 years (Figure 7 shows the range of Iraq's various missiles).

31. Iraq has managed to rebuild much of the missile production infrastructure destroyed in the Gulf War and in Operation Desert Fox in 1998 (see Part 2). New missile-related infrastructure is also under construction. Some aspects of this, including rocket propellant mixing and casting facilities at the al-Mamoun Plant, appear to replicate those linked to the prohibited Badr-2000 programme (with a planned range of 700–1000km) which were destroyed in the Gulf War or dismantled by UNSCOM. A new plant at al-Mamoun for indigenously producing ammonium perchlorate, which is a key ingredient in the production of solid propellant rocket motors, has also been constructed. This has been provided illicitly by NEC Engineers Private Limited, an Indian chemical engineering firm with extensive links in Iraq, including to other suspect facilities such as the Fallujah 2 chlorine plant. After an extensive investigation, the Indian authorities have recently suspended its export licence, although other individuals and companies are still illicitly procuring for Iraq.

32. Despite a UN embargo, Iraq has also made concerted efforts to acquire additional production technology, including machine tools and raw materials, in breach of UN Security Council Resolution 1051. The embargo has succeeded in blocking many of these attempts, such as requests to buy magnesium powder and ammonium chloride. But we know from intelligence that some items have found their way to the Iraqi ballistic missile programme. More will inevitably continue to do so. Intelligence makes it clear that Iraqi procurement agents and front companies in third countries are seeking illicitly to acquire propellant chemicals for Iraq's ballistic missiles. This includes production level quantities of near complete sets of solid propellant rocket motor ingredients such as aluminium powder, ammonium perchlorate and hydroxyl terminated polybutadiene. There have also been attempts to acquire large quantities of liquid propellant chemicals such as Unsymmetrical Dimethylhydrazine (UDMH) and diethylenetriamene. We judge these are intended to support production and deployment of the al-Samoud and development of longer-range systems.

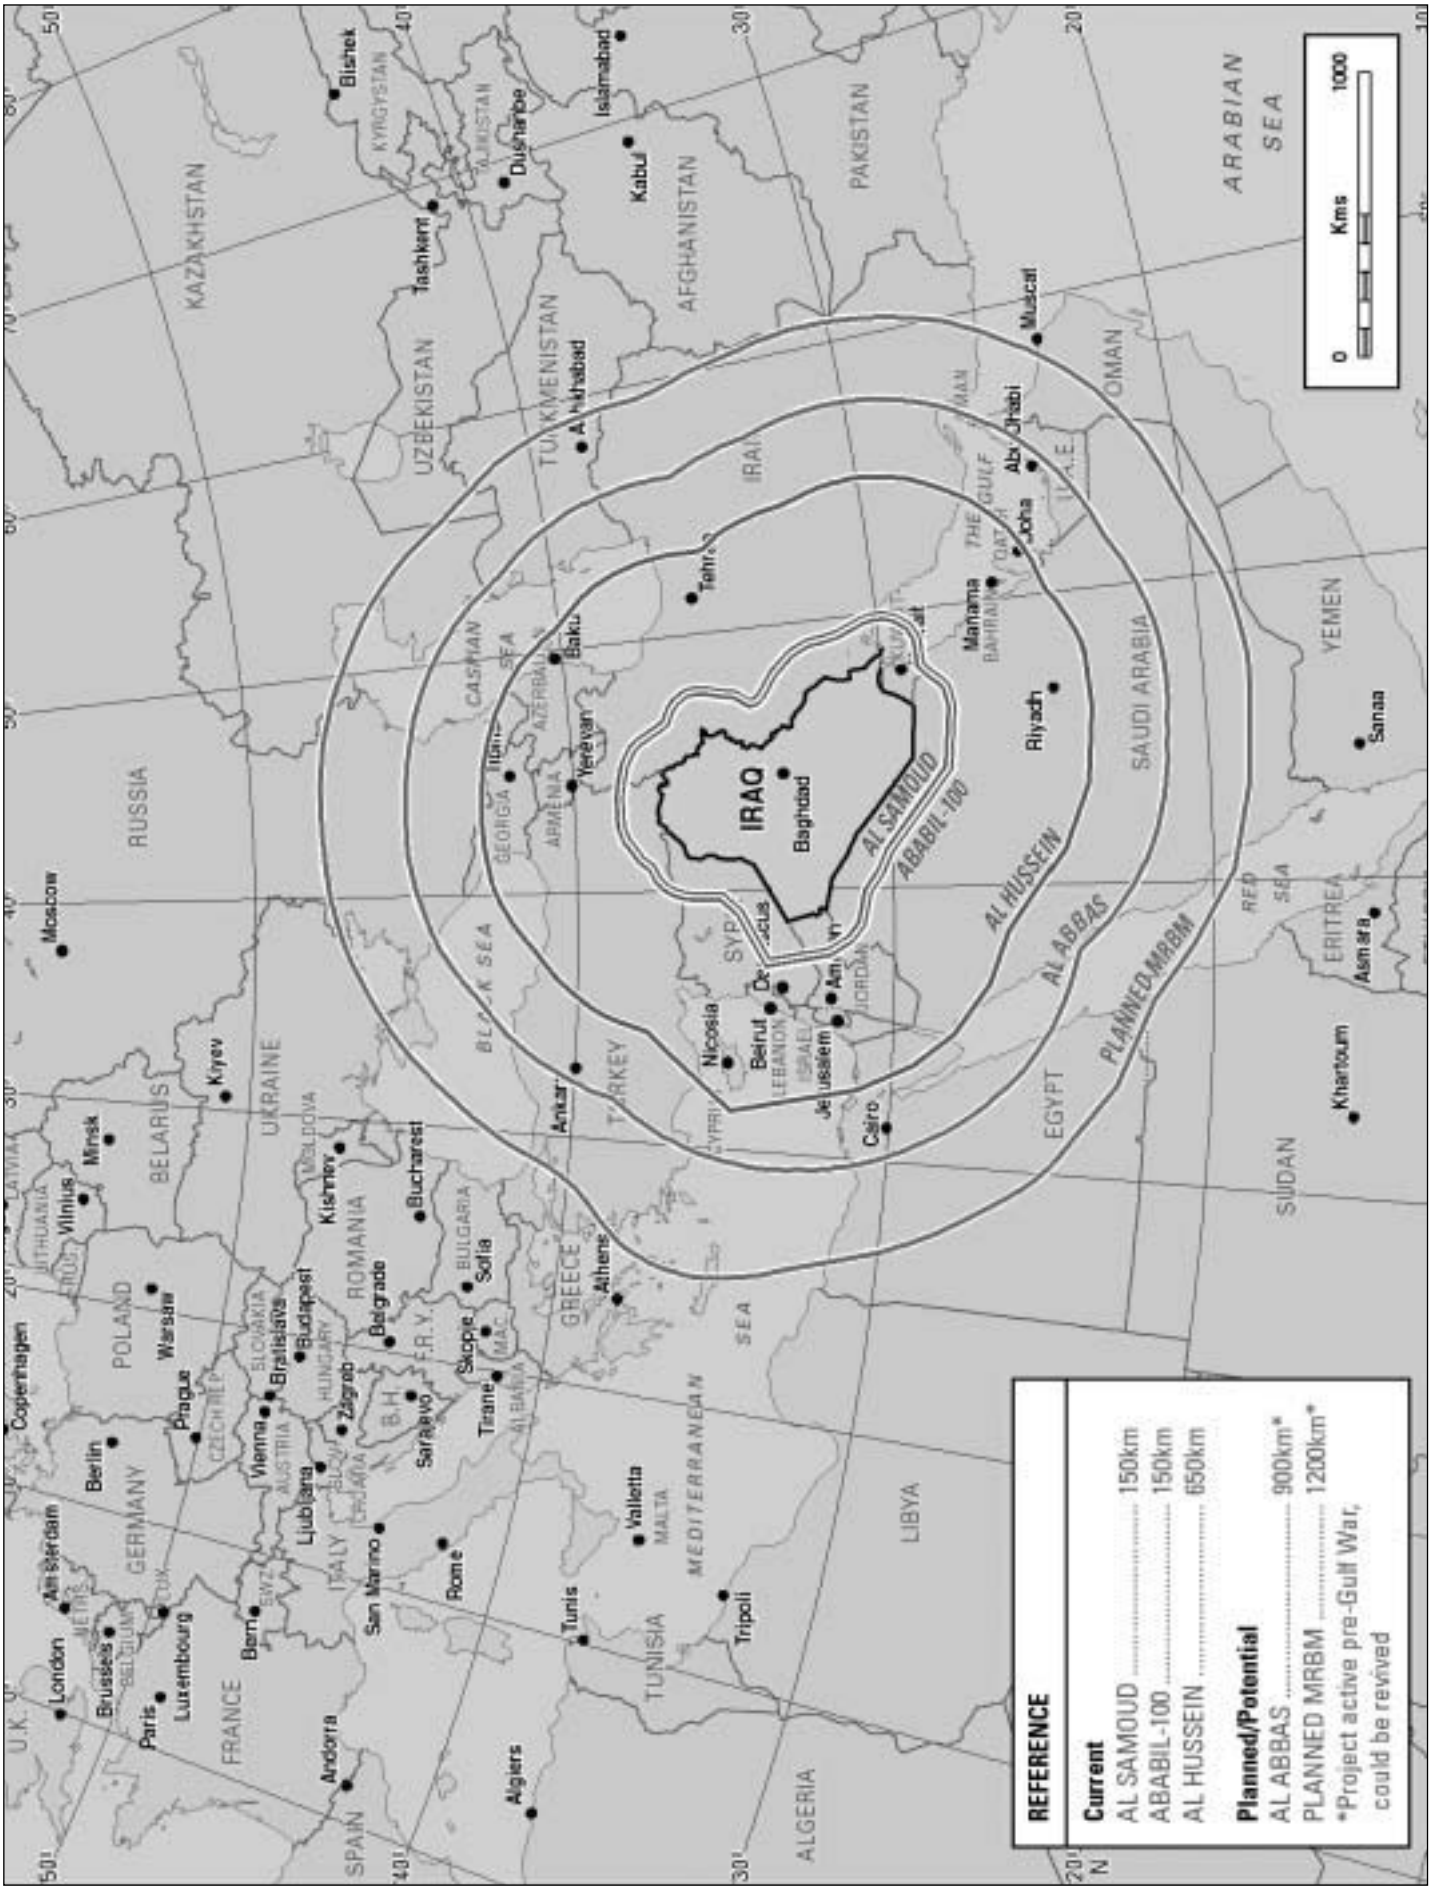

FIGURE 7: CURRENT AND PLANNED/POTENTIAL BALLISTIC MISSILES

FUNDING FOR THE WMD PROGRAMME

33. The UN has sought to restrict Iraq's ability to generate funds for its chemical, biological and other military programmes. For example, Iraq earns money legally under the UN Oil For Food Programme (OFF) established by UNSCR 986, whereby the proceeds of oil sold through the UN are used to buy humanitarian supplies for Iraq. This money remains under UN control and cannot be used for military procurement. However, the Iraqi regime continues to generate income outside UN control either in the form of hard currency or barter goods (which in turn means existing Iraqi funds are freed up to be spent on other things).

UN Sanctions

UN sanctions on Iraq prohibit all imports to and exports from Iraq. The UN must clear any goods entering or leaving. The UN also administers the Oil for Food (OFF) programme. Any imports entering Iraq under the OFF programme are checked against the Goods Review List for potential military or weapons of mass destruction utility.

34. These illicit earnings go to the Iraqi regime. They are used for building new palaces, as well as purchasing luxury goods and other civilian goods outside the OFF programme. Some of these funds are also used by Saddam Hussein to maintain his armed forces, and to develop or acquire military equipment, including for chemical, biological, nuclear and ballistic missile programmes. We do not know what proportion of these funds is used in this way. But we have seen no evidence that Iraqi attempts to develop its weapons of mass destruction and its ballistic missile programme, for example through covert procurement of equipment from abroad, has been inhibited in any way by lack of funds. The steady increase over the last three years in the availability of funds will enable Saddam to progress the programmes faster.

Iraq's illicit earnings

Year	Amount in $billions
1999	0.8 to 1
2000	1.5 to 2
2001	3
2002	3 (estimate)

PART 2

HISTORY OF UN WEAPONS INSPECTIONS

1. During the 1990s, beginning in April 1991 immediately after the end of the Gulf War, the UN Security Council passed a series of resolutions [see box] establishing the authority of UNSCOM and the IAEA to carry out the work of dismantling Iraq's arsenal of chemical, biological and nuclear weapons programmes and long-range ballistic missiles.

> **UN Security Council Resolutions relating to Weapons of Mass Destruction**
>
> **UNSCR 687, April 1991** created the UN Special Commission (UNSCOM) and required Iraq to accept, unconditionally, "the destruction, removal or rendering harmless, under international supervision" of its chemical and biological weapons, ballistic missiles with a range greater than 150km, and their associated programmes, stocks, components, research and facilities. The International Atomic Energy Agency (IAEA) was charged with abolition of Iraq's nuclear weapons programme. UNSCOM and the IAEA must report that their mission has been achieved before the Security Council can end sanctions. They have not yet done so.
>
> **UNSCR 707, August 1991,** stated that Iraq must provide full, final and complete disclosure of all its programmes for weapons of mass destruction and provide unconditional and unrestricted access to UN inspectors. For over a decade Iraq has been in breach of this resolution. Iraq must also cease all nuclear activities of any kind other than civil use of isotopes.
>
> **UNSCR 715, October 1991** approved plans prepared by UNSCOM and IAEA for the ongoing monitoring and verification (OMV) arrangements to implement UNSCR 687. Iraq did not accede to this until November 1993. OMV was conducted from April 1995 to 15 December 1998, when the UN left Iraq.
>
> **UNSCR 1051, March 1996** stated that Iraq must declare the shipment of dual-use goods which could be used for mass destruction weaponry programmes.

These resolutions were passed under Chapter VII of the UN Charter which is the instrument that allows the UN Security Council to authorise the use of military force to enforce its resolutions.

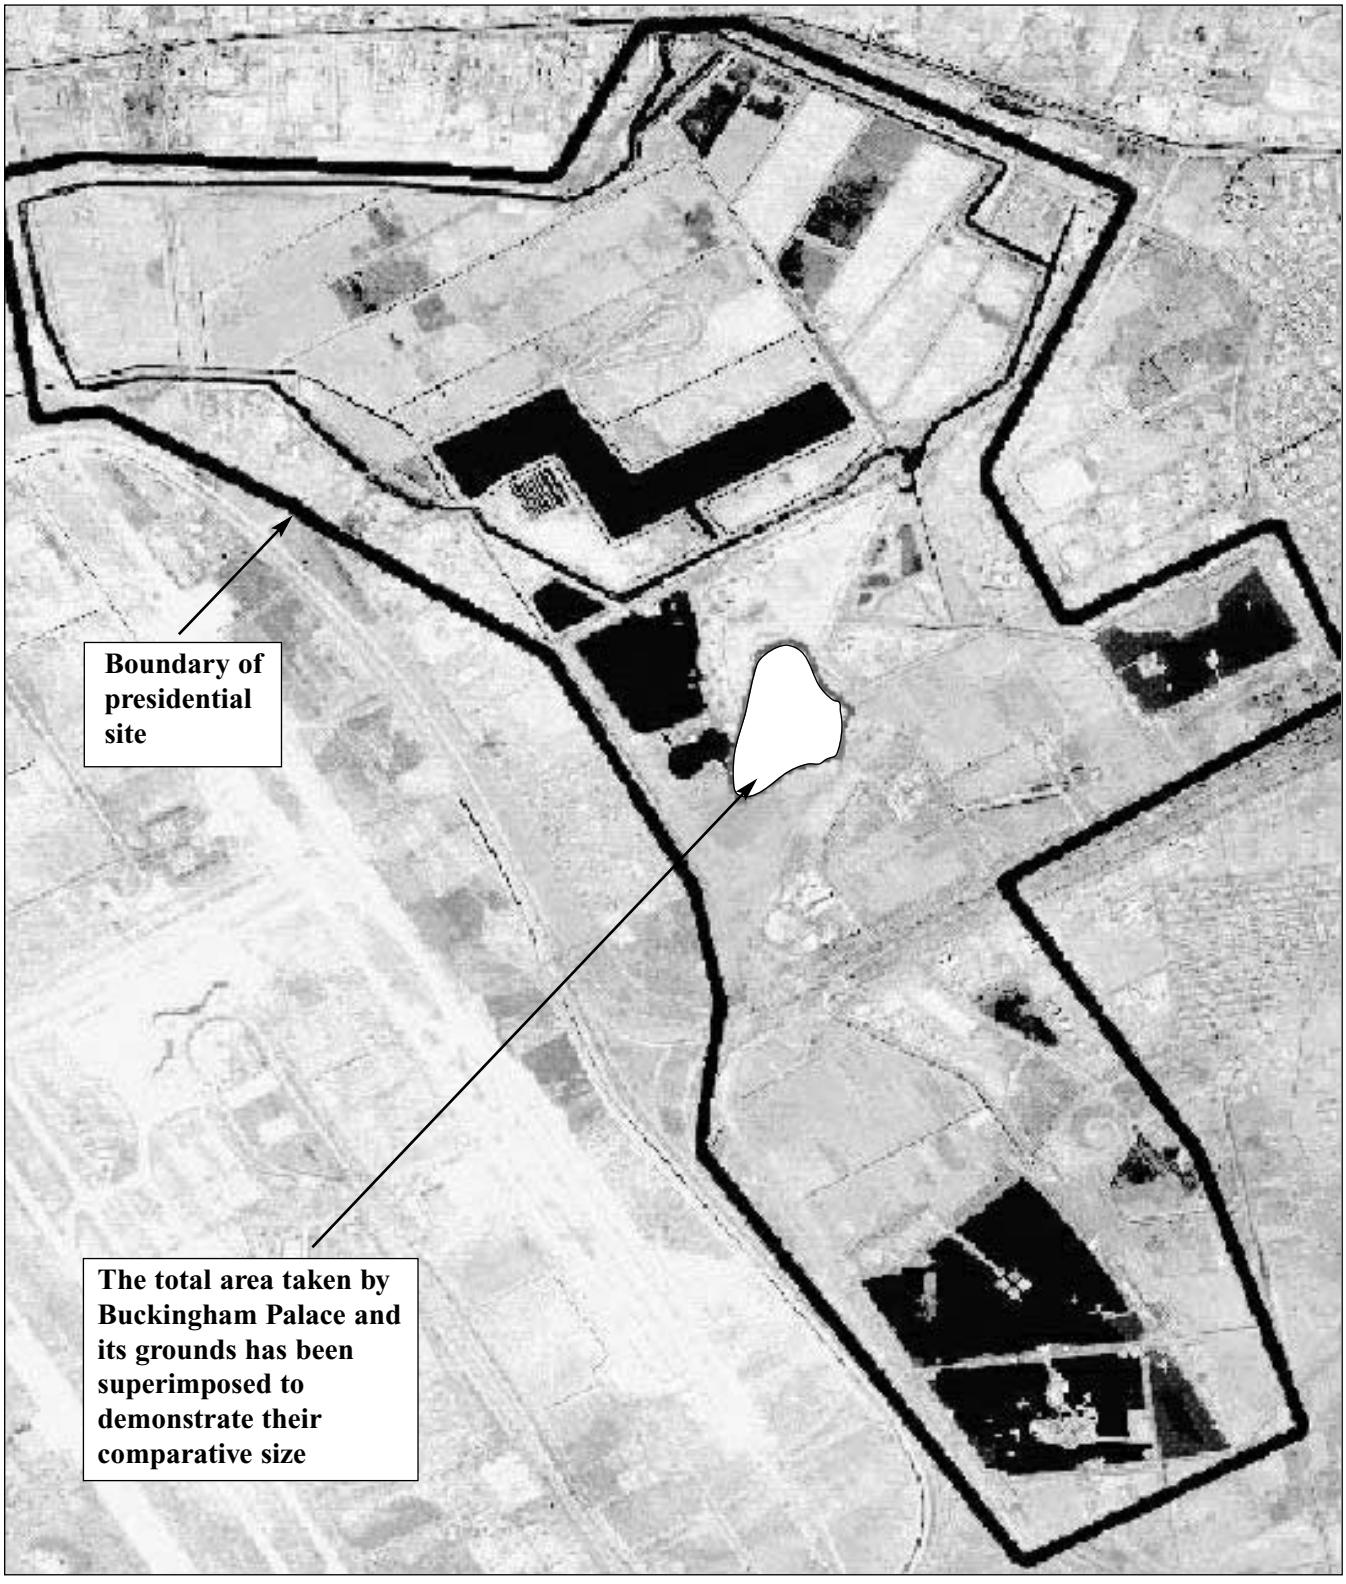
2. As outlined in UNSCR 687, Iraq's chemical, biological and nuclear weapons programmes were also a breach of Iraq's commitments under:

   - The 1925 Geneva Protocol which bans the use of chemical and biological weapons;

- the Biological and Toxin Weapons Convention which bans the development, production, stockpiling, acquisition or retention of biological weapons;
- the Nuclear Non-Proliferation Treaty which prohibits Iraq from manufacturing or otherwise acquiring nuclear weapons.

3. UNSCR 687 obliged Iraq to provide declarations on all aspects of its weapons of mass destruction programmes within 15 days and accept the destruction, removal or rendering harmless under international supervision of its chemical, biological and nuclear programmes, and all ballistic missiles with a range beyond 150km. Iraq did not make a satisfactory declaration within the specified time-frame.

   Iraq accepted the UNSCRs and agreed to co-operate with UNSCOM. The history of the UN weapons inspections was characterised by persistent Iraqi obstruction.



> UNSCOM and the IAEA were given the remit to designate any locations for inspection at any time, review any document and interview any scientist, technician or other individual and seize any prohibited items for destruction.

Iraqi Non-Co-operation with the Inspectors

4. The former Chairman of UNSCOM, Richard Butler, reported to the UN Security Council in January 1999 that in 1991 a decision was taken by a high-level Iraqi Government committee to provide inspectors with only a portion of its proscribed weapons, components, production capabilities and stocks. UNSCOM concluded that Iraqi policy was based on the following actions:
   - to provide only a portion of extant weapons stocks, releasing for destruction only those that were least modern;
   - to retain the production capability and documentation necessary to revive programmes when possible;
   - to conceal the full extent of its chemical weapons programme, including the VX nerve agent project; to conceal the number and type of chemical and biological warheads for proscribed long-range missiles;
   - and to conceal the existence of its biological weapons programme.

5. In December 1997 Richard Butler reported to the UN Security Council that Iraq had created a new category of sites, “Presidential” and “sovereign”, from which it claimed that UNSCOM inspectors would henceforth be barred. The terms of the ceasefire in 1991 foresaw no such limitation. However, Iraq consistently refused to allow UNSCOM inspectors access to any of these eight Presidential sites. Many of these so-called “palaces” are in fact large compounds which are an integral part of Iraqi counter-measures designed to hide weapons material (see photograph on p35).

A photograph of a "presidential site" or what have been called "palaces".

Iraq's policy of deception

Iraq has admitted to UNSCOM to having a large, effective, system for hiding proscribed material including documentation, components, production equipment and possibly biological and chemical agents and weapons from the UN. Shortly after the adoption of UNSCR 687 in April 1991, an Administrative Security Committee (ASC) was formed with responsibility for advising Saddam on the information which could be released to UNSCOM and the IAEA. The Committee consisted of senior Military Industrial Commission (MIC) scientists from all of Iraq's weapons of mass destruction programmes. The Higher Security Committee (HSC) of the Presidential Office was in overall command of deception operations. The system was directed from the very highest political levels within the Presidential Office and involved, if not Saddam himself, his youngest son, Qusai. The system for hiding proscribed material relies on high mobility and good command and control. It uses lorries to move items at short notice and most hide sites appear to be located close to good road links and telecommunications. The Baghdad area was particularly favoured. In addition to active measures to hide material from the UN, Iraq has attempted to monitor, delay and collect intelligence on UN operations to aid its overall deception plan.

Intimidation

6. Once inspectors had arrived in Iraq, it quickly became apparent that the Iraqis would resort to a range of measures (including physical threats and psychological intimidation of inspectors) to prevent UNSCOM and the IAEA from fulfilling their mandate.

7. In response to such incidents, the President of the Security Council issued frequent statements calling on Iraq to comply with its disarmament and monitoring obligations.

Iraqi obstruction of UN weapons inspection teams

- firing warning shots in the air to prevent IAEA inspectors from intercepting nuclear related equipment (June 1991);
- keeping IAEA inspectors in a car park for 4 days and refusing to allow them to leave with incriminating documents on Iraq's nuclear weapons programme (September 1991);
- announcing that UN monitoring and verification plans were "unlawful" (October 1991);
- refusing UNSCOM inspectors access to the Iraqi Ministry of Agriculture. Threats were made to inspectors who remained on watch outside the building. The inspection team had reliable evidence that the site contained archives related to proscribed activities;
- in 1991–2 Iraq objected to UNSCOM using its own helicopters and choosing its own flight plans. In January 1993 it refused to allow UNSCOM the use of its own aircraft to fly into Iraq;
- refusing to allow UNSCOM to install remote-controlled monitoring cameras at two key missile sites (June-July 1993);
- repeatedly denying access to inspection teams (1991- December 1998);
- interfering with UNSCOM's helicopter operations, threatening the safety of the aircraft and their crews (June 1997);
- demanding the end of U2 overflights and the withdrawal of US UNSCOM staff (October 1997);
- destroying documentary evidence of programmes for weapons of mass destruction (September 1997).

Obstruction

8. Iraq denied that it had pursued a biological weapons programme until July 1995. In July 1995, Iraq acknowledged that biological agents had been produced on an industrial scale at al-Hakam. Following the defection in August 1995 of Hussein Kamil, Saddam's son-in-law and former Director of the Military Industrialisation Commission, Iraq released over 2 million documents relating to its mass destruction weaponry programmes and acknowledged that it had

pursued a biological programme that led to the deployment of actual weapons. Iraq admitted producing 183 biological weapons with a reserve of agent to fill considerably more.

Inspection of Iraq's biological weapons programme

In the course of the first biological weapons inspection in August 1991, Iraq claimed that it had merely conducted a military biological research programme. At the site visited, al-Salman, Iraq had removed equipment, documents and even entire buildings. Later in the year, during a visit to the al-Hakam site, Iraq declared to UNSCOM inspectors that the facility was used as a factory to produce proteins derived from yeast to feed animals. Inspectors subsequently discovered that the plant was a central site for the production of anthrax spores and botulinum toxin for weapons. The factory had also been sanitised by Iraqi officials to deceive inspectors. Iraq continued to develop the al-Hakam site into the 1990s, misleading UNSCOM about its true purpose.

Another key site, the Foot and Mouth Disease Vaccine Institute at al-Dawrah which produced botulinum toxin and probably anthrax was not divulged as part of the programme. Five years later, after intense pressure, Iraq acknowledged that tens of tonnes of bacteriological warfare agent had been produced there and at al-Hakam.

As documents recovered in August 1995 were assessed, it became apparent that the full disclosure required by the UN was far from complete. Successive inspection teams went to Iraq to try to gain greater understanding of the programme and to obtain credible supporting evidence. In July 1996 Iraq refused to discuss its past programme and doctrine forcing the team to withdraw in protest. Monitoring teams were at the same time finding undisclosed equipment and materials associated with the past programme. In response, Iraq grudgingly provided successive disclosures of its programme which were judged by UNSCOM and specially convened international panels to be technically inadequate.

In late 1995 Iraq acknowledged weapons testing the biological agent ricin, but did not provide production information. Two years later, in early 1997, UNSCOM discovered evidence that Iraq had produced ricin.

9. Iraq tried to obstruct UNSCOM's efforts to investigate the scale of its biological weapons programme. It created forged documents to account for bacterial growth media, imported in the late 1980s, specifically for the production of anthrax, botulinum toxin and probably plague. The documents were created to indicate that the material had been imported by the State Company for Drugs and Medical Appliances Marketing for use in hospitals and distribution to local authorities. Iraq also censored documents and scientific papers provided to the first UN inspection team, removing all references to key individuals, weapons and industrial production of agents.

10. Iraq has yet to provide any documents concerning production of agent and subsequent weaponisation. Iraq destroyed, unilaterally and illegally, some biological weapons in 1991 and 1992 making accounting for these weapons impossible. In addition, Iraq cleansed a key site at al-Muthanna, its main research and development, production and weaponisation facility for chemical warfare agents, of all evidence of a biological programme in the toxicology department, the animal-house and weapons filling station.

11. Iraq refused to elaborate further on the programme during inspections in 1997 and 1998, confining discussion to previous topics. In July 1998 Tariq Aziz personally intervened in the inspection process stating that the biological programme was more secret and more closed than other mass destruction weaponry programmes. He also played down the significance of the programme. Iraq has presented the biological weapons programme as the personal undertaking of a few misguided scientists.

12. At the same time, Iraq tried to maintain its nuclear weapons programme via a concerted campaign to deceive IAEA inspectors. In 1997 the IAEA Director General stated that the IAEA was "severely hampered by Iraq's persistence in a policy of concealment and understatement of the programme's scope".

Inspection achievements

13. Despite the conduct of the Iraqi authorities towards them, both UNSCOM and the IAEA Action Team have valuable records of achievement in discovering and exposing Iraq's biological weapons programme and destroying very large quantities of chemical weapons stocks and missiles as well as the infrastructure for Iraq's nuclear weapons programme.

14. Despite UNSCOM's efforts, following the effective ejection of UN inspectors in December 1998 there remained a series of significant unresolved disarmament issues. In summarising the situation in a report to the UN Security Council, the UNSCOM Chairman, Richard Butler, indicated that:

    - contrary to the requirement that destruction be conducted under international supervision "Iraq undertook extensive, unilateral and secret destruction of large quantities of proscribed weapons and items";
    - and Iraq "also pursued a practice of concealment of proscribed items, including weapons, and a cover up of its activities in contravention of Council resolutions".

    Overall, Richard Butler declared that obstructive Iraqi activity had had "a significant impact upon the Commission's disarmament work".

UNSCOM and IAEA achievements

UNSCOM surveyed 1015 sites in Iraq, carrying out 272 separate inspections. Despite Iraqi obstruction and intimidation, UN inspectors uncovered details of chemical, biological, nuclear and ballistic missile programmes. Major UNSCOM/IAEA achievements included:

- the destruction of 40,000 munitions for chemical weapons, 2,610 tonnes of chemical precursors and 411 tonnes of chemical warfare agent;
- the dismantling of Iraq's prime chemical weapons development and production complex at al-Muthanna and a range of key production equipment;
- the destruction of 48 SCUD-type missiles, 11 mobile launchers and 56 sites, 30 warheads filled with chemical agents, and 20 conventional warheads;
- the destruction of the al-Hakam biological weapons facility and a range of production equipment, seed stocks and growth media for biological weapons;
- the discovery in 1991 of samples of indigenously-produced highly enriched uranium, forcing Iraq's acknowledgement of uranium enrichment programmes and attempts to preserve key components of its prohibited nuclear weapons programme;
- the removal and destruction of the infrastructure for the nuclear weapons programme, including the al-Athir weaponisation/testing facility.

Withdrawal of the inspectors

15. By the end of 1998 UNSCOM was in direct confrontation with the Iraqi Government which was refusing to co-operate. The US and the UK had made clear that anything short of full co-operation would make military action unavoidable. Richard Butler was requested to report to the UN Security Council in December 1998 and stated that, following a series of direct confrontations, coupled with the systematic refusal by Iraq to co-operate, UNSCOM was no longer able to perform its disarmament mandate. As a direct result on 16 December the weapons inspectors were withdrawn. Operation Desert Fox was launched by the US and the UK a few hours afterwards.

Operation Desert Fox (16–19 December 1998)

Operation Desert Fox targeted industrial facilities related to Iraq's ballistic missile programme and a suspect biological warfare facility as well as military airfields and sites used by Iraq's security organisations which are involved in its weapons of mass destruction programmes. Key facilities associated with Saddam Hussein's ballistic missile programme were significantly degraded.

The situation since 1998

16. There have been no UN-mandated weapons inspections in Iraq since 1998. In an effort to enforce Iraqi compliance with its disarmament and monitoring obligations, the UN Security Council passed Resolution 1284 in December 1999. This established the United Nations Monitoring, Verification and Inspection Commission (UNMOVIC) as a successor organisation to UNSCOM and called on Iraq to give UNMOVIC inspectors "immediate, unconditional and unrestricted access to any and all areas, facilities, equipment, records and means of transport". It also set out the steps Iraq needed to take in return for the eventual suspension and lifting of sanctions. A key measure of Iraqi compliance would be full co-operation with UN inspectors, including unconditional, immediate and unrestricted access to any and all sites, personnel and documents.

17. For the past three years, Iraq has allowed the IAEA to carry out an annual inspection of a stockpile of nuclear material (depleted natural and low-enriched uranium). This has led some countries and western commentators to conclude erroneously that Iraq is meeting its nuclear disarmament and monitoring obligations. As the IAEA has pointed out in recent weeks, this annual inspection does "not serve as a substitute for the verification activities required by the relevant resolutions of the UN Security Council".

18. Dr Hans Blix, the Executive Chairman of UNMOVIC, and Dr Mohammed El-Baradei, the Director General of the IAEA, have declared that in the absence of inspections it is impossible to verify Iraqi compliance with its UN disarmament and monitoring obligations. In April 1999 an independent UN panel of experts noted that "the longer inspection and monitoring activities remain suspended, the more difficult the comprehensive implementation of Security Council resolutions becomes, increasing the risk that Iraq might reconstitute its proscribed weapons programmes".

19. The departure of the inspectors greatly diminished the ability of the international community to monitor and assess Iraq's continuing attempts to reconstitute its chemical, biological, nuclear and ballistic missile programmes.

PART 3

IRAQ UNDER SADDAM HUSSEIN

Introduction

1. The Republic of Iraq is bounded by Turkey, Iran, Kuwait, Saudia Arabia, Jordan, Syria and the Persian Gulf. Its population of around 23 million is ethnically and religiously diverse. Approximately 77% are Arabs. Sunni Muslims form around 17% of the Arab population and dominate the government. About 60% of Iraqis are Shias and 20% are Kurds. The remaining 3% of the population consists of Assyrians, Turkomans, Armenians, Christians and Yazidis.

> **Saddam Hussein's rise to power**
>
> Saddam Hussein was born in 1937 in the Tikrit district, north of Baghdad. In 1957 he joined the Ba'ath Party. After taking part in a failed attempt to assassinate the Iraqi President, Abdul Karim Qasim, Saddam escaped, first to Syria and then to Egypt. In his absence he was sentenced to 15 years imprisonment.
>
> Saddam returned to Baghdad in 1963 when the Ba'ath Party came to power. He went into hiding after the Ba'ath fell from power later that year. He was captured and imprisoned, but in 1967 escaped and took over responsibility for Ba'ath security. Saddam set about imposing his will on the Party and establishing himself at the centre of power.
>
> The Ba'ath Party returned to power in 1968. In 1969 Saddam became Vice-Chairman of the Revolutionary Command Council, Deputy to the President, and Deputy Secretary General of the Regional Command of the Ba'ath. In 1970 he joined the Party's National Command and in 1977 was elected Assistant Secretary General. In July 1979, he took over the Presidency of Iraq. Within days, five fellow members of the Revolutionary Command Council were accused of involvement in a coup attempt. They and 17 others were summarily executed.

2. Public life in Iraq is nominally dominated by the Ba'ath Party (see box on p44). But all real authority rests with Saddam and his immediate circle. Saddam's family, tribe and a small number of associates remain his most loyal supporters. He uses them to convey his orders, including to members of the government.

3. Saddam uses patronage and violence to motivate his supporters and to control or eliminate opposition. Potential rewards include social status, money and better access to goods. Saddam's extensive security apparatus and Ba'ath Party network provides oversight of Iraqi society, with informants in social, government and military organisations. Saddam practises torture, execution and

other forms of coercion against his enemies, real or suspected. His targets are not only those who have offended him, but also their families, friends or colleagues.

The Iraqi Ba'ath Party

The Ba'ath Party is the only legal political party in Iraq. It pervades all aspects of Iraqi life. Membership, around 700,000, is necessary for self-advancement and confers benefits from the regime.

4. Saddam acts to ensure that there are no other centres of power in Iraq. He has crushed parties and ethnic groups, such as the communists and the Kurds, which might try to assert themselves. Members of the opposition abroad have been the targets of assassination attempts conducted by Iraqi security services.

Saddam Hussein's security apparatus

Saddam relies on a long list of security organisations with overlapping responsibilities. The main ones are:

- The **Special Security Organisation** oversees Saddam's security and monitors the loyalty of other security services. Its recruits are predominantly from Tikrit.
- The **Special Republican Guard** is equipped with the best available military equipment. Its members are selected on the basis of loyalty to the regime.
- The **Directorate of General Security** is primarily responsible for countering threats from the civilian population.
- The **Directorate of General Intelligence** monitors and suppresses dissident activities at home and abroad.
- The **Directorate of Military Intelligence's** role includes the investigation of military personnel.
- The **Saddam Fidayeen**, under the control of Saddam's son Udayy, has been used to deal with civil disturbances.

5. Army officers are an important part of the Iraqi government's network of informers. Suspicion that officers have ambitions other than the service of the President leads to immediate execution. It is routine for Saddam to take pre-emptive action against those who he believes might conspire against him.

Internal Repression – the Kurds and the Shias

6. Saddam has pursued a long-term programme of persecution of the Iraqi Kurds, including through the use of chemical weapons. During the Iran-Iraq war, Saddam appointed his cousin, Ali Hasan al-Majid, as his deputy in the north. In

1987-88, al-Majid led the "Anfal" campaign of attacks on Kurdish villages. Amnesty International estimates that more than 100,000 Kurds were killed or disappeared during this period.

Repression and control: some examples

- A campaign of mass arrests and killing of Shia activists led to the execution of the Ayatollah Baqir al-Sadr and his sister in April 1980.
- In 1983 80 members of another leading Shia family were arrested. Six of them, all religious leaders, were executed.
- A massive chemical weapons attack on Kurds in Halabja town in March 1988 killing 5000 and injuring 10,000 more.
- A large number of officers from the Jabbur tribe were executed in the early 1990s for the alleged disloyalty of a few of them.

7. After the Gulf War in 1991 Kurds in the north of Iraq rose up against Baghdad's rule. In response the Iraqi regime killed or imprisoned thousands, prompting a humanitarian crisis. Over a million Kurds fled into the mountains and tried to escape Iraq.

8. Persecution of Iraq's Kurds continues, although the protection provided by the northern No-Fly Zone has helped to curb the worst excesses. But outside this zone the Baghdad regime has continued a policy of persecution and intimidation.

9. The regime has used chemical weapons against the Kurds, most notably in an attack on the town of Halabja in 1988 (see Part 1 Chapter 2 paragraph 9). The implicit threat of the use of chemical weapons against the Kurds and others is an important part of Saddam's attempt to keep the civilian population under control.

10. The regime has tried to displace the traditional Kurdish and Turkoman populations of the areas under its control, primarily in order to weaken Kurdish claims to the oil-rich area around the northern city of Kirkuk. Kurds and other non-Arabs are forcibly ejected to the three northern Iraqi governorates, Dohuk, Arbil and Sulaimaniyah, which are under de facto Kurdish control. According to the United Nations Commission on Human Rights (UNCHR) Special Rapporteur for Iraq, 94,000 individuals have been expelled since 1991. Agricultural land owned by Kurds has been confiscated and redistributed to Iraqi Arabs. Arabs from southern Iraq have been offered incentives to move into the Kirkuk area.

11. After the 1979 revolution that ousted the Shah in Iran, Saddam intensified a campaign against the Shia Muslim majority of Iraq, fearing that they might be encouraged by the new Shia regime in Iran.

12. On 1 March 1991, in the wake of the Gulf War, riots broke out in the southern city of Basra, spreading quickly to other cities in Shia-dominated southern Iraq.

The regime responded by killing thousands. Many Shia tried to escape to Iran and Saudi Arabia.

13. Some of the Shia hostile to the regime sought refuge in the marshland of southern Iraq. In order to subjugate the area, Saddam embarked on a large-scale programme to drain the marshes to allow Iraqi ground forces to eliminate all opposition there. The rural population of the area fled or were forced to move to southern cities or across the border into Iran.

Saddam Hussein's Wars

14. As well as ensuring his absolute control inside Iraq, Saddam has tried to make Iraq the dominant power of the region. In pursuit of these objectives he has led Iraq into two wars of aggression against neighbours, the Iran-Iraq war and the invasion of Kuwait.

15. With the fall of the Shah in Iran in 1979, relations between Iran and Iraq deteriorated sharply. In September 1980 Saddam renounced a border treaty he had agreed with Iran in 1975 ceding half of the Shatt al-Arab waterway to Iran. Shortly thereafter, Saddam launched a large-scale invasion of Iran. He believed that he could take advantage of the state of weakness, isolation and disorganisation he perceived in post-revolutionary Iran. He aimed to seize territory, including that ceded to Iran a few years earlier, and to assert Iraq's position as a leader of the Arab world. Saddam expected it to be a short, sharp campaign. But the conflict lasted for eight years. Iraq fired over 500 ballistic missiles at Iranian targets, including major cities.

Opposition to Saddam during the Iran-Iraq war

During the war Saddam's security apparatus ensured that any internal dissent or opposition was quickly eliminated. In 1982 he quickly purged a group within Iraq's ruling clique which had suggested that the war might be brought to an end more quickly if Saddam stood down.

16. It is estimated that the Iran-Iraq war cost the two sides a million casualties. Iraq used chemical weapons extensively from 1984. Some twenty thousand Iranians were killed by mustard gas and the nerve agents tabun and sarin, all of which Iraq still possesses. The UN Security Council considered the report prepared by a team of three specialists appointed by the UN Secretary General in March 1986, following which the President made a statement condemning Iraqi use of chemical weapons. This marked the first time a country had been named for violating the 1925 Geneva Convention banning the use of chemical weapons.

17. The cost of the war ran into hundreds of billions of dollars for both sides. Iraq gained nothing. After the war ended, Saddam resumed his previous pursuit of primacy in the Gulf. His policies involved spending huge sums of money on new

military equipment. But Iraq was burdened by debt incurred during the war and the price of oil, Iraq's only major export, was low.

18. By 1990 Iraq's financial problems were severe. Saddam looked at ways to press the oil-producing states of the Gulf to force up the price of crude oil by limiting production and waive the $40 billion that they had loaned Iraq during its war with Iran. Kuwait had made some concessions over production ceilings. But Saddam blamed Kuwait for over-production. When his threats and blandishments failed, Iraq invaded Kuwait on 2 August 1990. He believed that occupying Kuwait could prove profitable.

Abuses by Iraqi forces in Kuwait

- Robbery and rape of Kuwaitis and expatriates.
- Summary executions.
- People dragged from their homes and held in improvised detention centres.
- Amnesty International has listed 38 methods of torture used by the Iraqi occupiers. These included beatings, breaking of limbs, extracting finger and toenails, inserting bottle necks into the rectum, and subjecting detainees to mock executions.
- Kuwaiti civilians arrested for "crimes" such as wearing beards.

19. Saddam also sought to justify the conquest of Kuwait on other grounds. Like other Iraqi leaders before him, he claimed that, as Kuwait's rulers had come under the jurisdiction of the governors of Basra in the time of the Ottoman Empire, Kuwait should belong to Iraq.

20. During its occupation of Kuwait, Iraq denied access to the Red Cross, which has a mandate to provide protection and assistance to civilians affected by international armed conflict. The death penalty was imposed for relatively minor "crimes" such as looting and hoarding food.

21. In an attempt to deter military action to expel it from Kuwait, the Iraqi regime took hostage several hundred foreign nationals (including children) in Iraq and Kuwait and prevented thousands more from leaving, in direct contravention of international humanitarian law. Hostages were held as human shields at a number of strategic military and civilian sites.

22. At the end of the Gulf War, the Iraqi army fleeing Kuwait set fire to over 1,160 Kuwaiti oil wells with serious environmental consequences.

23. More than 600 Kuwaiti and other prisoners of war and missing persons are still unaccounted for. Iraq refuses to comply with its UN obligation to account for the missing. It has provided sufficient information to close only three case-files.

Abuse of human rights

24. This section draws on reports of human rights abuses from authoritative international organisations, including Amnesty International and Human Rights Watch.

25. Human rights abuses continue within Iraq. People continue to be arrested and detained on suspicion of political or religious activities or often because they are related to members of the opposition. Executions are carried out without due process of law. Relatives are often prevented from burying the victims in accordance with Islamic practice. Thousands of prisoners have been executed.

Human rights: abuses under Saddam Hussein

- 4000 prisoners were executed at Abu Ghraib Prison in 1984.
- 3000 prisoners were executed at the Mahjar Prison between 1993 and 1998.
- About 2500 prisoners were executed between 1997 and 1999 in a "prison cleansing" campaign.
- 122 male prisoners were executed at Abu Ghraib prison in February/ March 2000. A further 23 political prisoners were executed there in October 2001.
- In October 2000 dozens of women accused of prostitution were beheaded without any judicial process. Some were accused for political reasons.
- Women prisoners at Mahjar are routinely raped by their guards.
- Methods of torture used in Iraqi jails include using electric drills to mutilate hands, pulling out fingernails, knife cuts, sexual attacks and 'official rape'.
- Prisoners at the Qurtiyya Prison in Baghdad and elsewhere are kept in metal boxes the size of tea chests. If they do not confess they are left to die.

26. Saddam has issued a series of decrees establishing severe penalties for criminal offences. These include amputation, branding, cutting off ears, and other forms of mutilation. Anyone found guilty of slandering the President has their tongue removed.

Human Rights – mistreatment in Abu Ghraib Prison

Abdallah, a member of the Ba'ath Party whose loyalty became suspect was imprisoned for four years at Abu Ghraib in the 1980s. On the second day of his imprisonment, the men were forced to walk between two rows of five guards each to receive their containers of food. While walking to get the food, they were beaten by the guards with plastic telephone cables. They had to return to their cells the same way, so that a walk to get breakfast resulted in twenty lashes. According to Abdallah, "It wasn't that bad going to get the food, but coming back the food was spilled when we were beaten." The same procedure was used when the men went to the bathroom. On the third day, the torture continued. "We were removed from our cells and beaten with plastic pipes. This surprised us, because we were asked no question. Possibly it was being done to break our morale", Abdallah speculated. The torture escalated to sixteen sessions daily. The treatment was organised and systematic. Abdallah was held alone in a 3x2-meter room that opened onto a corridor. "We were allowed to go to the toilet three times a day, then they reduced the toilet to once a day for only one minute. I went for four years without a shower or a wash", Abdallah said. He also learned to cope with the deprivation and the hunger that accompanied his detention: "I taught myself to drink a minimum amount of water because there was no placed to urinate. They used wooden sticks to beat us and sometimes the sticks would break. I found a piece of a stick, covered with blood, and managed to bring it back to my room. I ate it for three days. A person who is hungry can eat anything. Pieces of our bodies started falling off from the beatings and our skin was so dry that it began to fall off. I ate pieces of my own body. "No one, not Pushkin, not Mahfouz, can describe what happened to us. It is impossible to describe what living this day to day was like. I was totally naked the entire time. Half of the original groups [of about thirty men] died. It was a slow type of continuous physical and psychological torture. Sometimes, it seemed that orders came to kill one of us, and he would be beaten to death". *(Source: Human Rights Watch)*

Saddam Hussein's family

27. Saddam's son Udayy maintained a private torture chamber known as the Red Room in a building on the banks of the Tigris disguised as an electricity installation. He created a militia in 1994 which has used swords to execute victims outside their own homes. He has personally executed dissidents, for instance in the Shia uprising at Basra which followed the Gulf War.

28. Members of Saddam's family are also subject to persecution. A cousin of Saddam, Ala Abd al-Qadir al-Majid, fled to Jordan from Iraq citing disagreements with the regime over business matters. He returned to Iraq after the Iraqi Ambassador in Jordan declared publicly that his life was not in danger. He was met at the border by Tahir Habbush, Head of the Directorate of General Intelligence (the Mukhabarat), and taken to a farm owned by Ali Hasan al-Majid. At the farm Ala was tied to a tree and executed by members of his immediate family who, following orders from Saddam, took it in turns to shoot him

29. Some 40 of Saddam's relatives, including women and children, have been killed. His sons-in-law Hussein and Saddam Kamil had defected in 1995 and returned to Iraq from Jordan after the Iraqi government had announced amnesties for them. They were executed in February 1996.

Human Rights –individual testimony

In December 1996, a Kurdish businessman from Baghdad was arrested outside his house by plainclothes security men. Initially his family did not know his whereabouts and went from one police station to another inquiring about him. Then they found out that he was being held in the headquarters of the General Security Directorate in Baghdad. The family was not allowed to visit him. Eleven months later the family was told by the authorities that he had been executed and that they should go and collect his body. His body bore evident signs of torture. His eyes were gouged out and the empty eye sockets filled with paper. His right wrist and left leg were broken. The family was not given any reason for his arrest and subsequent execution. However, they suspected that he was executed because of his friendship with a retired army general who had links with the Iraqi opposition outside the country and who was arrested just before his arrest and also executed. *(Source: Amnesty International)*

Human Rights – individual testimony

"…I saw a friend of mine, al-Shaikh Nasser Taresh al-Sa'idi, naked. He was handcuffed and a piece of wood was placed between his elbows and his knees. Two ends of the wood were placed on two high chairs and al-Shaikh Nasser was being suspended like a chicken. This method of torture is known as al-Khaygania (a reference to a former security director known as al-Khaygani). An electric wire was attached to al-Shaikh Nasser's penis and another one attached to one of his toes. He was asked if he could identify me and he said "this is al-Shaikh Yahya". They took me to another room and then after about 10 minutes they stripped me of my clothes and a security officer said "the person you saw has confessed against you". He said to me "You followers of [Ayatollah] al-Sadr have carried out acts harmful to the security of the country and have been distributing anti-government statements coming from abroad". He asked if I have any contact with an Iraqi religious scholar based in Iran who has been signing these statements. I said "I do not have any contacts with him"… I was then left suspended in the same manner as al-Shaikh al-Sa'idi. My face was looking upward. They attached an electric wire on my penis and the other end of the wire is attached to an electric motor. One security man was hitting my feet with a cable. Electric shocks were applied every few minutes and were increased. I must have been suspended for more than an hour. I lost consciousness. They took me to another room and made me walk even though my feet were swollen from beating… They repeated this method a few times." *(Source: Amnesty International, testimony from an Iraqi theology student from Saddam City)*

US Nuclear Weapon Accidents

UNCLASSIFIED

Nuclear Weapon Accident--Definition

DOD Directive 5100.52

"An unexpected event involving nuclear weapons or nuclear components that results in any of the following:

(1) Accidental or unauthorized launching, firing, or use by U.S. forces or U.S. supported allied forces of a nuclear capable weapon system.

(2) An accidental, unauthorized, or unexplained nuclear detonation.

(3) Non-nuclear detonation or burning of a nuclear weapon or nuclear component.

(4) Radioactive contamination.

(5) Jettisoning of a nuclear weapon or nuclear component.

(6) Public hazard, actual or perceived."

UNCLASSIFIED

UNCLASSIFIED

Accidents (mainly air-delivered systems) eventually led to reexamination of the premature nuclear yield criteria and to the present nuclear detonation safety design criteria.

UNCLASSIFIED

UNCLASSIFIED

Need for a Safety Process

- As the deployment dates for sealed pit weapons approached, the Armed Forces Special Weapons Project (AFSWP) and the Services became uncomfortable with their lack of knowledge and understanding of weapon safety designs.

- 1957, AFSWP convened a safety Board to examine the sealed pit weapon systems becoming available.

- Between 1957 and 1960, the Air Force convened joint safety study groups as weapons entered the stockpile.

- A formal, Joint DoD/DOE Nuclear Weapons System Safety process was established in 1960.

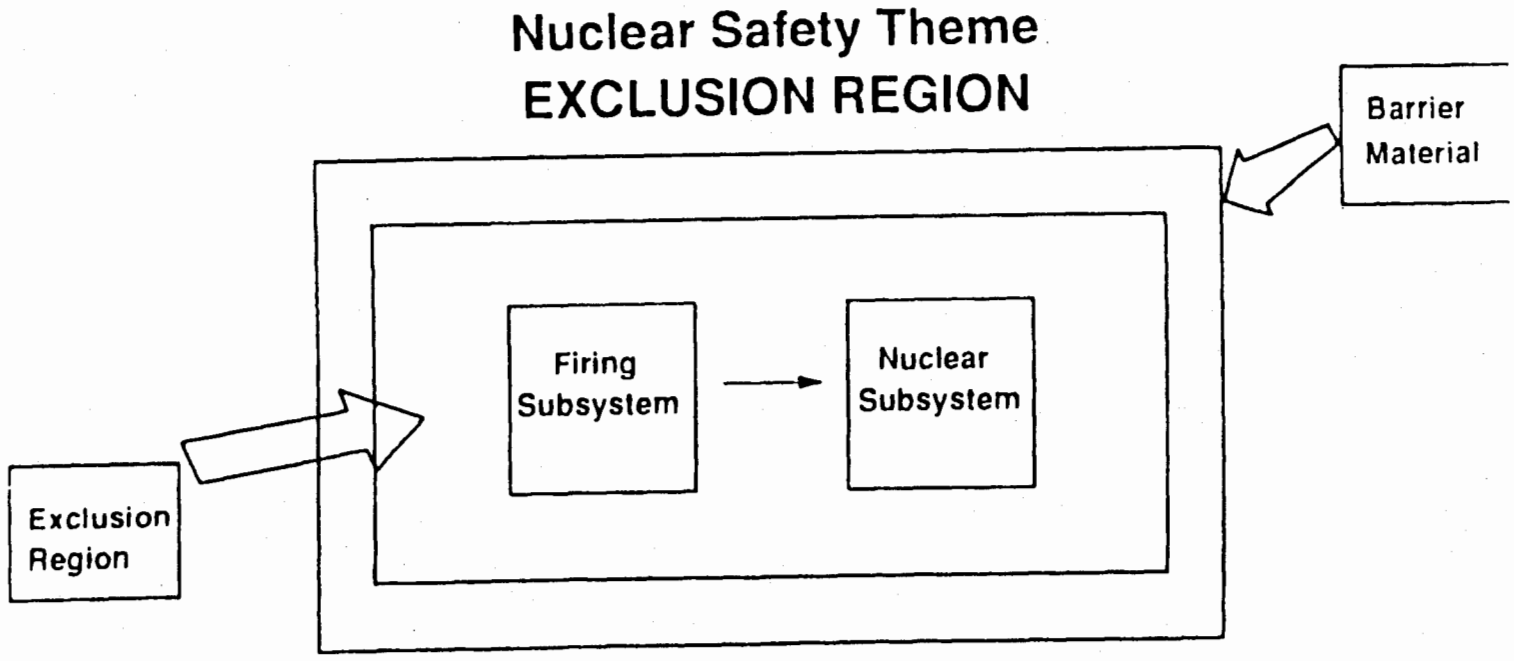
Safety Goals for Abnormal Environments

- Assured, predictable, safe response of the warhead electrical system
- Maintain predictable, safe response until intended use
- Minimize safety critical components and dependence on knowing accident scenario

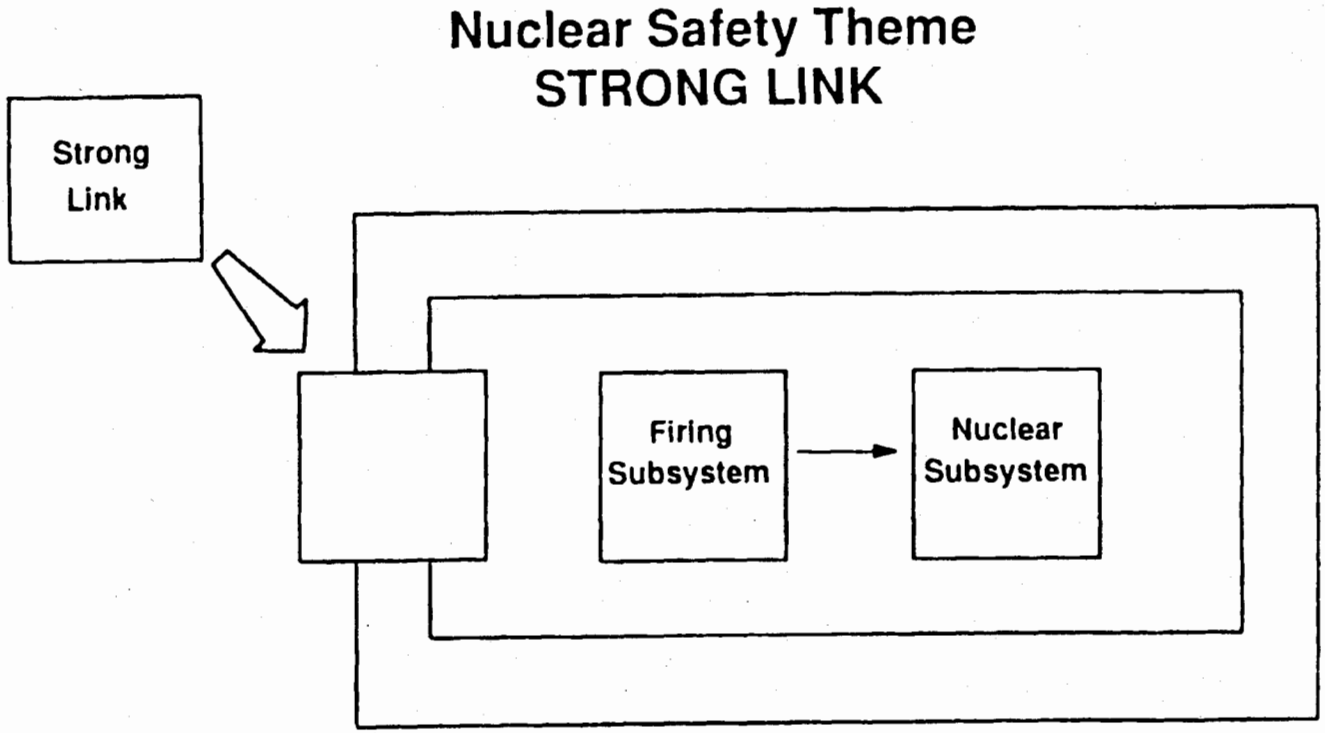
UNCLASSIFIED



MORE SPECIFICALLY THE SAFETY GOALS ARE TO

UNCLASSIFIED

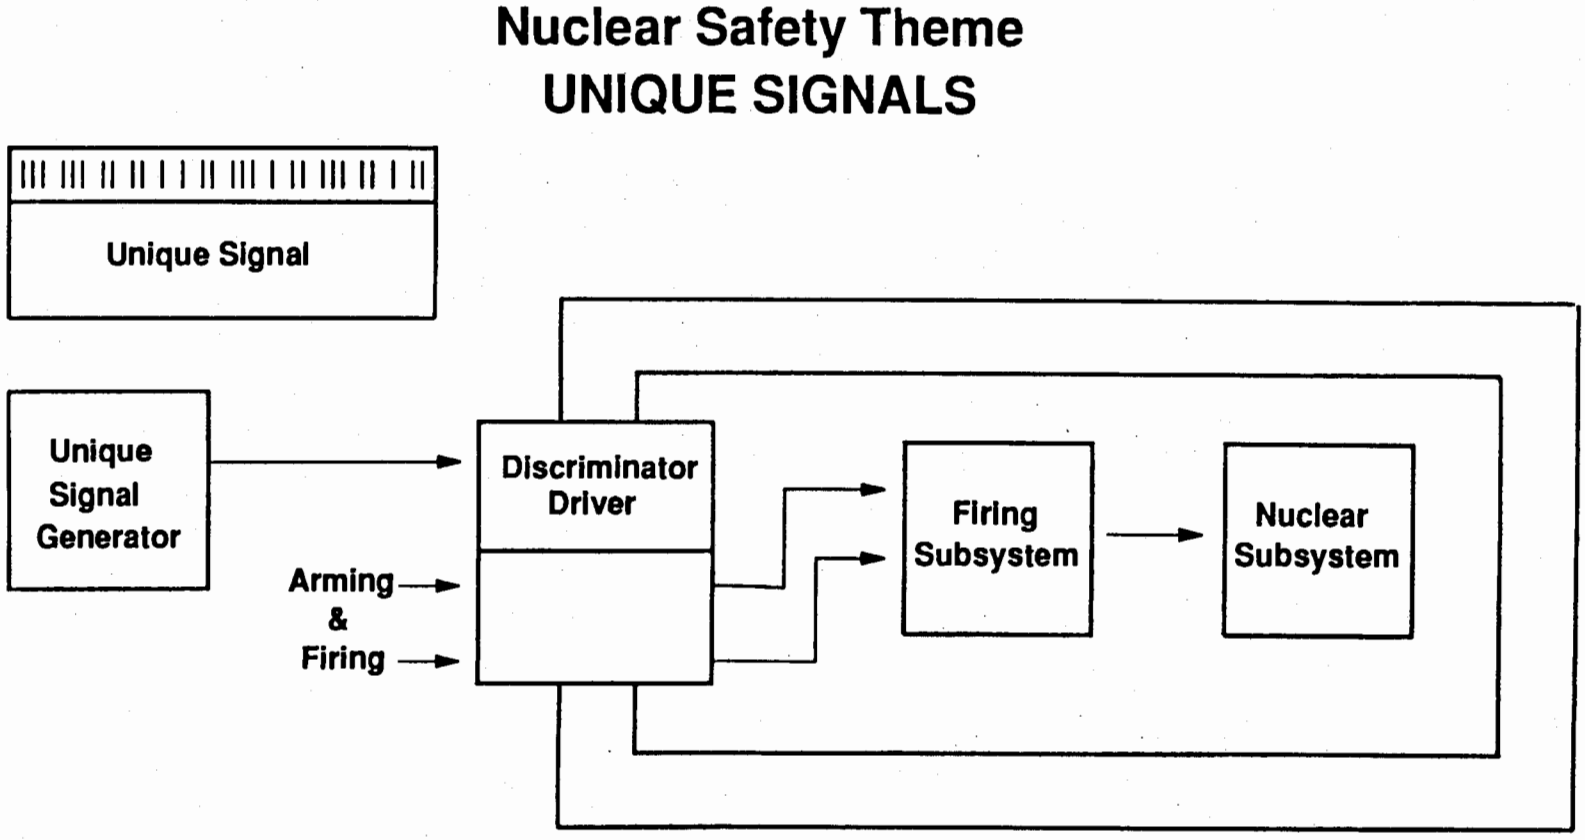
MODERN SAFETY DESIGN PHILOSOPHY



Co-locate detonation-essential components and protect them from abnormal environments by an exclusion region

UNCLASSIFIED
UNCLASSIFIED
UNCLASSIFIED

MODERN SAFETY DESIGN PHILOSOPHY (cont)

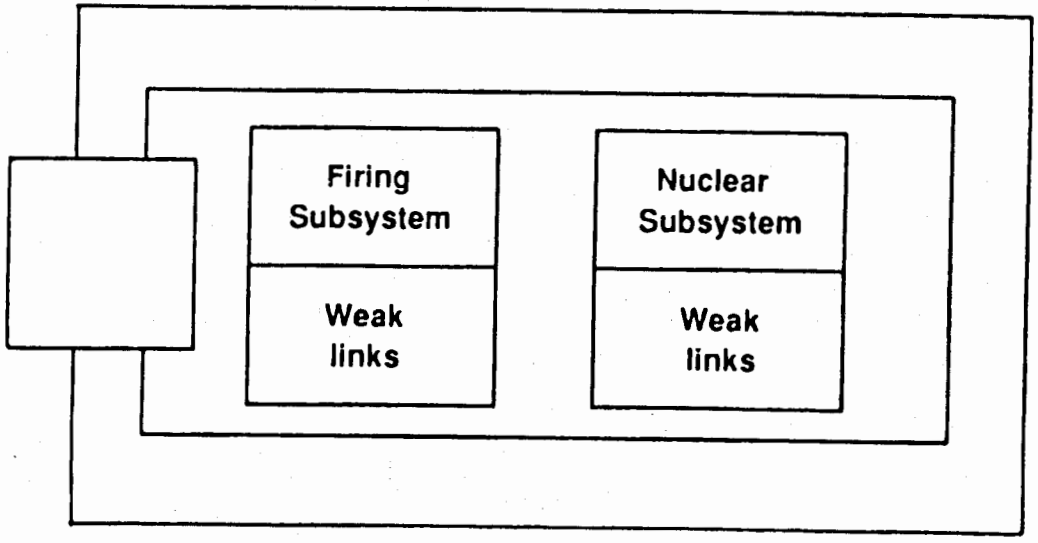


Allow energy/signals into the exclusion region only through a strong link

UNCLASSIFIED

MODERN SAFETY DESIGN PHILOSOPHY (cont)

Control the strong link(s) with a unique signal -- not duplicated elsewhere in the system

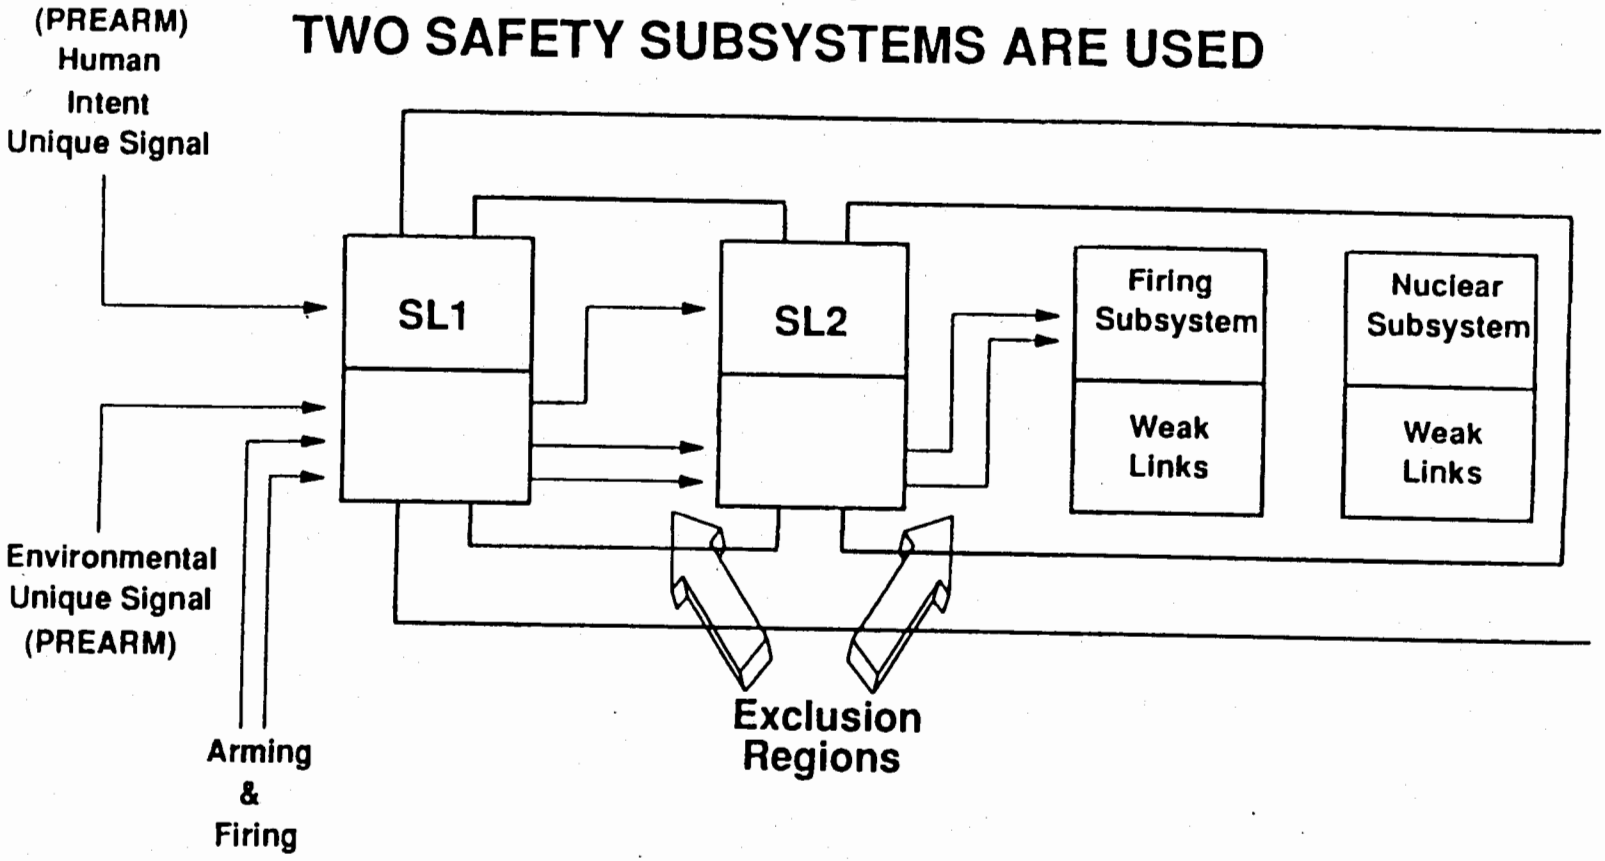


UNCLASSIFIED
UNCLASSIFIED

MODERN SAFETY DESIGN PHILOSOPHY (cont)

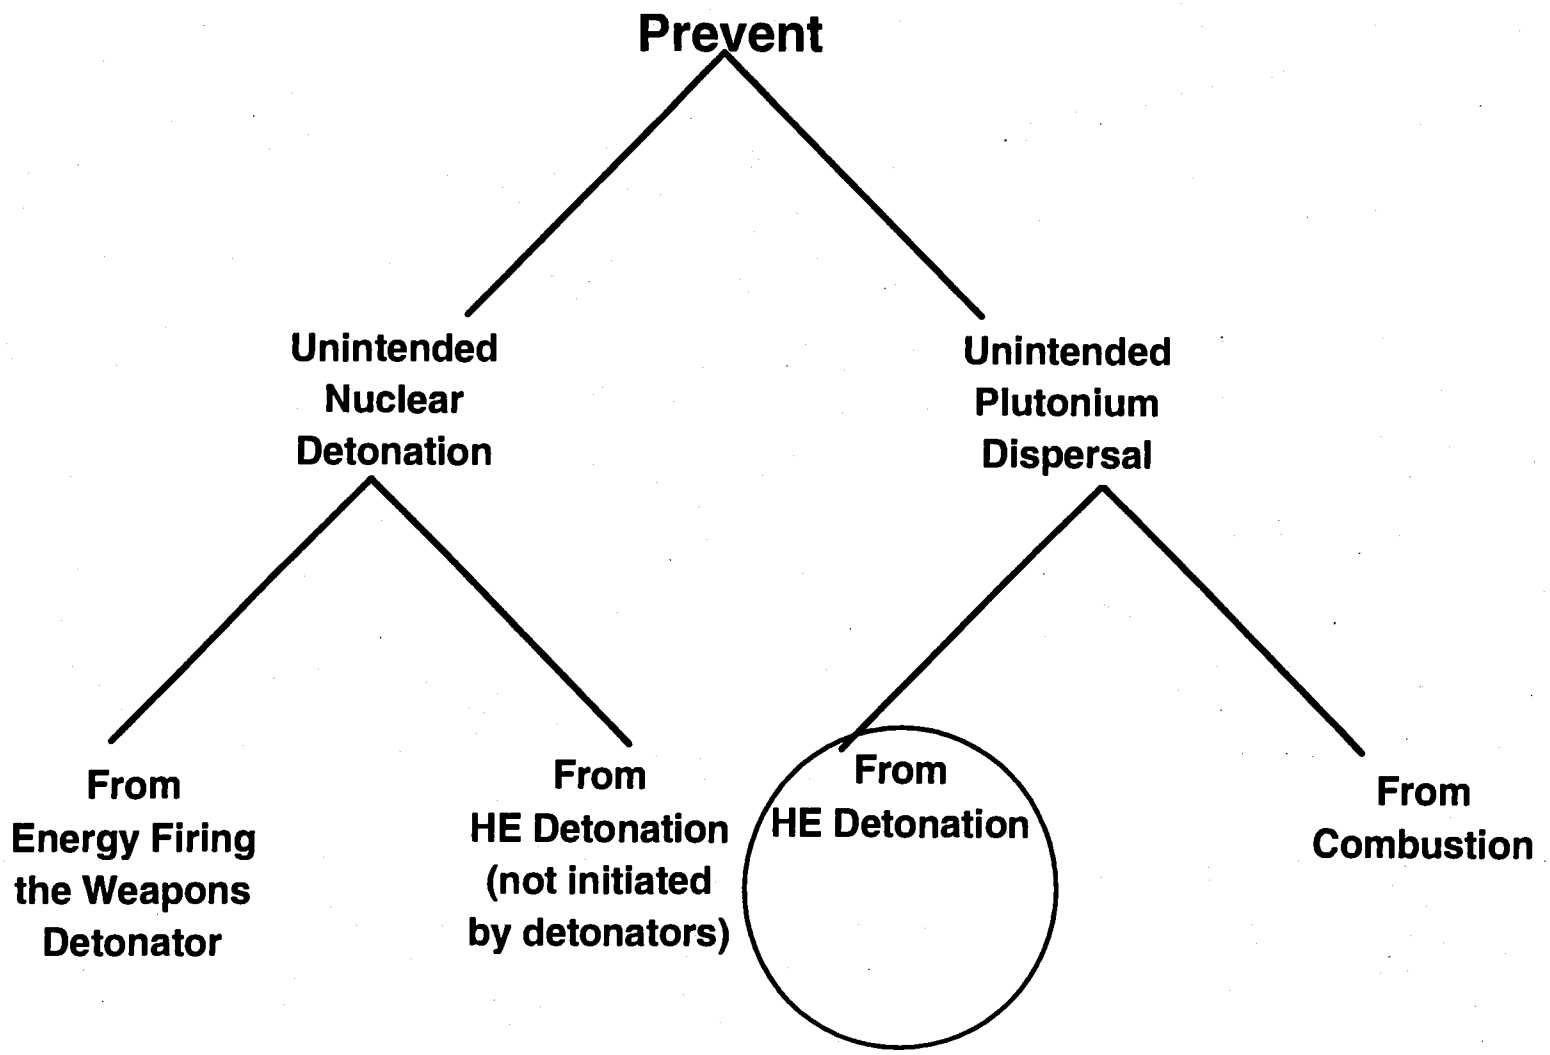
Finally, to address credible but catastrophically severe environments, co-locate *weak link* detonation-essential components which will predictably become inoperable prior to the barrier or strong links losing their integrity.

Nuclear Safety Theme
WEAK LINKS



UNCLASSIFIED

UNCLASSIFIED



BECAUSE THE REQUIREMENT (LESS THAN ONE-IN-A-MILLION) IS QUITE STRINGENT

Nuclear Safety Theme

TWO SAFETY SUBSYSTEMS ARE USED

UNCLASSIFIED

UNCLASSIFIED

UNCLASSIFIED

An Overview of the Evolution of Aircraft Monitor and Control (AMAC) Systems

- System 1 offered many improved features in safety and compatibility.
- The requirements for a Unique Signal Generator (USG) first appeared in July 1975 to enhance weapon safety in abnormal environments.
- The requirements for CAT D PAL first appeared in August 1975.
- The requirements for Command Disable (CD) first appeared in October 1981 to provide the ability to render a weapon useless from the cockpit.
- All aircraft nuclear weapon interfaces built to date have been analog.
- A system 2 AMAC specification exists that defines a digital interface for possible use in future nuclear weapons.

UNCLASSIFIED
UNCLASSIFIED

An Overview of the Evolution of Aircraft Monitor and Control (AMAC) Systems

- The result of this effort resulted in the T249 AMAC for bomber and fighter aircraft usage.

- New bombs designed during the mid to late '50s were made compatible with the T249 rather than building a unique AMAC for a specific bomb.

- AMAC design specifications, defined jointly by the DOE and DoD, first appeared in December 1961.

- The requirements for Category (CAT) B Permissive Action Link (PAL) first appeared in June 1963 to enhance weapon security.

- Today's nuclear-capable aircraft, with few exceptions, have what is known as a System 1 AMAC interface.

- The System 1 specification first appeared in September 1963.

The Gang of Four

$^{238}U_{92}$ % in nature - 99.27 When the $^{238}U_{92}$ is extracted, it is called depleted ^{238}U or TUBALLOY or D38 (from UK WWII effort - TUBE ALLOY). Will fission but not fissile Physically separated	^{239}Pu % in nature - essentially zero (mine in South Africa) Made in Reactor: N + ^{238}U = ^{239}Pu
^{235}U % in nature - 00.73 Concentrated to 93.5%. Called ORALLOY for Oak Ridge Alloy	^{240}Pu % in nature - essentially zero Made by reactor. If you leave the ^{239}Pu in "too long," it will absorb a N → ^{240}Pu. Spontaneously fissions (originally a problem for pre-ignition).

UNCLASSIFIED

CALCULATION OF ENERGY RELEASE

$$_{92}U^{235} + {}_{o}n^{1} \longrightarrow {}_{42}Mo^{95} + {}_{57}La^{139} + {}_{-1}e^{o} + 2\,{}_{o}n^{1}$$

235.0439	94.905837
1.0087	138.906400
	.003850
	2.017340
236.0526 amu ⟶	235.8334 amu

MASS DEFECT OF .219 amu

n = 1.00867 amu
p = 1.00728 amu
e = .00055 amu

$$(.219 \text{ amu})\ (931.4\ \tfrac{\text{MeV}}{\text{amu}}) \simeq 204 \text{ MeV}$$

THE EXAMPLE STARTED WITH

$$_{54}Xe^{139} \xrightarrow{3\,ß} {}_{57}La^{139} \quad \text{AND} \quad {}_{38}SR^{95} \xrightarrow{4\,ß} {}_{42}Mo^{95}$$

FISSION CHAIN

UNCLASSIFIED
UNCLASSIFIED

THEORETICAL FISSION ENERGY

- THERE ARE $\frac{6.025X10^{23}}{235.0439}$ ATOMS PER GRAM OF $_{92}U^{235}$
- THEREFORE, 1 kg OF $_{92}U^{235}$ HAS $2.5634X10^{24}$ ATOMS
- HENCE, @ 180 MeV PER FISSION 1 kg OF $_{92}U^{235}$ WOULD PRODUCE
- $4.6141x10^{26}$ MeV IF EACH ATOM WERE FISSIONED.
- CONVERTING TO KILOTONS
- $(4.6141X10^{26}\ \text{MeV})\ (3.824X10^{-26}\ \frac{kT}{MeV}) \simeq 18\ kT$

KEY Points

1. Each γ gives a downward traveling compton electron.
2. The electrons are turned by the earth's magnetic field.
3. The realistic electrons radiate energy downward.
4. The γ's and EMP radiation travel at the same speed.
   This leads to constructive interference of radiation from all electrons.

A REVIEW OF THERMAL BATTERY TECHNOLOGY

B. H. Van Domelen and R. D. Wehrle
Sandia Laboratories
Albuquerque, New Mexico

ABSTRACT

This report reviews the evolution of thermal battery technology from World War II to the present. It discusses the first applied work with thermal cells, the transfer of this laboratory technology to the United States, the development of the initial cup technology by the U. S., and the evolution of this technology to the later pellet technology. The paper by P. Tepper will then discuss the performance of thermal batteries and compare this performance with that of other ordnance batteries.

INTRODUCTION

The electrochemical power sources used in nuclear weapons to date have been lead-acid, nickel-cadmium, silver-zinc, and thermal batteries. The lead-acid battery was used in the first atomic bomb and in later weapon systems until 1953, when it was replaced by the nickel-cadmium battery, followed shortly by the silver-zinc battery. These aqueous electrolyte batteries all had a critical deficiency: their wet stand time was so short that either the battery had to be frequently recharged or the electrolyte had to be carried separately and injected into the battery just before its use. The thermally activated battery, introduced in 1955, solved the wet stand problem. Since then, it has been the sole power source used by Sandia Laboratories for nuclear weapon systems.

The thermal battery is so called because it contains a pyrotechnic heat source that, when ignited, thermally activates the battery by melting the electrolyte, which is a salt mixture. Salt mixtures are solid and chemically inert at room temperature, but when fused become fluid and highly conductive. These properties of the electrolyte provide the long shelf life and good electrical performance of the thermal battery (1,2).

The origin of the thermal battery dates back to World War II when Dr. Ing. Georg Otto Erb, working in Germany, developed the first practical cells, using a salt mixture as an electrolyte. Dr. Erb investigated the performance of several couples and electrolytes, the effects of salts with water of hydration, and the effects of water in unhydrated electrolyte salts. He also conceived and developed batteries for several ordnance applications, including the V-I and V-II rockets and artillery fusing systems; however, none of these batteries was produced for field use. Dr. Erb was interrogated by British Intelligence at the end of the war and his studies were reported to them in a paper entitled "The Theory and Practice of Thermal Cells" (3,4). This information was conveyed by the British, and possibly through other channels, to the United States Ordnance Development Division of the National Bureau of Standards, which later became Harry Diamond Laboratories (HDL). In this paper the authors will discuss only the channel for which documentation is presently available.

Prior to August 1946 (5) Mr. Grenville Ellis, U. S. Signal Corps (now the U. S. Army Electronics Command) brought copies of Dr. Erb's report to a meeting of the Joint Battery Advisory Committee. This committee of about ten people representing the Navy, Army, Air Force, and Industry met informally to exchange ordnance battery information. Dr. A. G. Hellfritzsch, of the Naval Ordnance Laboratory and a member of this committee, recognized the relevance of Dr. Erb's work to the battery needs of the VT (Variable Time) Fuze Panel under the National Research and Development Board. Dr. Hellfritzsch conveyed this report to Roger W. Curtis, who was chairman of the VT Fuze Panel and was also in the Ordnance Development Division of the National Bureau of Standards (6). Within a few weeks Curtis and his co-workers had demonstrated the capabilities of thermal cells for ordnance applications. Combining this with the work under contract to Catalyst Research Corporation to develop gasless pyrotechnics, they developed a self-contained thermal battery (6).

In the late forties the Wurlitzer Corporation began production of HDL's first thermal battery. This battery was used in a mortar round and the total production reached over a million batteries (7).

In 1952 Curtis reported on thermal battery technology at a symposium attended by various ordnance groups (8). Because of its desirable ordnance characteristics, the thermal battery system was adopted by the military for ordnance applications and by the U. S. AEC for nuclear weapon systems.

The early thermal battery designs are frequently referred to as "cup," "pad," "cup and cover," "closed-cup," and "conventional" batteries. These early batteries had three distinguishing characteristics: heat-paper pads, electrolyte and depolarizer pads, and intercell electrical connectors, which are discussed in more detail later. These three characteristics distinguish the earlier batteries from the later pellet-type batteries

UNCLASSIFIED

which use heat powder pellets, electrolyte-depolarizer pellets, and an intercell connectors. The evolution from the earlier batteries to the present pellet-type batteries was gradual, and there were several hybrid batteries which included both technologies, such as the Naval Ordnance Laboratory/Eureka-Williams battery which was the first to use a pellet.

This review describes the early cup technology (9,10,11), one of the later hybrid systems (2,10,12), and the present pellet technology (11,13,14). Performance characteristics of the thermal battery are discussed with reference to the Ca/LiCl-KCl/$CaCrO_4$ electrochemical system and the pellet technology which is the principal system used by this Laboratory. Discussion of other electrochemical systems and references to these systems are given by Jeanloz (15).

THE CUP TECHNOLOGY

Figure 1 shows the typical structure of a single cell in the cup design. In the cell are the anode, the electrolyte pads, the depolarizer pads, the cup in which these are enclosed, and a heat pad to thermally activate the cell.

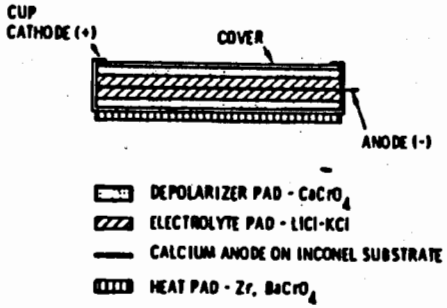

Fig. 1. - Single thermal cell - cup technology

The anode consists of calcium affixed to both sides of a metallic substrate[1] that serves both as the anode current collector and as the negative terminal by virtue of a tab extending through a slit in the side of the cell case. Although not shown in the figure, the anode is electrically insulated from the cathode cup.

The electrolyte pads are adjacent to the calcium surfaces and contain the electrolyte, the eutectic mixture of the lithium-chloride/potassium-chloride system (59 mole % LiCl-41 mole % KCl), which has a melting point of 352 C. The pads are formed by passing a fiberglass tape through a vat of molten electrolyte and punching pads from the tape after it has cooled and the electrolyte has solidified.

1. Inconel, iron, stainless steel, and nickel are the metals most often used.

The depolarizer[2] pads, adjacent to the electrolyte pads, complete the active cell stack. These pads are punched from a paper-like sheet formed by pressing and drying a slurry containing the calcium chromate depolarizer along with glass and ceramic fibers.

The active cell stack is then placed in a metallic cup, covered with a metallic disc, and the sides of the cup are crimped over the disc as a seal. The cup and disc thus hold the cell components in place and serve as the cathode current collector and positive terminal of the cell.

The last component of the single cell is the heat pad, which activates the cell by raising its temperature to the operating range of 500 to 600 C. The pad is punched from heat paper sheets formed by a process similar to that used for the depolarizer pads, but involving a slurry containing zirconium fuel and barium-chromate oxidizer instead of the depolarizer. (The slurry also contained asbestos fibers. Later, Sandia eliminated the asbestos because it releases water of hydration when heated.)

For simplicity, only the basic components of the cup cell have been described. When one includes intercell connecting tabs, wire-mesh current collectors, electrical insulators, etc., there can be as many as 27 individual parts in a cup cell as compared to the 3 parts of the later pellet cells.

It should also be noted that with the cup technology, as well as with the pellet technology, most of the battery materials either absorb or react with water, particularly the electrolyte which is very hygroscopic. Since battery performance is severely degraded if the components are exposed to water vapor concentrations greater than 1500 ppm[3], all processes are carried out in dry rooms. At this Laboratory for example, the dry rooms are maintained at less than 300 ppm; and in addition, all battery components are vacuum dried at 100 C prior to assembly.

Figure 2 illustrates thermal battery construction using the single cell described above. The active battery stack is formed by first welding the appropriate number of cells together, the negative tab of one to the positive case of the next, and then inserting a heat pad between each pair of cells to heat them and to insulate them from each other electrically. Electrical leads are attached and a narrow fuse strip of heat paper is laid up the side of the stack and across the top cell. The stack is then capped on each end

2. Depolarizer is an historic battery term used to identify the active cathode material which is reduced electrochemically during battery discharge.

3. At 25 C, 1500 ppm is 5% relative humidity.

UNCLASSIFIED

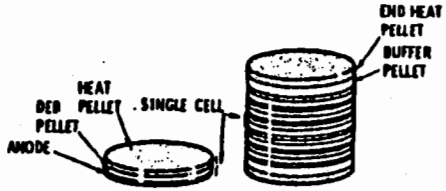

Fig. 5. - Single cell and battery stack - pellet technology

lithium-sulfate/sodium-chloride eutectic, which melts at 493 C and has a heat-of-fusion of about 84 calories per gram. Part of the heat from the end heat pellets is used to melt the eutectic salt in the buffer pellet. When the end of the battery stack cools to 493 C, the eutectic solidifies and releases its heat-of-fusion to maintain the battery temperature for a longer time.

As shown in Figure 6, the assembly of a pellet thermal battery is completed with the addition of electrical leads, match, fuse train, insulation, and battery case. The thermal insulation used is Fiberfrax for regular applications and Johns-Manville's Min-K 2002 for long-life applications. The Min-K 2002 was originally developed under AEC contract for thermoelectric generators and selected for thermal batteries after an extensive evaluation program (13,14). It is composed of silica, quartz fibers, and titanium dioxide.

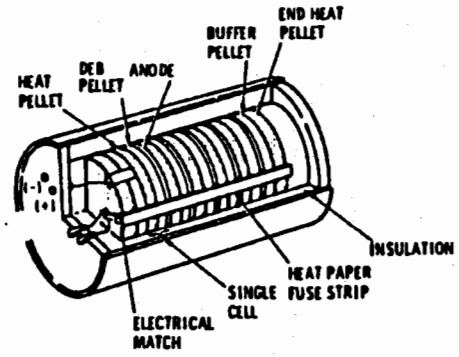

Fig. 6 - Thermal battery construction - pellet technology

Figure 7 shows the steps of battery construction and the use of center bolt construction to ensure concentricity of the plates. In this construction, a quartz-covered steel bolt is passed through center holes in the battery stack and two steel end plates. The result is a concentric, integral, rugged subassembly that can be easily handled and inspected.

Fig. 7 - Thermal battery - pellet technology

The pellet battery offers several improvements over the cup battery: longer activated life, more reproducible performance, greater ruggedness, no intercell connectors, lighter battery cases, better control of materials and processing, simplified fabrication, reduction of inspection and testing, elimination of hazardous heat pads, and lower cost. In addition, the pellet battery design is simpler and thus more amenable to investigation. This in turn has led to improved performance and further advancements, particularly with respect to longer life. Production has been completed on a thermal battery having an activated life of 15 minutes (21) and exploratory thermal batteries under development at Sandia have demonstrated activated lives of over 60 minutes (22).

ACKNOWLEDGEMENTS

The authors acknowledge the assistance of the individuals who provided much of the information concerning the early history of thermal batteries: A. Attewell of the Royal Air Force Establishment in the British Ministry of Defense, E. V. Foreman and C. W. Jennings of Sandia Laboratories, B. Kaplan of Harry Diamond Laboratories, R. T. Mead of Wilson Greatbatch, Ltd., R. D. Walker of the University of Florida, I. D. Yalen of the Naval Ordnance Laboratory, and particularly A. G. Hellfritsch of the Naval Ordnance Laboratory.

Firing Set Types (U)

FE — Ferroelectric

The FE firing set consists of an explosive plane wave generator and a poled ferroelectric ceramic element. A pressure pulse produced by detonation of the explosive in the plane wave generator causes the release of bound charge from the ceramic element in the detonator load. This technology is also used as the power source in explosive neutron generators.

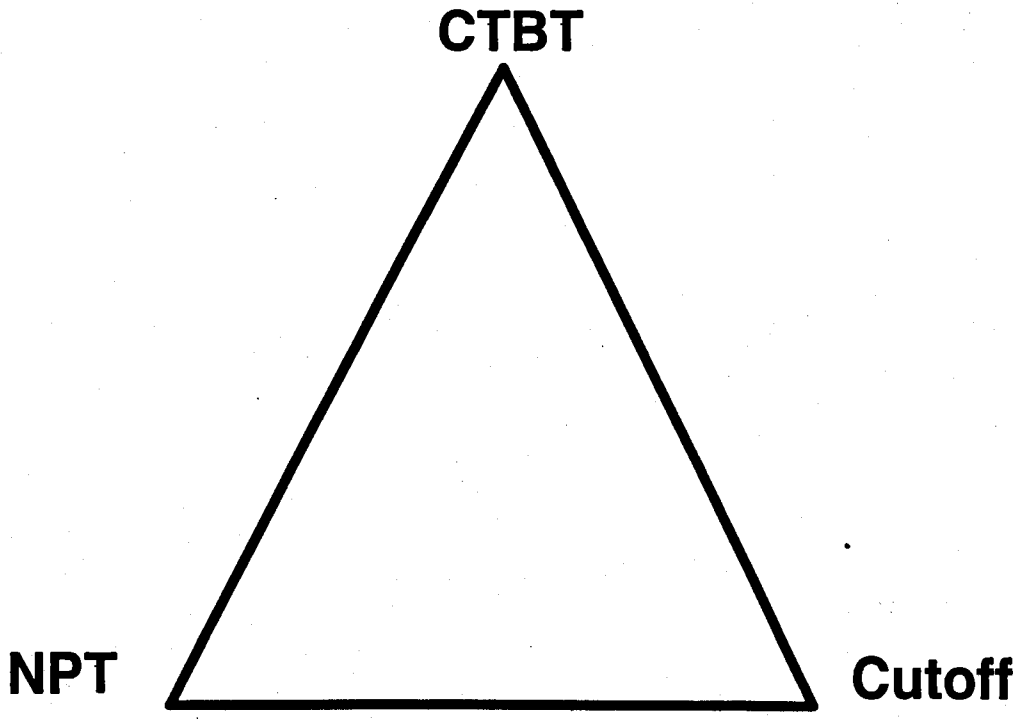
Books of interest

The Making of the Atomic Bomb, Richard Rhodes, 1986.
Pulitzer prize winner, follows the scientific discoveries that led to the bomb, particularly good at the personalities involved, finishes with vivid descriptions of Hiroshima and Nagasaki. Excellent and entertaining.

At the Highest Levels, Michael R. Beschloss and StrobeTalbott, 1993.
Intimate details of the end of the Cold War, as seen at the top.



Lenin's Tomb, David Remnick, 1993.
Details the end of the Soviet Union from the viewpoint of the Russian people and their legacy. Choppy, but a very human picture of the great event.

The Wizards of Armageddon, Fred Kaplan, 1983.
Follows the policy and strategy decision regarding nuclear weapons, much emphasis on the early RAND personalities. Very good and readable.

Some Definitions

Proliferation is the spread of weapons of mass destruction (WMD)-- typically nuclear, biological, and chemical weapons--and the systems which deliver them.

Nonproliferation is the use of the full range of political, economic and military tools to prevent proliferation, reverse it diplomatically, or protect our interest against an opponent armed with WMD or missiles.

Counterproliferation measures are the activities of the DoD across the full range of U.S. efforts to combat proliferation.

What Constitutes a Weapon of Mass Destruction

- Indiscriminate nature of use
- Effect not confined to Belligerents
- Excessive injury -- "cruel and unusual"
- Inability to defend against effectively
- Use would overwhelm medical and evacuation resources
- Notion of "terror"

UNCLASSIFIED

ARMS CONTROL IN THE ANCIENT WORLD (CONT'D)

400-500 BC	Athens and Sparta agree to dismantle fortifications although during the negotiations the Athenians hedged their bet by continuing to build their ramparts "high enough to be defended" (Peloponnesian War, Thucydides). Note that, according to the Aristophanes, the women of Athens and Sparta, under the leadership of Lysistrata, tried a different approach to forcing an end to hostilities!
450 BC	Socrates to Glaucon -- no use of poisoned weapons or poisoned water (The Republic, Plato).
300-400 BC	No weapons concealed in wood, no barbed or poisoned points, no points "blazing with fire" (India's Book of Man).
202 BC	After the battle of Zama, Carthage is required to surrender all war elephants and all but 10 triremes to Rome (Book XXX, Livy).

Why Not Zero?

Many nations and individuals want us to completely eliminate weapons -- attractive philosophy but dubious policy:

There may be things worse than nuclear weapons (e.g. biologics)

UNCLASSIFIED

UNCLASSIFIED

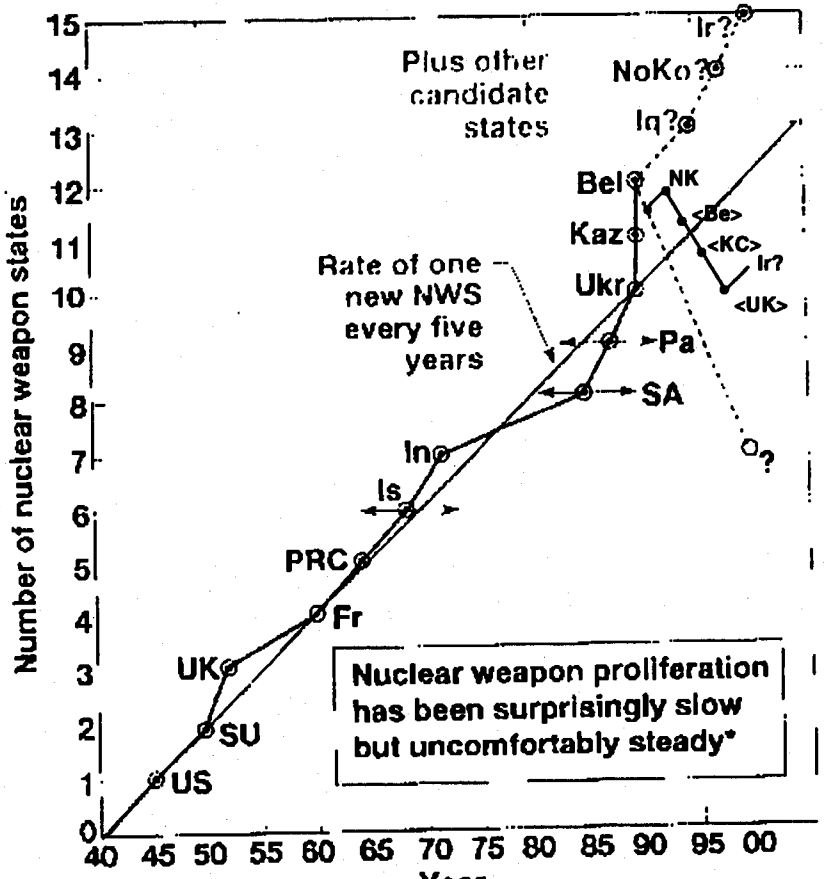
There have been some Nonproliferation Successes

-- Sweden abandoned its programs in the 1970s.

-- South Africa stopped its programs in 1992 (6 weapons).

-- Argentina and Brazil renounced their programs.

-- Taiwan and South Korea abandoned their programs in the 1980s.



-- Iraq's program "put on hold" by Desert Storm and UN Resolution 687 and 715.

-- Belarus, Kazakhstan, and Ukraine (?) have agreed to return the FSU weapons to Russia.

Secondary Impacts of Nonproliferation Initiatives

o NPT//NPT Extension Conference (1995):
  -- New and more intrusive inspections regimes
  -- An increased call for transparency
  -- More downward pressure on the stockpile from the "have nots"
  -- Continued pressure against nuclear testing

o Negotiations on controls on fissile materials:
  -- Codify in-place current US and Russian practices
  -- Inspection regimes and transparency
  -- Possible attempts to restrict tritium production

o Export Controls
  -- Heightened concern over "dual use" systems and commodities

DEPARTMENT OF DEFENSE

NARRATIVE SUMMARIES OF ACCIDENTS
INVOLVING U.S. NUCLEAR WEAPONS
1950-1980

Attached are unclassified summaries describing the circumstances surrounding 32 accidents involving nuclear weapons. Also attached is the Department of Defense (DOD)/Department of Energy (DOE) definition of "accident" used in researching this project.

Twenty-six of these summaries were first released by the Air Force in 1977; another was prepared following the Titan II explosion in Arkansas in September 1980. Those previously-released summaries are marked with a figure "1"; in some cases they include new material made available as a result of more recent research.*

There never has been even a partial inadvertant U.S. nuclear detonation despite the very severe stresses imposed upon the weapons involved in these accidents. All "detonations" reported in the summaries involved conventional high explosives (HE) only. Only two accidents, those at Palomares and Thule, resulted in a widespread dispersal of nuclear materials.

Nuclear weapons are never carried on training flights. Most of the aircraft accidents represented here occurred during logistic/ferry missions or airborne alert flights by Strategic Air Command (SAC) aircraft. Airborne alert was terminated in 1968 because of:

-- Accidents, particularly those at Palomares and Thule,

-- The rising cost of maintaining a portion of the SAC bomber force constantly on airborne alert, and,

-- The advent of a responsive and survivable intercontinental ballistic missile force which relieved the manned bomber force of a part of its more time-sensitive responsibilities. (A portion of the SAC force remains on nuclear ground alert.)

Since the location of a nuclear weapon is classified defense information, it is Department of Defense policy normally neither to confirm nor deny the presence of nuclear weapons at any specific place. In the case of an accident involving nuclear weapons, their presence may or may not be divulged at the time depending upon the possibility of public hazard or alarm. Therefore, in some of the events summarized here, the fact of the presence of nuclear weapons or materials may not have been confirmed at the time. Furthermore, due to diplomatic considerations, it is not possible to specify the location of the accidents that occurred overseas, except for Palomares and Thule.

Most of the weapon systems involved in these accidents are no longer in the active inventory. Those include the B-29, B-36, B-47, B-50, B-58, C-124, F-100 and P-5M aircraft, and the Minuteman I missile.

DEFINITION OF AN ACCIDENT

An "accident involving nuclear weapons" is defined as

-An unexpected event involving nuclear weapons or nuclear weapons components that results in any of the following:

--Accidental or unauthorized launching, firing, or use, by U.S. forces or supported allied forces, of a nuclear-capable weapon system which could create the risk of an outbreak of war.

--Nuclear detonation.

--Non-nuclear detonation or burning of a nuclear weapon or radioactive weapon component, including a fully assembled nuclear weapon, an unassembled nuclear weapon, or a radioactive nuclear weapon component.

--Radioactive contamination.

--Seizure, theft, or loss of a nuclear weapon or radioactive nuclear weapon component, including jettisoning.

--Public hazard, actual or implied.

Narrative Summaries of Accidents Involving U.S. Nuclear Weapons 1950-1980

February 13, 1950/ B-36 / Pacific Ocean, off Coast of British Columbia

The B-36 was enroute from Eielson AFB, Alaska to Carswell AFB, Texas on a simulated combat profile mission. The weapon aboard the aircraft had a dummy capsule installed. After six hours of flight, the aircraft developed serious mechanical difficulties, making it necessary to shut down three engines. The aircraft was at 12,000 feet altitude. Icing conditions complicated the emergency and level flight could not be maintained. The aircraft headed out over the Pacific Ocean and dropped the weapon from 8,000 feet. A bright flash occurred on impact, followed by a sound and shock wave. Only the weapon's high explosive material detonated. The aircraft was then flown over Princess Royal Island where the crew bailed out. The aircraft wreckage was later found on Vancouver Island.

April 11, 1950 / B-29 / Manzano Base, New Mexico

Aircraft departed Kirtland AFB at 9:38 p.m. and crashed into a mountain on Manzano Base approximately three minutes later killing the crew. Detonators were installed in the bomb on board the aircraft. The bomb case was demolished and some high explosive (HE) material burned in the gasoline fire. Other pieces of unburned HE were scattered throughout the wreckage. Four spare detonators in their carrying case were recovered undamaged. There were no contamination or recovery problems. The recovered components of the weapon were returned to the Atomic Energy Commission. Both the weapon and the capsule of the nuclear material were on board the aircraft but the capsule was not inserted for safety reasons. A nuclear detonation was not possible.

July 13, 1950 / B-50 / Lebanon, Ohio

The B-50 was on a training mission from Biggs AFB, Texas. The aircraft was flying at 7,000 feet on a clear day. Aircraft nosed down and flew into the ground killing four officers and twelve airmen. The high explosive portion of the weapon aboard detonated on impact. There was no nuclear capsule aboard the aircraft.

August 5, 1950 / B-29 /Fairfield Suisun-AFB, California

A B-29 carrying a weapon, but no capsule, experienced two runaway propellers and landing gear retraction difficulties on takeoff from Fairfield-Suisun AFB (now Travis AFB). The aircraft attempted an emergency landing and crashed and burned. The fire was fought for 12-15 minutes before the weapon's high explosive material detonated. Nineteen crew members and rescue personnel were killed in the crash and/or the resulting detonation, including General Travis.

November 10, 1950 / B-50 / Over Water, outside United States

Because of an in-flight aircraft emergency, a weapon containing no capsule of nuclear material was jettisoned over water from an altitude of 10,500 feet. A high-explosive detonation was observed.

March 10, 1956 / B-47 / Mediterranean Sea

The aircraft was one of a flight of four scheduled for non-stop deployment from MacDill AFB to an overseas air base. Take-off from MacDill and first refueling were normal. The second refueling point was over the Mediterranean Sea. In preparation for this, the flight penetrated solid cloud formation to descend to the refueling level of 14,000 feet. Base of the clouds was 14,500 feet and visibility was poor. The aircraft, carrying two nuclear capsules in carrying cases, never made contact with the tanker.

An Extensive search failed to locate any traces of the missing aircraft or crew. No weapons were aboard the aircraft, only two capsules of nuclear weapons material in carrying cases. A nuclear detonation was not possible.

July 27, 1956 / B-47 / Overseas Base

A B-47 aircraft with no weapons aboard was on a routine training mission making a touch and go landing when the aircraft suddenly went out of control and slid off the runway, crashing into a storage igloo containing several nuclear weapons. The bombs did not burn or detonate. There were no contamination or cleanup problems. The damaged weapons and components were returned to the Atomic Energy Commission. The weapons that were involved were in storage configuration. No capsules of nuclear materials were in the weapons or present in the building.

May 22, 1967 / B-36 / Kirtland AFB, New Mexico

The aircraft was ferrying a weapon from Biggs AFB, Texas, to Kirtland AFB. At 11:50 a.m. MST, while approaching Kirtland at an altitude of 1,700 feet, the weapon dropped from the bomb bay taking the bomb bay doors with it. Weapon parachutes were deployed but apparently did not fully retard the fall because of the low altitude. The impact point was approximately 4.5 miles south of the Kirtland control tower and .3 miles west of the Sandia Base reservation. The high explosive material detonated, completely destroying the weapon and making a crater approximately 25 feet in diameter and 12 feet deep. Fragments and debris were scattered as far as one mile from the impact point. The release mechanism locking pin was being removed at the time of release. (It was standard procedure at that time that the locking pin be removed during takeoff and landing to allow for emergency jettison of the weapon if necessary.) Recovery and cleanup operations were conducted by Filed Command, Armed Forces Special Weapons Project. Radiological survey of the area disclosed no radioactivity beyond the lip of the crater at which pint the level was 0.5 millirocntgens. There were no health or safety problems. Both the weapon and capsule were on board the aircraft but the capsule was not inserted for safety reasons. A nuclear detonation was no possible.

July 28, 1957 / C-124 / Atlantic Ocean

Two weapons were jettisoned from a C-124 aircraft on July 28 off the east coast of the United States. There were three weapons and one nuclear capsule aboard the aircraft at the time. Nuclear components were not installed in the weapons. The C-124 aircraft was enroute from Dover AFB, Delaware when a loss of power from number one and two engines was experienced. Maximum power was applied to the remaining engines; however, level flight could not be maintained. At this point, the decision was made to jettison cargo in the interest of safety of the aircraft and crew. The first weapon was jettisoned at 4,500 feet altitude. The second weapon was jettisoned at approximately 2,500 feet altitude. No detonation occurred from either weapon. Both weapons are presumed to have been damaged from impact with the ocean surface. Both weapons are presume to have submerged almost instantly. The ocean varies in depth in the area of the jettisonings. The C-124 landed at an airfield in the vicinity of Atlantic City, New Jersey, with the remaining weapon and the nuclear capsule aboard. A search for the weapons or debris had negative results.

October 11, 1957 / B-47 / Homestead AFB, Florida

The B-47 departed Homestead AFB shortly after midnight on a deployment mission. Shortly after liftoff one of the aircraft's outrigger tires exploded. The aircraft crashed in an uninhabited area approximately 3,800 feet from the end of the runway. The aircraft was carrying one weapon in ferry configuration in the bomb bay and one nuclear capsule in a carrying case in the crew compartment. The weapon was enveloped in flames which burned and smoldered for approximately four hours after which time it was cooled with water. Two low order high explosive detonations occurred during the burning. The nuclear capsule and its carrying case were recovered intact and only slightly damaged by heat. Approximately one-half of the weapon remained. All major components were damaged but were identifiable and accounted for.

January 31, 1958 / B-47 / Overseas Base

A B-47 with one weapon in strike configuration was making a simulated takeoff during an exercise alert. When the aircraft reached approximately 30 knots on the runway, the left rear wheel casting failed. The tail struck the runway and a fuel tank ruptured. The aircraft caught fire and burned for seven hours. Firemen fought the fire for the allotted ten minutes fire fighting time for high explosive contents of that weapon, then evacuated the area. The high explosive did not detonate, but there was some contamination in the immediate area of the crash. After the wreckage and the asphalt beneath it were removed and the runway washed down, no contamination was detected. One fire truck and one fireman's clothing showed slight alpha contamination until washed. Following the accident, exercise alerts were temporarily suspended and B-47 wheels were checked for defects.

February 5, 1958 / B-47 / Savannah River, Georgia

The B-47 was on a simulated combat mission that originated at Homestead AFB, Florida. While near Savannah, Georgia, the B-47 had a mid-air collision at 3:30 a.m. with an F-86 aircraft.. Following the collision the B-47 attempted three times to land at Hunter AFB, Georgia, with a weapon aboard. Because of the condition of the aircraft, its airspeed could not be reduced enough to insure a safe landing. Therefore, the decision was made to jettison the weapon rather than expose Hunter AFB to the possibility of a high explosive detonation. A nuclear detonation was not possible since the nuclear capsule was not aboard the aircraft. The weapon was jettisoned into the water several miles from the mouth of the Savannah River (Georgia) in Wassaw Sound off Tybee Beach. The precise weapon impact point is unknown. The weapon was dropped form an altitude of approximated 7,200 feet at an aircraft speed of 180-190 knots. Not detonation occurred. After jettison the B-47 landed safely. A three square mile area was searched using a ship with divers and underwater demolition team technicians using Galvanic drag and hand-held sonar devices. The weapon was not found. The search was terminated April 16, 1958. The weapon was considered to be irretrievably lost.

March 11, 1958 / B-47 / Florence, South Carolina

On March 11, 1958 at 3:53 p.m. EST, a B-47E departed Hunter AFB, Georgia as number three aircraft in a flight of four enroute to an overseas base. After level off at 15,000 feet, the aircraft accidentally jettisoned an unarmed nuclear weapon which impacted in a sparsely populated area 6 1/2 miles east of Florence, South Carolina. The bomb's high explosive material exploded on impact. The detonation caused property damage and several injuries on the ground. The aircraft returned to base without further incident. No capsule of nuclear materials was aboard the B-47 or installed in the weapon.

November 4, 1958 / B-47 / Dyess AFB, Texas

A B-47 caught fire on take-off. Three crew members successfully ejected; one was killed when the aircraft crashed from an altitude of 1,500 feet. One nuclear weapon was on board when the aircraft crashed. The resultant detonation of the high explosive made a crater 35 feet in diameter and six feet deep. Nuclear materials were recovered near the crash site.

November 26, 1958 / B-47 / Chennault AFB, Louisiana

A B-47 caught fire on the ground. The single nuclear weapon on board was destroyed by the fire. Contamination was limited to the immediate vicinity of the weapon residue within the aircraft wreckage.

January 18. 1959 / F-100 / Pacific Base

The aircraft was parked on a revetted hardstand in ground alert configuration. The external load consisted of a weapon on the left intermediate station and three fuel tanks (both inboard stations and the right intermediate station). When the starter button was depressed during a practice alert, an explosion and fire occurred when the external fuel tanks inadvertently jettisoned. Fire trucks at the scene put out the fire in about seven minutes. The capsule was not in the vicinity of the aircraft and was not involved in the accident. There were no contamination or cleanup problems.

July 6, 1959 / C-124 / Barksdale AFB, Louisiana

A C-124 on a nuclear logistics movement mission crashed on take-off. The aircraft was destroyed by fire which also destroyed one weapon. No nuclear or high explosive detonation occurred - safety devices functioned as designed. Limited contamination was present over a very small area immediately below the destroyed weapon. This contamination did not hamper rescue or fire fighting operations.

September 25, 1959 / P-5M / Pacific Ocean, off Washington-Oregon Coast

A U.S. Navy P-5M aircraft, assigned to NAS Whidbey Island, Washington, crashed in the Pacific Ocean about 100 miles west of the Washington-Oregon border. It was carrying an unarmed unclear antisubmarine weapon containing no nuclear material. The weapon was not recovered.

October 15, 1959 / B-52 / KC-135 / Hardinsberg, Kentucky

The B-52 departed Columbus Air Force Base, Mississippi at 2:30 p.m. CST, October 15, 1959. This aircraft assumed the #2 position in a flight of two. The KC-135 departed Columbus Air Force Base at 5:33 p.m. CST as the #2 tanker aircraft in a flight of two scheduled to refuel the B-52's. Rendezvous for refueling was accomplished in the vicinity of Hardinsberg, Kentucky at 32,000 feet. It was night, weather was clear, and there was no turbulence. Shortly after the B-52 began refueling from the KC-135, the two aircraft collided. The instructor pilot and pilot of the B-52 ejected, followed by the electronic warfare officer and the radar navigator. The co--pilot, navigator, instructor navigator, and tail gunner failed to leave the B-52. All four crewmembers in the KC-135 were fatally injured. The B-52's two unarmed nuclear weapons were recovered intact. One had been partially burned but this did not result in the dispersion of any nuclear material or other contamination.

June 7, 1960 / BOMARC / McGuire AFB, New Jersey

A BOMARC air defense missile in ready storage condition (permitting launch in two minutes) was destroyed by explosion and fire after a high pressure helium tank exploded and ruptured the missile's fuel tanks. The warhead was also destroyed by the fire although the high explosive did not detonate. Nuclear safety devices acted as designed. Contamination was restricted to an area immediately beneath the weapon and an adjacent elongated area

January 24, 1961 / B-52 / Goldsboro, North Carolina

During a B-52 airborne alert mission structural failure of the right wing resulted in two weapons separating from the aircraft during aircraft breakup at 2,000 - 10,000 feet altitude. One bomb parachute deployed and the weapon received little impact damage. The other bomb fell free and broke apart upon impact. No explosion occurred. Five of the eight crew members survived. A portion of one weapons, containing uranium, could not b recovered despite excavation in the waterlogged farmland to a depth of 50 feet. The Air Force subsequently purchased an easement requiring permission for anyone to dig there. There is no detectable radiation and no hazard to the area.

March 14, 1961 / B-52 / Yuba City, California

A B-52 experienced failure of the crew compartment pressurization system forcing descent to 10,000 feet altitude. Increased fuel consumption caused fuel exhaustion before rendezvous with a tanker aircraft. The crew bailed out at 10,000 feet except for the aircraft commander who stayed with the aircraft to 4,000 feet steering the plane away from a populated area. The two nuclear weapons on board were torn from the aircraft on ground impact. The high explosive did not detonate. Safety devices worked as designed and there was no nuclear contamination.

November 13, 1963 / Atomic Energy Commission Storage Igloo / Median Base, T

An explosion involving 123,000 pounds of high explosive components of nuclear weapons caused minor injuries to three Atomic Energy Commission employees. There was little contamination from the nuclear components stored elsewhere in the building. The components were from obsolete weapons being disassembled.

January 13, 1964 / B-52 / Cumberland, Maryland

A B-52D was enroute from Westover Air Force Base, Massachusetts, to its home base at Turner Air Force Base, Georgia. The crash occurred approximately 17 miles SW of Cumberland, Maryland. The aircraft was carrying two weapons. Both weapons were in a tactical ferry configuration (no mechanical or electrical connections had been made to the aircraft and the safing switches were in the "SAFE" position). Prior to the crash, the pilot had requested a change of altitude because of severe air turbulence at 29,500 feet. The aircraft was cleared to climb to 33,000 feet. During the climb, the aircraft encountered violent air turbulence and aircraft structural failure subsequently occurred. Of the five aircrew members, only the pilot and co-pilot survived. The gunner and navigator ejected but died of exposure to sub-zero temperatures after successfully reaching the ground. The radar navigator did no eject and died upon aircraft impact. The crash site was an isolated mountainous and wooded area. The site had 14 inches of new snow covering the aircraft wreckage which was scattered over an area of approximately 100 yards square. The weather during the recovery and cleanup operation involved extreme cold and gusty winds. Both weapons remained in the aircraft until it crashed and were relatively intact in the approximate center of the wreckage.

December 5, 1964 / LGM 30B (Minuteman ICBM) / Ellsworth AFB, South Dakota

The LGM 30B Minuteman I missile was on strategic alert at Launch Facility (LF) L-02, Ellsworth AFB, South Dakota. Two airmen were dispatched to the LF to repair the inner zone (IZ) security system. In the midst of their checkout of the IZ system, one retrorocket in the spacer below the Reentry Vehicle (RV) fired, causing the RV to fall about 75 feet to the floor of the silo. When the RV struck the bottom of the silo, the arming and fusing/altitude control subsystem containing the batteries was torn loose, thus removing all sources of power from the RV. The RV structure received considerable damage. All safety devices operated properly in that they did not sense the proper sequence of events to allow arming the warhead. There was no detonation or radioactive contamination.

December 8, 1964 / B-58 / Bunker Hill (Now Grissom) AFB, Indiana

SAC aircraft were taxiing during an exercise alert. As one B-58 reached a position directly behind the aircraft on the runway ahead of it, the aircraft ahead brought advanced power. As a result of the combination of the jet blast from the aircraft ahead, the icy runway surface conditions, and the power applied to the aircraft while attempting to turn onto the runway, control was lost and the aircraft slid off the left hand side of the taxiway. The left main landing gear passed over a flush mounted taxiway light fixture and 10 feet further along in its travel, grazed the left edge of a concrete light base. The feet further, the left main landing gear struck a concrete electrical manhole box, and the aircraft caught on fire. When the aircraft came to rest, all three crew members aboard began abandoning the aircraft. The aircraft commander and defensive systems operator egressed with minor injuries. The navigator ejected in his escape capsule, which impacted 548 feet from the aircraft. He did not survive. Portions of the five nuclear weapons on-board burned; contamination was limited to the immediate area of the crash and subsequently removed.

October 11, 1965 / C-124 / Wright-Patterson AFB, Ohio

The aircraft was being refueled in preparation for a routine logistics mission when a fire occurred at the aft end of the refueling trailer. The fuselage of the aircraft, containing only components of nuclear weapons and a dummy training unit, was destroyed by the fire. There were no casualties. The resultant radiation hazard was minimal. Minor contamination was found on the aircraft, cargo and clothing of explosive ordnance disposal and fire fighting personnel, and was removed by normal cleaning.

December 5, 1965 / A-4 / At Sea, Pacific

An A-4 aircraft loaded with one nuclear weapon rolled off the elevator of a U.S. aircraft carrier and fell into the sea. The pilot, aircraft, and weapon were lost. The incident occurred more that 500 miles from land.

January 17, 1966 / B-52 / KC-135 / Palomares, Spain

The B-52 and the KC-135 collided during a routine high altitude air refueling operation. Both aircraft crashed near Palomares, Spain. Four of the eleven crewmembers survived. The B-52 carried four nuclear weapons. One was recovered on the ground, and one was recovered from the sea, on April 7, after extensive search and recovery operations. Two of the weapons' high explosive materials exploded on impact with the ground, releasing some radioactive materials. Approximately 1400 tons of slightly contaminated soil and vegetation were removed to the United States for storage at an approved site. Representatives of the Spanish government monitored the cleanup operation.

January 21, 1968 / B-52 / Thule, Greenland

A B-52 from Plattsburgh AFB, New York, crashed and burned some seven miles southwest of the runway at Thule AB, Greenland while approaching the base to land. Six of the seven crewmembers survived. The bomber carried four nuclear weapons, all of which were destroyed by fire. Some radioactive contamination occurred in the area of the crash, which was on the sea ice. Some 237,000 cubic feet of contaminated ice, snow and water, with crash debris, were removed to an approved storage site in the United States over the course of a four-month operation. Although an unknown amount of contamination was dispersed by the crash, environmental sampling showed normal readings in the area after the cleanup was completed. Representatives of the Danish government monitored the cleanup operations.

Spring 1968 / At Sea, Atlantic

Details remain classified.

September 19, 1980 / Titan II ICBM / Damascus, Arkansas

During routine maintenance in a Titan II silo, an Air Force repairman dropped a heavy wrench socket, which rolled off a work platform and fell toward the bottom of the silo. The socket bounced and struck the missile, causing a leak from a pressurized fuel tank. The missile complex and the surrounding area were evacuated and a team of specialists was called in from Little Rock Air Force Base, the missile's main support base. About 8 1/2 hours after the initial puncture, fuel vapors within the silo ignited and exploded. The explosion fatally injured one member of the team. Twenty-one other USAF personnel were injured. The missile's re-entry vehicle, which contained a nuclear warhead, was recovered intact. There was no radioactive contamination.

NUCLEAR ACCIDENTS AT PALOMARES, SPAIN IN 1966 AND THULE, GREENLAND IN 1968

FOREWARD

(U)This brief account of the diplomatic history of the Palomares, Spain and Thule, Greenland nuclear weapon accidents was commissioned for the purpose of providing some insight into the demands which could be made on United States' ambassadors and their staffs should such an accident happen again.

(U)We have been fortunate that we have not had a major overseas accident of the scale of Palomares or Thule since 1968. One of the unfortunate by-products of this excellent nuclear safety record has been the atrophying of expertise and consciousness of the lessons learned from those accidents.

(U)In a number of important respects today's environment overseas is different from that of the late 1960's. A small but vocal opposition to Intermediate Nuclear Force deployments--quiescent now--is lurking just below the surface lacking a cause celebre. A potentially widening "nuclear allergy" exists, brought about through emerging, left of center-nuclear-free minded second generation leaderships in the post-World War II international system. These adverse "trends" are fueled by a concerted effort by the Soviet Union to undermine allied support for U.S. nuclear deployments.

~~(S)~~ U.S. nuclear weapon deployments will remain a feature of deterrence in our alliance system for the forseeable future. Deployed weapons are subject to accidents and incidents. It is simply a fact of life. Although every effort is made to reduce the risk of an accident with the deployed stockpile, the simple fact that deployed weapons must be maintained, modernized, trained with, and exercised means that some accident risk remains. ~~B1~~

~~(S)~~ In addition to reducing accident risk to a minimum, we must be prepared to deal with the consequences of an accident should one happen. The Washington interagency group is convinced that the degree of damage to U.S. national security from any future nuclear accident or incident would depend in large measure on the quality of U.S. Government and host ~~B1~~

government management of the emergency. In short, if handled smoothly and effectively, the political costs could be minimized. If managed poorly, negative effects will be magnified.

(~~S~~)The United States' ambassador and his staff will play a key role in effective management of the U.S. Government response to an accident. As noted herein, embassies are generally ill-equipped to deal with such exigencies. The Department of State recently transmitted guidance to [redacted] key posts in the form of a mdoel plan each ambassador will adapt to local conditions and install as part of his emergency action plan. Although modest, the plan constitutes a first step toward the goal of embassy preparedness--in partnership with the Departments of Defense and Energy, and host nation officials--to minimize any adverse impact on Alliance solidarity resulting from a nuclear accident or incident.

(U)Dr. James E. Miller of the Office of the Historian, Department of State, has done an outstanding job of surfacing the diplomatic problems of Palomares and Thule in a paper which is interesting reading. I hope this contribution to our understanding of the kinds of demands which could be made on our embassies is useful but continues to be unused.

Colonel Michael Barrett Seaton
Bureau of Political-Military Affairs
April 1985

SUMMARY

(~~S~~)The January 17, 1966 and January 21, 1968 crashes of nuclear-weapons-equipped SAC B-52 bombers on the territory of two U.S. allies thrust the Embassies in Spain and Denmark into complex and ultimately unsuccessful negotiations to retain rights for SAC overflights and for the storage of nuclear weapons. Other important and interrelated responsibilities assumed by the Embassies included managing a public relations effort designed to influence the citizens of the host state, assisting in efforts to clean up the contaminated crash sites, and settling the damage claims filed by the nationals of the host nation. All of these functions were carried out in cooperation with the Department of Defense. A clear division of responsibility emerged: the military concentrated on clean-up and claims settlement while the Embassy or Department of State assumed primary responsibility for retaining U.S. nuclear weapons rights. In Spain public relations matters constituted the major cause of conflict between the Embassy and military, while geographic separation gave the Department of Defense primary control of public relations in Greenland. The role of the American Ambassador and the depth of Embassy involvement during these crises varied in accordance with the circumstances of the accidents, the form of government of the host nation, and the character of the U.S. chief of mission.

(U)Certain clear lessons emerge from the two accidents. Within the limits imposed by atomic weapons information security, the United States should seek to provide the press with with all available information as quickly as possible. Expert technical assistance should be provided both at the crash site and at the Embassy as soon as possible after an accident. The United States should be ready to provide quick service for claims arising from an accident. The U.S. Ambassador must be in a position to assert his responsibility for all political activities in the host nation.

B1, B3

PALOMARES, SPAIN, JANUARY 1966

The Incident

(U)At approximately 10:22 a.m., January 17, 1966, a KC 135 refueling aircraft operating from Moron AFB collided with a B-52 bomber of the Strategic Air Command in the skies over the southern Spanish village of Palomares. Seven U.S. airmen were killed. The four unarmed nuclear devices which the aircraft was carrying apparently broke lose from their moorings during the disintegration of the B-52. One bomb fell with other wreckage into the sea off Palomares; the other three bombs landed around the village. The non-nuclear charges on two of these devices exploded releasing quantities of plutonium into the air and onto the ground. Wreckage of the two aircraft was strewn over a wide area around the village, but, fortunately no townspeople were injured by the falling debris or by plutonium contamination.

~~(S)~~The U.S. Air Force took full control of on-site efforts to recover the wreckage and nuclear armament and to decontaminate the crash site. The Department of Defense also took charge of the settlement of claims arising from the accident. The U.S. Embassy in Spain initially had an exclusively political role: dealing with the impact of the accident on U.S.-Spanish relations. Subsequently, it moved into areas which initially had been under exclusive control of the Department of Defense: the settlement of claims arising from the accident, and the clean-up operations. The objective of American diplomacy was to retain Spanish defense cooperation even at the cost of modifying existing arrangements for nuclear overflights and accepting damaging restrictions on the release of information concerning Palomares imposed by the Spanish Government.

~~(S)~~The U.S. Embassy at Madrid was informed of the accident at Palomares by phone by its military liaison group within an hour of the crash. In turn it notified the Department of State of the available details of the crash and initial Spanish Government and public reaction. Ambassador Angier Biddle Duke had been attending a meeting of a major business association when an aide arrived to verbally inform him of the accident. He immediately left the meeting and drove to the Spanish Foreign Office to seek a meeting with Foreign Minister Ferdinando Maria Castiella. However, the Foreign Minister was not in his office and Duke reported the available details of the accident to the Under Secretary for Political Affairs,

THULE, GREENLAND, JANUARY 1968

(U)At approximately 3:40 pm, January 21, 1968, a SAC B-52 bomber carrying nuclear weapons crashed on the 7-foot-thick ice of North Star Bay approximately 7 miles from the runway at Thule AFB. The aircraft had been attempting an emergency landing after a fire broke out in its heating system. Six crewmen bailed out successfully and were subsequently rescued. A seventh died during the bailout procedure. The four nuclear devices remained within the aircraft and broke up upon impact. Alpha radiation was released in the crash site area. In addition, small fragments from the aircraft passed through the ice pack and settled at the bottom of North Star Bay.

(U)The B-52 crash occurred at a particularly sensitive time for the government of Danish Prime Minister Jens Otto Krag, since a national election campaign was in its final days. The Danish Government, upon receipt of information of the crash (apparently through military channels), released a statement (January 22, 1968) which claimed that Denmark did not permit flights by nuclear armed aircraft over any part of its national territory, including Greenland, and stressed that the plane had been attempting an emergency landing after encountering inflight problems. The text of this statement was not cleared with the U.S. Government prior to its release. The United States had operated its nuclear armed aircraft over Greenland since the conclusion of a 1957 agreement with the Government of Denmark.[34]

(U)Because the wreckage was located in a remote and lightly populated area, claims did not play a major role in the Thule incident. The distance between the crash site and Denmark reinforced the clear division of responsibility between the military and U.S. Embassy already evident after the Palomares accident. The Department of Defense took charge of the recovery and clean-up operations at the crash site, and assumed responsibility for the payment of claims arising from the accident. In addition, the Defense Department public relations teams took charge of the press covering the recovery operation in Greenland and were the primary source of information for reporters in Washington. However, Denmark's democratic politics put an even greater premium on the skillful handling of public relations by Ambassador Katherine White and the Embassy staff in Copenhagen.

B1, B3

PALOMARES, SPAIN, JANUARY 1966

The Incident

(U)At approximately 10:22 a.m., January 17, 1966, a KC 135 refueling aircraft operating from Moron AFB collided with a B-52 bomber of the Strategic Air Command in the skies over the southern Spanish village of Palomares. Seven U.S. airmen were killed. The four unarmed nuclear devices which the aircraft was carrying apparently broke lose from their moorings during the disintegration of the B-52. One bomb fell with other wreckage into the sea off Palomares; the other three bombs landed around the village. The non-nuclear charges on two of these devices exploded releasing quantities of plutonium into the air and onto the ground. Wreckage of the two aircraft was strewn over a wide area around the village, but, fortunately no townspeople were injured by the falling debris or by plutonium contamination.

~~(S)~~The U.S. Air Force took full control of on-site efforts to recover the wreckage and nuclear armament and to decontaminate the crash site. The Department of Defense also took charge of the settlement of claims arising from the accident. The U.S. Embassy in Spain initially had an exclusively political role: dealing with the impact of the accident on U.S.-Spanish relations. Subsequently, it moved into areas which initially had been under exclusive control of the Department of Defense: the settlement of claims arising from the accident, and the clean-up operations. The objective of American diplomacy was to retain Spanish defense cooperation even at the cost of modifying existing arrangements for nuclear overflights and accepting damaging restrictions on the release of information concerning Palomares imposed by the Spanish Government.

~~(S)~~The U.S. Embassy at Madrid was informed of the accident at Palomares by phone by its military liaison group within an hour of the crash. In turn it notified the Department of State of the available details of the crash and initial Spanish Government and public reaction. Ambassador Angier Biddle Duke had been attending a meeting of a major business association when an aide arrived to verbally inform him of the accident. He immediately left the meeting and drove to the Spanish Foreign Office to seek a meeting with Foreign Minister Ferdinando Maria Castiella. However, the Foreign Minister was not in his office and Duke reported the available details of the accident to the Under Secretary for Political Affairs,

Adolfo Cortina. In his meetings with Cortina and other senior officials of the Spanish Foreign Office Duke attempted to coordinate aresponse to the accident and expressed U.S. apologies for the incident. Despite the fact that many of the details of the accident were known to both the Spanish and foreign press, Spanish officials requested that the "nuclear aspect" be "played down . . . in any public releases" and that Spain be "disassociated from any nuclear implications." Ambassador Duke instructed all U.S. agencies in Spain to follow the press guidance set out in a March 1964 "USAFE nuclear accident information plan" and withheld authorization for any public reference to the B-52's nuclear armament.[1] An initial press statement which did not mention the nuclear aspects of the accident was cleared with the Government of Spain and released at Torrejon AFB at 9:45 p.m. local time on January 17.

Initial Public Relations

(U)From the start of the Palomares recovery operation, the Embassy faced two interconnected public relations problems: 1) insuring accurate reporting in the media and 2) winning the agreement of Spanish authorities to provide as complete information on the operation as security considerations permitted. Without access to more information, the tendency of the press toward misrepresentation and sensationalism increased. The Franco regime, however, in spite of a certain mellowing of its authoritarian nature after a quarter century in power, saw the press as an adversary to be fended off rather than placated.

(~~S~~)From the beginning, Department of State officials wanted to deal publicly with the nuclear issue. The Spanish Government, however, strenuously objected to providing any details to the press, an attitude initially shared by U.S. military representatives on the scene at Palomares.[2] U.S. officials recognized that holding on to the trust and cooperation of the Franco regime was critical to the successful conclusion of the recovery of the bombs and to maintaining its basing and overflight rights. Thus, the Spanish Government held a veto power over the release of information. In order to maintain Spanish confidence, the Embassy and recovery teams at Palomares made conscious efforts to assure that the Spanish Government was kept fully informed of all apsects of the recovery operation. Ambassador Duke met frequently with Spanish officials, JUSMG kept the High General Staff informed of the Defense Department's actions at Palomares, while Secretary of State Rusk and General Earl Wheeler, the Chairman of the Joint Chiefs of Staff, sent personal messages to their Spanish counterparts thanking them for their cooperation and

~~B1, B3~~
~~B1, B3~~

assuring them that the recovery operation was receiving constant attention at the highest levels of the U.S. Government.[3]

~~(S)~~ The Franco regime's efforts to avoid mention of the B-52's nuclear armament collapsed on January 19 when United Press International reported not only that the B-52 was carrying nuclear bombs but that one was missing and hundreds of geiger counter equipped U.S. troops were combing the countryside around Palomares searching for signs of radioactivity. On January 20, the Spanish Government authorized release of a statement which admitted the B-52 carried nuclear armament but insisted that initial radiological surveys had established that no public health danger existed in the Palomares area. The statement represented a Spanish redrafting of an Embassy-proposed press release which provided fuller details of the nuclear aspects of the accident.[4] By January 21 the nuclear contamination issue was receiving full play in the Spanish press. The failure of the U.S. and Spanish Governments to provide accurate information on the crash combined with the problem of the missing nuclear weapon created serious public relations problems for the Embassy for months afterwards.

(S)The concern of Spanish officials with the public relations aspects increased as the size of the foreign press corps covering the accident grew. In an effort to impose censorship on the Spanish public, the Franco Government banned the sale of foreign newspapers and news magazines. On January 21, the Spanish Foreign Office called in Duke to complain about an alarmist American wireservice story which attributed its sources to the U.S. Embassy. Franco had read the article and was upset. The Spanish Government threatened to take unspecified "independent action," in retaliation for the leak. Duke was able to refute that story's attribution to U.S. sources by contacting the UPI bureau chief in Madrid and thus to preserve close intergovernmental ccoperation.[5]

~~(S)~~The key motivations for the Franco Government's sensitivity were its concern about the impact which stories about nuclear contamination would have on southern Spain's lucrative tourist industry and its fears that the underground and semi-legal opposition forces, including the outlawed Communist Party, would effectively exploit the incident in their campaign to topple the regime. Ironically, the sensationalism of the Communist-controlled and clandestine "Independent Spanish Radio" would have considerable effect on the populace of Palomares precisely because the information provided by their own government was both sketchy and believed unreliable. U.S. officials also suspected that the Government of Spain intended to use the bomb accident as a bargaining chip

in the next round of base negotiations scheduled for 1968.[6] B1, B3

(S) For U.S. officials, the critical issue was limiting adverse publicity which could trigger a formal Spanish demand for the cessation of overflights of its territory by nuclear armed aircraft. The threat that such permission would be withdrawn first surfaced on January 19 when Spanish Vice President Munoz Grandes suggested that in future the United States conduct its refueling operations over international waters. Officials at the Spanish Foreign Office also complained to Embassy officials about holding refueling operations over their territory. Duke warned Washington that the speedy recovery of the missing fourth nuclear device was the key to reducing press coverage which could force the Spanish Government to suspend overflight permission. Continued intense press coverage would force the Spanish Government to take dramatic action to reassure restive domestic public opinion.[7]

(S) Duke's warning proved instantly prophetic. On January 22 Munoz Grandes met with the Chief of the U.S. JUSMG, Major General Stanley J. Donovan, to request the suspension of the overflight of Spanish territory by nuclear-armed U.S. aircraft. The Spanish Foreign Office initially told reporters that any changes in the flight paths of its aircraft were unilaterally made by U.S. authorities. However, in the face of continued intense press coverage of Palomares and rising discontent among influential segments of the Spanish intelligentsia and bureaucracy, Spanish Information Minister M. Fraga Iribarne told a January 29 press conference that U.S. nuclear armed overflights of Spain had been "permanently" suspended, adding that all U.S. medium bombers were being withdrawn from Torrejon AFB and that no nuclear armaments were stored on that base. Fraga did not hold any consultations with U.S. officials prior to making this statement.[8] B1, B3

The Question of a Joint Statement

(S) The United States, following its established policy, refrained from public comment on issues relating to its nuclear defense operations. The Embassy, however, was actively attempting to counter misinformation originating from the recovery site. Because of the isolated location of the recovery operation, security measures enforced by the government, and the limited value of news relating to the land clean-up operation, the majority of the foreign press covering the Palomares story stayed in Madrid, awaiting fresh developments in the recovery operations. All of these conditions produced misinformation and sensationalism.

The Embassy was also concerned about the lack of information being provided by the Department of Defense's on site press-spokesman. The paucity of factual information provided correspondents visiting the scene tended to exacerbate already unfavorable reporting. In an effort to counter these factors, Ambassador Duke toured the recovery site on February 3 and upon his return to Madrid held a news conference at which he explained the progress of the clean-up operation as well as the technical difficulties facing the Navy in its search for the missing bomb. Duke's continued concern over accurate press coverage of the clean-up and salvage operations led him to strongly endorse a suggestion by the DOD press representative at the crash site for a press conference, jointly sponsored by the Embassy and Spanish government, and preferably held at Palomares, which would dispell rumors about contamination. The Spanish Government did not act upon this suggestion due to internal disagreements. After State Department-DOD consultations the idea was vetoed as "undesirable" by the U.S. Government.[9]

(~~C~~) Inaccurate reporting dogged U.S. officials. The day after Duke's February 3 press conference, the New York Times erroneously quoted him as identifying the missing bomb as an hydrogen device. In view of Spanish sensitivity to any discussion of the bomb's characteristics (particularly its killing power and radius), Duke obtained a retraction from the Times' Spanish correspondent, Tad Szulc.[10]

(~~S~~) Meanwhile the Embassy continued to press the Spanish Government for the release of a joint statement which would clarify the details of the Palomares accident and clean-up. In mid-February 1966, the Embassy submitted to the Foreign Office, the Spanish Atomic Energy Commission (JEN), and Vice President Munoz Grandes a State Department draft of a joint U.S.-Spanish statement. While initial reaction to the U.S. proposal was generally favorable, all three forwarded suggestions for changes in the text. An internal Spanish Government debate on the text effectively blocked the issuance of any statement. Vice President Munoz Grandes, in particular, was opposed to any public statement on the accident at a time when the Soviet Union had initiated a major propaganda offensive. He feared that the Soviet Union would simply exploit additional information to keep the issue before world public opinion. Information Minister Fraga and the JEN favored release of the text, while the Ministry of Foreign Affairs was divided on the issue. Finally, Franco vetoed any further disclosures. On February 25, the Embassy suggested that the United States considerd issuing a unilateral statement.[11]

(~~S~~)On March 1, the press impasse was finally broken by the action of the Chairman of the JEN, Jose Maria Otero. Without clearance from either the Foreign Office or High General Staff of the Spanish Army, he discussed the contamination issue, outlined clean up operations, and confirmed that one of the nuclear weapons was still missing in a press interview. U.S. officials speculated that Otero's actions were encouraged by Information Minister Fraga, a leading proponent of openness with the press.[12] The following day, the Department of State released a previously prepared statement stressing the safety features of U.S. nuclear weapons and confirming the details of Otero's interview.

(~~C~~)On March 8 Ambassador Duke, Information Minister Fraga, and members of their families went swimming in the sea off Palomares to demonstrate the safety of the area for tourists. The germ of this idea may have originated with Spanish Desk Officer Frank Ortiz who in January 1966 suggested that "newsworthy" visitors patronize hotels near the crash site. The Spanish Government had scheduled a new hotel for opening in March at Mojacar close by Palomares and was very concerned that the adverse publicity would destroy the tourist season in that area. Duke conceived the idea of attending the opening and taking a swim. Joined by most of his staff, he took the plunge into the icy waters in the morning. Later that afternoon, Fraga and Duke took a second swim. The impact on world public opinion was immediate and highly favorable. This vivid proof that the sea was not endangered by contamination probably saved the tourist season in Southern Spain.[13]

(~~C~~)As the clean-up operation progressed successfully and local claims procedures began operating effectively, the major public relations problem facing Embassy officials was providing information on the effort to recover the missing nuclear weapon. In view of security considerations and the difficulties of securing Spanish agreement to the release of information, the Embassy secured the concurrance of the Air Force command in Spain for its recommendation that the United States inform the Franco Government that it intended to make appropriate information on recovery operations available to the press without prior consultations.[14]

Location of the Missing Bomb

(~~S~~)After an exhausting search, the missing bomb was finally located and tentatively identified on March 15, 1966. However, the reluctance of the commander on the scene, Rear Admiral William Guest, to release information without definite confirmation that the object was in fact the missing bomb

forced the Embassy to cancel precipitously an early morning press conference on March 16. At the same time, leaks within the military chain of command outside Spain put increasing pressure on the Embassy and military recovery operation to provide some sort of information. Finally, on March 17 after confirmation that the bomb had been located, the Embassy issued a statement which had previously been prepared through consultations with the Department of State. Equipment problems and the loss of contact with the bomb for 9 days delayed final recovery.[15]

(~~S~~)The long search and subsequent recovery problems combined with the scarcity of information available reinforced press tendencies toward sensationalism. At the urging of U.S. representatives in Spain, including Ambassador Duke, the Department of Defense approved a plan to permit representatives of the press to view the bomb shortly after it was hauled aboard a U.S. Navy recovery vessel. The Embassy had apparently initially wanted the press to be present during the recovery operation to establish U.S. credibility but accepted military objections to this plan. As an alternative it suggested that Spanish officials and press pool representatives view the recovered bomb and that the press then receive a formal briefing on the recovery operation.[16]

(~~S~~)During the recovery operation, leaks from the Spanish representative at Palomares created additional press problems and Ambassador Duke sent an Embassy representative to the recovery site to "insure . . . press treatment . . . recovery operations protects and advances U.S. interests," through strict control of the information released. In a largely unsuccessful effort to minimize speculation, the United States had established a daily Navy-Air Force joint briefing at Palomares. However, the long delay in recovery of the missing bomb, the limited information being provided by military officials, isolation of the site, and the attendant growth of rumors defeated this aspect of the public relations effort and spawned sensationalistic accounts, particularly in the Western European press. In addition, the long simmering differences between the Embassy staff and the DOD press representatives at Palomares surfaced when Embassy officers made their unhappiness known to members of the press, complaining that the military treated them as "nuisances."[17]

(U)The Navy's inability to retrieve quickly the lost nuclear weapon after its discovery created additional problems for the Embassy. On the international level the Soviet Union was exploiting U.S. difficulties to attack the stationing of nuclear weapons outside U.S. national territory and demanding international verification of the recovery. Meanwhile a large and growing group of journalists was waiting in Madrid for

permission to visit the crash site and view the results of the recovery operation. Press coverage of the clean up and recovery was limited, first by the need to keep everyone not associated with the operation away from areas of potential contamination at the land sites and then by security considerations and the practical impossibility of accomodating large numbers of press representatives on the recovery ships. The Franco Government, of course, preferrred to keep the press away from the site entirely. Its aims were facilitated by the isolation of Palomares and the slow progress and generally unnewsworthy nature of daily recovery and clean-up operations. The vast majority of the press gladly preferred to await major developments in the comfort of Madrid's hotels.[18]

~~(S)~~ On April 7, 1966, the naval task force retrieved the missing bomb. The Embassy notified the Spanish Foreign Office and Information Ministry while JUSMG reported the succesful recovery to the High General Staff, Air Ministry and JEN. Ambassador Duke proceeded to the recovery site together with representatives of the Spanish Government.[19] On April 8, the Spanish officials boarded a U.S. Navy recovery vessel and viewed the weapon. A small number of press representatives were brought alongside the recovery ship for a glimpse of the bomb and the U.S. military provided a briefing on the recovery operation for the the entire press corps. At the request of the Government of Spain, relayed through the Embassy, the recovery ship with its atomic cargo immediately departed for the United States without docking at any Spanish port. A majority of the press departed soon after the weapon recovery was completed.[20]

~~(S)~~ Palomares remained a public relations problem for the Embassy for nearly a decade afterwards. The annual anniversaries of the accident were marked by television and press retrospectives focusing on the effects of the crash on the people of Palomares. The Embassy was frequently requested to provide technical assistance for these inquiries and to explain the U.S. position. The population of the village declined rapidly as the soil became increasingly alkaline and incapable of supporting the area's primary cash crop, tomatoes. In addition, many villagers departed out of fear of radiation effects. Internal opponents of the Franco regime, initially spearheaded by the Duchess of Medinia-Sidonia, attacked the Spanish Government, claiming it had failed to safeguard the interests of its own citizens, particularly their rights to claim damages from the United States. The Embassy originated a plan to show U.S appreciation to the people of Palomares for the assistance they rendered to the downed aviators and their patience during the subsequent clean up by building a water desalination plant to assist in irrigation

projects. The idea, which Washington approved with some reservations, ran into a series of bureaucratic impasses in Spain.[21]

Conditional Reinstatement of Permission for Overflights

~~B1~~

(~~S~~)Once the Spanish Government suspended overflight permission for SAC nuclear armed bombers, the Embassy, through the JUSMG, was the primary channel through which the United States sought a reinstatement of its former privilege. Initially, the Embassy counseled Washington to avoid bringing up the overflight issue until the fourth atomic device was recovered. Negotiations for basing rights for three U.S. fighter squadrons assigned to NATO (from which Spain was excluded) and the approach of the renegotiation of the U.S.-Spanish Defense Cooperation Agreement further complicated the U.S. position.[22]

(~~S~~)Shortly after the recovery of the missing bomb, the Embassy advised the Department of State that it believed the Spanish Government would agree to permit flights of nuclear equipped-aircraft over the Straits of Gibraltar, but that this concession would increase Spanish resistance to allowing nuclear armed aircraft to overfly its territory,adding that it could not judge "when, if indeed ever, . . . GOS would be willing again . . . expose itself to . . . possibility, however remote, of another Palomares."[23]

(~~S~~)Nevertheless, acting on instructions from the Departments of State and Defense, the chief of JUSMG met with Munoz Grandes on May 3, 1966 to begin a long and ultimately unsuccessful effort to resume SAC flights over Spanish territory. While Munoz Grandes appeared willing to consider permitting U.S. aircraft to cross southern Spain via the base at Rota, strong opposition to any rescinding of the ban on overflights, led by the Spanish Foreign Office, delayed any final action on the U.S. request. Finally, at the end of December 1966, Munoz-Grandes informed the chief of JUSMG that the resumption of overflights by nuclear armed aircraft was "out of the question" for the forseeable future. Munoz Grandes did leave open, subject to further study by the Spanish Government, the possible use of Rota airfield "as (a) stopover."[24]

Settlement of Claims

(~~S~~) Although the Embassy showed no desire to interfere with the on-site operations of the Air Force and Navy it was slowly dragged into a more active role in the Palomares area by the complaints of local residents (magnified through the reporting of the Spanish and international press) that claims settlements were progressing too slowly. Ambassador Duke urged that the process be sped up. On February 12, 1966, at a meeting of the chief of JUSMG and the High General Staff, Spanish officers requested that the claims agreements forms used by the United States be reworded to permit filing later or supplementary claims for 10 to 20 years after the accident. They pointed out that the effects of the crash on the citizens and land of Palomares might not be fully revealed for many years after the accident. The Embassy contacted the Department of State and urged speedy consideration and action on the position of the Spanish Government.[25] Meanwhile, claims processing was suspended at Spanish request. After consideration of the legal aspects of the Spanish request, the Department of State forwarded a letter for delivery to the Spanish Government which explained the procedures outlined in the Foreign Claims Act and provided assurances that claims could be filed for an extended period of time following the accident. Negotiations on the claims settlements issue took place on February 19 and 21, 1966 between the chief of JUSMG and a representative of the Spanish High General Staff. The negotiators reached agreement that the assurances contained in the U.S. letter satisfied Spanish concerns.[26]

(~~C~~) Claims settlements continued for years after the accident. Francisco Simo Orts, the Spanish fisherman who saw the fourth bomb land at sea and assisted in rescuing downed US airmen, filed a series of claims against the United States which embarrassed both U.S. and Spanish officials and kept the issue of U.S. fairness in the press. The Embassy also inherited responsibility for handling claims after the military clean-up teams left Palomares, serving as a clearing house for the inquiries and complaints of the Spanish Government. The satisfaction of claims of Spanish citizens remained an irritant in U.S.-Spanish relations for nearly a decade. In 1976, the Embassy braced for major demonstrations which would mark the tenth anniversary of the Palomares crash. None took place. Internal political matters connected with the transition from dictatorship to democracy in Spain had evidently lessened public interest in the 1966 crash.[27]

Clean-Up Operations

(U)As was the case with claims issues, the Embassy initially left the clean-up operations to the representatives of the Department of Defense at Palomares. However, the requirements of an effective public relations effort and of effective communication with the Spanish Government inevitably led to an increased Embassy role in these matters.

~~(S)~~Initially, Ambassador Duke's major requirement was accurate information on the on-site operations. Teams of nuclear experts from the Department of Defense and the Atomic Energy Commission had arrived at the crash site within days of the accidents and were directing the clean-up and bomb land portion of the search for the missing nuclear bomb. The Embassy lacked a specialist in nuclear matters Duke relied upon his military attaches to provide the Embassy with full information on the recovery and decontamination operations. Utilizing their contacts with the 16th Air Force, the attaches were able to provide the Ambassador with a frequent (initially daily) written report on operations at Palomares which was then summarized and passed on to the State Department.[28]

~~(C)~~In early February the first concern of U.S. officials in Spain was rapid completion of a safe clean-up operation. The thoroughness of the operations carried out to insure the safety of the local population had the paradoxical effect of increasing public concern with the effects of radiation and of keeping the Palomares story in the forefront of news for the Spanish and international press. In addition, the tourist season was approaching. Tourism was a principal element in the rapid expansion of the Spanish economy in the 1960's and a critical factor in the modernization of Spanish politics and society. Both the United States and Spanish Governments were eager to eliminate the memories of Palomares in order to assure the continued growth of this key element in Spain's development. However, accelerating the pace of the decontamination effort proved difficult. On February 2, 1966, General Delmar Wilson, the on-site commander of the clean-up operation signed an agreement with the Spanish on-site representative, General Arturo Montel, which committed the United States to build a disposal pit near Palomares in which all contaminated soil registering 7,000 counts per minute (cpm) on a geiger counter would be stored. U.S. military officials quickly discovered that these ground rules for removal of contaminated soil could not be met by the deadline established by the tourist season. They also concluded that these figures were excessive from the safety standpoint and would seriously

~~B1, B3~~

B1, B3

complicate efforts to remove contaminated materials. Finally, the Embassy and JUSMG opposed the creation of a nuclear dump in Spain since this would only become a monument which anti-nuclear and anti-American forces could utilize for the political purposes. DOD officials argued that a reading of 50,000 cpm was perfectly safe and requested the Embassy to secure Spanish approval for using this level as the benchmark for soil removal. The Department of Defense proposed to remove all soil with readings above this level and to plow under and water down soil with lesser readings.[29]

(~~S~~)Based on advice provided by the U.S Atomic Energy Commission, the Department of State believed that a reading level of 100,000 cpm was perfectly satisfactory to protect public health and instructed the Embassy to seek an accord on soil removal based on that level as the benchmark. In order to assist Embassy and Department of Defense representatives in Spain, the Atomic Energy Commission sent two American nuclear energy specialists to Madrid in early February. Dr. John Hall was the Assistant Director for International Relations for the AEC. Dr. Wright Langham was the AEC's expert on plutonium contamination. He had previously worked at the Palomares site. Langham would remain in Madrid until mid-March to serve both as the Embassy contact with the JEN and as a special advisor to Ambassador Duke on nuclear matters. In addition to providing advice for Ambassador Duke, both men were instructed to provide technical explanations to buttress the U.S. positions in negotiations with the Spanish Goverment over soil clean-up operations. The State Department also provided the Embassy with a Washington interagency-approved position paper on detcontamination for use in dealing with the Spanish Government. This paper reiterated U.S. concern that the Spanish cpm level guideline for soil removal was much too low and would needlessly delay decontamenation operations to the detriment of both Spanish tourism and public relations aspects of the Palomares recovery while feeding local fears regarding the effects of radiation.[30]

(~~S~~)Armed with this technical aid, the Embassy arranged a meeting between U.S. and Spanish atomic energy experts on February 15. American scientists argued that the 100,000 cpm benchmark for soil removal was adequate for public health and safety. The Spanish scientists did not contest this position on technical grounds but would not accept it as the basis for continuing decontamination operations. U.S. officials were aware that clearance of their proposal would require action at a higher and political level of the Spanish Government. On February 17, the U.S. scientists and the chief of JUSMG met with representatives of the High General Staff. The Spaniards continued to press for soil removal to the 7000 cpm level. The

B1, B3

U.S. representatives repeated their arguments for utilization of a 100,000 cpm benchmark. Finally, the two sides reached a compromise. The United States would plow up two plots of ground registering a 60,000 cpm reading. In one plot the plowing would reach a depth of 8 inches. This land would be watered and broken up in the internationally-accepted manner proscribed for decontamination. The second plot would be plowed to the depth of 4 inches--the depth normally plowed by Spanish farmers. If readings taken on these two plots were at a normal level, the Spanish Government would abandon its demands for soil removal to the 7,000 cpm level. A copy of the Washington interagency paper and a copy of the telegram outlining the verbal agreement are attached as appendices C and D respectively.[31]

~~(S)~~The Department of State approved the compromise but expressed reservations about utilizing a 60,000 cpm benchmark for soil removal, arguing that this might set a precedent for future decontamination operations which would needlessly complicate U.S. efforts. It provided suggested wording for an agreement with the Spanish Government which would permit the United States to hold to a 100,000 cpm level as the benchmark for future clean-up operations.[32]

~~(S)~~The soil testing was completed on February 21, 1966. U.S. and Spanish scientists agreed that the cpm levels registered after the experiment were at "reasonable levels" for public heath and safety. Based on these conclusions, the Spanish Government abandoned its 7,000 cpm benchmark. Contaminated soil already collected was shipped to the United States for final disposal. The remaining areas were plowed under and watered down. The benchmark of 60,000 cpm became the practical measure for soil removal.[33]

THULE, GREENLAND, JANUARY 1968

(U)At approximately 3:40 pm, January 21, 1968, a SAC B-52 bomber carrying nuclear weapons crashed on the 7-foot-thick ice of North Star Bay approximately 7 miles from the runway at Thule AFB. The aircraft had been attempting an emergency landing after a fire broke out in its heating system. Six crewmen bailed out successfully and were subsequently rescued. A seventh died during the bailout procedure. The four nuclear devices remained within the aircraft and broke up upon impact. Alpha radiation was released in the crash site area. In addition, small fragments from the aircraft passed through the ice pack and settled at the bottom of North Star Bay.

(U)The B-52 crash occurred at a particularly sensitive time for the government of Danish Prime Minister Jens Otto Krag, since a national election campaign was in its final days. The Danish Government, upon receipt of information of the crash (apparently through military channels), released a statement (January 22, 1968) which claimed that Denmark did not permit flights by nuclear armed aircraft over any part of its national territory, including Greenland, and stressed that the plane had been attempting an emergency landing after encountering inflight problems. The text of this statement was not cleared with the U.S. Government prior to its release. The United States had operated its nuclear armed aircraft over Greenland since the conclusion of a 1957 agreement with the Government of Denmark.[34]

(U)Because the wreckage was located in a remote and lightly populated area, claims did not play a major role in the Thule incident. The distance between the crash site and Denmark reinforced the clear division of responsibility between the military and U.S. Embassy already evident after the Palomares accident. The Department of Defense took charge of the recovery and clean-up operations at the crash site, and assumed responsibility for the payment of claims arising from the accident. In addition, the Defense Department public relations teams took charge of the press covering the recovery operation in Greenland and were the primary source of information for reporters in Washington. However, Denmark's democratic politics put an even greater premium on the skillful handling of public relations by Ambassador Katherine White and the Embassy staff in Copenhagen.

Initial Public Relations Efforts

(~~S~~)Within hours of the first news of the crash, the Embassy faced a mounting volume of requests from Danish journalists to travel to Thule. These requests were referred through the Air Attache to the USAF Foreign Liaison Office. The Embassy cautioned both the Departments of State and of Defense that U.S. failure to grant permission to travel to Thule AFB and to facilitate the work of the press in this frigid area would create serious political problems since it would be interpreted as an affront to Danish territorial sovereignty.[35]

(~~S~~)The lessons of Palomares concerning the need for a good public relations program were in the forefront of U.S. Government concern in Washington. On January 23, the Assistant Secretary of State for European Affairs, John Leddy, met with Danish Ambassador Torben Ronne. Leddy opened the discussion by stressing the need for providing the press with as much information as possible, consonant with security requirements, on both the crash and the clean-up operation. He pointedly cited the bad precedents created by press censorship at Palomares. Leddy secured Ambassador Ronne's approval for a Department of Defense press release describing the findings of a ground survey team at the crash site. Ronne urged the quickest possible release of the document. The United States repeatedly cleared its press releases with the Danish Government during the first stages of the Thule operation. This action may have been designed to establish reciprocity with the Danes on public relations issues. If so, the effort failed. The Danish Government repeatedly issued statements without prior U.S. approval.[36]

(U)The immediate problem for both governments was insuring the availability of proper support and transportation for Danish and American reporters desiring to visit Greenland. In addition to troublesome climatic conditions, the arrival of reporters threatened to overwhelm the limited facilities of Thule AFB already straining under the requirements of supporting recovery operations in sub-zero temperatures. In spite of protests by local commanders, the U.S. Government insisted that facilities be provided for the press. Fortunately, the forbidding conditions in Greenland and other major stories (in particular the capture of the U.S.S. Pueblo and the Tet offensive) quickly diverted international press attention. By early February the press corps had left Thule but the story remained a major item of interest in Denmark.[37]

Reaction in Denmark

(U)The need to provide accurate and credible information on the Thule accident was underlined by the response of the Danish press. Anti-American feeling, fueled by the war in Vietnam, reached its peak in Europe during the late 1960's. Even normally pro-American parts of that press publicly called into question the honesty of the U.S. Government and reported that U.S. aircraft had frequently overflown Greenland, fueling suspicion that the United States had violated its agreements with the Danish Government. Danish participation in the study of the nuclear effects of the crash, however, strengthened the credibility of U.S. public statements.[38]

(U)Due to the distances and time problems involved in coordinating information between Washington, Thule, and Copenhagen, Embassy press officers played a limited role in the U.S. public relations effort which was the primary responsibility of Air Force public relations teams at Thule AFB and in Washington. The Embassy information officer, in cooperation with the Air Attache and Embassy press office, arranged transportation for 21 Danish and European journalists to Thule and accompanied them on the visit. The press office also managed to coordinate a nearly simultaneous release of information with Washington by taking down the texts of Department of Defense press bulletins over the phone, copying them, and then providing them to Danish journalists. Department of Defense films on nuclear safety were flown from Washington to Copenhagen for screening by the Danish press. The European Command of the U.S. Army provided the Embassy with a specialist in nuclear matters who assisted press office personnel in preparing and delivering press briefings on such potentially sensitive subjects as safe levels of radioactivity and decontamination procedures. The Embassy also reported that it found a Department of Defense guidance on nuclear matters, prepared after the Palomares accident, of value in its dealings with the press.[39]

(U)On February 5, 1968, the U.S. command at Thule began sending a daily report to Washington and the Embassy on the clean-up operations, designed for briefing the press. The daily information summary was replaced on March 16, 1968 by a system of infrequent releases marking new stages in the progress of the clean-up operation. In the meantime, Danish press interest in the Thule crash began to recede. U.S. cooperation with the Government of Denmark on health and environmental safety overcame the effects of initially hostile press reporting and reestablished credibility with the Danish

public. As early as February 8 Danish scientists returning from Thule reported that no evidence existed of immediate danger to the population of Greenland from the crash.[40] To further strengthen the sense of U.S. concern, Ambassador White made a personal visit to the Thule area on February 24-28. White initially proposed a personal visit to the site on February 2. The Ambassador was accompanied by her Deputy Chief of Mission and by a delegation of Danish Government officials and press. Both White and Danish officials stressed the speed and efficiency of the clean-up operations at a press conference.[41] The program of combining the quick release of accurate information, facilitating the travel and accommodations of Danish and foreign journalists, and cooperation with the Government of Denmark paid major dividends for the United States by improving the tone of Danish press coverage and increasing public confidence in the ability and determination of the United States to handle the clean-up operations safely.

Clean-Up Operations

(~~S~~)The inhabitants of the Thule area, an estimated 650 Greenlanders, were never in any danger of direct contamination from the crash. The area around the crash site was immediately sealed off By Thule AFB personnel to prevent any chance of contamination of the population. Local concern about the effects of radiation centered on indirect contamination through the entry of plutonium into the food chain. Of particular concern was the possibility that radioactive wreckage might have passed through the ice flow and contaminated the sea floor. Statements issued by scientists from the Danish Atomic Energy Commission who participated in the clean-up operations and by thesubsequent follow-up examination of the ocean floor conducted during the summer of 1968 by the Department of Defense greatly allayed these fears.[42]

(U)During the winter, Department of Defense directed clean-up operations centered on recovery of aircraft wreckage, including pieces of the four nuclear weapons, and the collection of contaminated ice and snow. The major problems facing the military were delays caused by bad weather and the assembling of adequate equipment. Core samples were taken from the ice to ascertain the depth to which radioactivity had penetrated. The clean-up proceeded from the edges of the crash site to the center so the burned-out crash impact area was the last to be cleaned up. Recovered debris together with contaminated water were then packed and shipped to the United States for final disposal.

~~(S)~~The clean-up operations produced only minimal economic disruption for the inhabitants of Thule. Most of the restricted area was reopened for use in April and the SAC clean-up operation was finished by mid-April. Tests run by Danish scientists on the plant and marine life in the area during the spring indicated that the crash had had no effect on the local ecology. In August 1968, U.S. submarine vehicles scanned the ocean floor for missing debris, [redacted] A few small pieces of debris which did not pose a threat of contamination were discovered.[43] Most of the discussions relating to nuclear clean-up and monitoring of the crash site were carried out by scientific teams representing the two governments. The U.S. team was organized and led by the Department of Defense. The Embassy played no significant role in clean-up operations.

~~B1, B3~~
B1, B3

Nuclear Overflight and Storage

(U)In matters relating to nuclear policy the Embassy in Denmark played a much more restricted role than did the Embassy in Spain after the Palomares accident. The Danish Government chose to utilize its Embassy in Washington to convey its views and carry on most of the substantive negotiations on nuclear policy questions with the United States.

~~(S)~~The major objective of the Government of Denmark in its discussions with the United States was to secure a joint statement that no atomic weapons were stored in Greenland and that the frequently-observed B-52 flights into Thule and over Greenland were by aircraft that did not carry nuclear armament. (The Danish press was full of stories quoting Greenlanders who claimed that B-52 aircraft regularly flew over the island and landed at Thule AFB.) The United States, as a matter of policy, wished to avoid any statements regarding the storage or transporation of its nuclear armaments. On January 26, 1968, U.S. Assistant Secretary of State Leddy submitted to the Danes a draft statement which avoided any mention of the nuclear issue. Leddy noted that [redacted] the United States and Denmark had agreed in 1957 that their 1951 defense accord granted the United States the right both to store weapons at Thule AFB and to overfly Greenland with nuclear armed aircraft. Leddy also underlined U.S. irritation over the Danish Govenment's failure to consult with it prior to making public statements on nuclear policy.[44]

B1, B3

~~(S)~~On February 7, shortly after the formation of a new Danish Government, Ambassador White met with Foreign Minister Poul Hartling at the Dane's request. Hartling presented White

with the text of a statement which he planned to read to the Danish parliamentary committee on foreign affairs. This statement assured parliament that no nuclear weapons were stored in Greenland and that the new ministry was entering into negotiations with the United States to insure that none would in the future. White replied that U.S. policy was neither to confirm nor deny matters relating to nuclear arms. Hartling assured the Ambassador that this statement did not imply that his government intended to seek to renegotiate the 1951 defense cooperation agreement. These assurances were repeated to White by Ambassador Ronne, who had returned to Copenhagen for consultations following the formation of a new ministry. Ronne stressed the need for U.S. comprehension of Denmark's position. The Danish Government apparently hoped to win Embassy endorsement for its action in making a public statement on nuclear storage and overflights.[45] ~~B1, B3~~

(U) The following day the Danish parliament passed a motion instructing its government to seek "absolute guarantees" from the United States that Denmark would remain a nuclear-free zone.

(~~S~~) During the negotiations which followed, the Embassy played a secondary role: providing information on public opinion, the attitudes of Danish civilian and military officials, and the negotiating positions of the Danish Government and suggesting U.S. negotiation strategy based on this information. Talks between the United States and Denmark took place in Washington.[46]

(~~S~~) The United States sought to preserve its rights to nuclear storage and overflights as outlined in the 1957 agreement. Negotiations conducted by Assistant Secretary of State Leddy and Ambassador Ronne resulted in a May 31, 1968 exchange of notes between the two governments which supplemented the 1951 defense agreement. The United States agreed that it would neither store atomic weapons in Greenland nor initiate overflights of Danish territory without prior consultations with the Government of Denmark. However, in a separate oral statement to Ronne (May 10), Leddy noted that conditions of extreme and sudden peril to the Atlantic Alliance which did not permit sufficient time for consultations with the Danish Government might lead the United States unilaterally to resume overflights of Greenland. The Danish Government dropped its request for a U.S. statement endorsing its position on nuclear weapons (May 16) and subsequently issued a unilateral declaration which reaffirmed its earlier statements. In keeping with its standing policy, the United States made no comment.[47] ~~B1, B3~~

Coordination Between the Embassy and the Recovery Operation

(U)Distance and the isolation of the crash site warrented the Embassy policy of non-interference in recovery operations. In addition, the Embassy had no contingency plans for coping with a nuclear accident and the Embassy officers had no training in this field. Moreover, the Mission in Denmark lacked specialists in nuclear affairs and in the days following the crash urgently sought the loan of a qualified specialist in nuclear affairs from the Embassy in Stockholm. As earlier noted, the Department of Defense came to the rescue when it authorized the loan of an officer from the European Command with the necessary technical expertise and the ability to deal with the press.

(~~C~~)Nevertheless, the Embassy played an important though limited role in facilitating contact between U.S. and Danish scientists. Ambassador White insisted on acting as the go-between for Defense Department scientists and their Danish counterparts. The Embassy did the groundwork for a joint meeting at Copenhagen between a team of U.S. scientists led by Dr. Carl Walske, Assistant Secretary of Defense for Nuclear Energy, and representatives of the Danish Atomic Energy Agency. All messages between the U.S. scientific team and the Danish Government were sent through the Embassy in order to maintain . . . excellent coordination among all American agencies which has characterized . . . B-52 crash."[48] The Embassy also provided communications facilities between the Department of Defense Science Team and Washington. Initially, communications between the DOD and Danish representatives travelled through a number of channels. However, once the Embassy became aware of this, it insisted that all future contacts must go through it, permitting the State Department to stay up to date with the scientific and technical aspects of the negotiations over the clean-up operation.[49]

(~~S~~)The Embassy also played an important role in the coordination of the texts of joint U.S.-Danish statements on scientific and technical aspects of the clean-up and recovery operations. Finally, during the summertime U.S. and Danish ecological surveys of North Star Bay and environs, Embassy officials worked with the representatives of the Danish Government on the public information program.[50]

(U)Overall cooperation between the Embassy and Department of Defense representatives was extremely close and appears to have been unmarred by any serious policy or personality disputes.

Claims

(U)The Danish Government declined to press any claims against the United States arising from the accident. The Department of Defense handled the payment of local claims arising from the accident. These claims were minimal and the Embassy does not appear to have taken any role in the settlement procedures.[51]

CONCLUSIONS

(U)While the documentation available for this study was not sufficient to trace the daily activities of either the Ambassador or the Embassy staffs during the crises which followed the crash of B-52's at Palomares and Thule, it does permit certain conclusions concerning the role of the Ambassador, the tasks performed by the Embassy, and the relationship of the Embassy to the U.S. military during the recovery and clean-up operations.

(U)Both Ambassadors confined themselves to traditional diplomatic functions, seeking to establish cooperation with the host government and to provide information which would put U.S. actions in the most favorable light before the publics of Spain, Denmark, and Greenland. Still, a good deal of flexibility existed for the definition of the ambassadorial role during these incidents and the degree to which the Ambassador took a hand in the resolution of events was determined by the circumstances of the accident and the personality of the incumbent. On the whole, Ambassador Duke took a more active role than Ambassador White both in diplomatic exchanges with the host government and in the public diplomacy function of his mission.

(U)Geography was a factor in the role which Ambassadors had in these crises. Although Palomares was situated in a remote part of Spain, it was on the European mainland and close enough to the centers of Spain's booming tourism trade to endanger part of Spain's economy as well as heighten concern about the possibility of an accidental nuclear explosion throughout the western Mediterranean area and northern Europe. The B-52 crash near Thule occured in a virtually uninhabited area, offshore, and close to a U.S. military facility. These factors in the Thule incident led to greater Department of Defense control and less Embassy involvement.

(U)The differing experiences and managerial styles of the two Ambassadors also interacted with the particular circumstances of the two incidents. Both Ambassadors were political appointees, but Duke had previously served as Chief of Protocol at the Department of State and, possessing a more complete knowledge of the foreign policy-making apparatus in Washington, was potentially in a better position to gain acceptance of his views. More importantly, Duke's particular situation required a more aggressive representation of U.S. interests. The United States was seeking to preserve its nuclear rights and to widen the scope of the information made

issues related to the clean up and to claims arising from the accident. This made the Embassy in Spain and the Ambassador a key figure in the complex negotiations which finally resolved the Palomares incident.

(~~S~~)On the other hand, within hours of the crash at Thule, the Danish Government began aggressively seeking concessions from the United States through their Ambassador in Washington. Thus the Embassy in Denmark was largely bypassed on matters of policy and handled more routine matters. Moreover, the documentation indicates that Ambassador White handed responsibility for these matters to her deputy chief of mission who, while very active, probably lacked the weight with both the highest levels of the Danish Government and senior U.S. officials which an Ambassador often enjoys.

(U)The Embassy role in both episodes was almost exclusively non-technical in character. Inadequately staffed to handle the scientific and technical problems arising from the accidents, both Embassies relied upon the Department of Defense, the Atomic Energy Commission, and the Department of State for technical advice. This essential technical support was quickly available in Spain but was not immediately available in the Danish case. Coordination on technical matters, such as clean-up, decontamination, and weapons recovery, was performed primarily by the Defense attaches who utilized their familiarity with the agencies and commands of the Defense Department and with the military establishment of the host nation to provide the Embassy with accurate information and advice. In addition, in Spain, the Chief of JUSMG was able to utilize a close relationship with Munoz Grandes to improve inter-governmental cooperation on the recovery and clean-up operations and to assist the Embassy's ultimately unsuccessful efforts to regain Spanish permission for overflights by nuclear armed aircraft

(U)Throughout both incidents the overriding concerns of the Embassy were the impact of the accident on the U.S. public image and the retention of special rights and privileges relating to the movement and storage of nuclear weapons. The Embassy in Spain faced almost unsurmountable public relations problems due to the authoritarian nature of the Spanish regime which sought to impose a heavy-handed censorship on the press and thus increased public concerns and suspicions. Profiting from the lessons of the Palomares incident and from the requirements of Danish democracy, the Embassy in Denmark was able to create a more successful public relations effort after the Thule accident.

(~~S~~) Neither Embassy was able to influence significantly the host government on the matter of U.S. nuclear weapons rights. In the case of Denmark, the decision was made to revoke those rights within hours of the Thule crash. In the case of Spain, the Embassy's efforts were undercut by the inability of U.S. recovery teams to find the missing nuclear device and a resultant public outcry which drove the Franco regime toward a cancellation of permission for U.S overflights.

(U) Cooperation between the agencies of the Defense Department and the Embassies was good. In Spain, the Embassy felt compelled to prod the military over the speed of its claims repayment operation, but also provided the Department of Defense with badly-needed assistance in negotiations over both claims settlements procedures and standards for contamination clean-up.[52]

(U) Finally, both missions inherited responsibility for final settlement of legal problems arising from the crash. In the case of the Embassy in Denmark, these responsibilities were very limited due to the site of the crash and the disinclination of the Danish Government to press any claims. The Palomares crash, however, produced a long lasting series of headaches for the Embassy in Spain, arising primarily from legal claims but also involving the actions of opponents of the Franco regime. The Embassy in Spain continues to take action on problems related to the 1966 crash at Palomares.

NOTE ON SOURCES

(U)This study was based on the files of the Department of State. In preparing it, primary reliance was placed on the Madrid and Copenhagen Post files and upon the files of the Danish Desk. The Central files of the Department of State were also consulted but they yielded little useful information. Other sources included press accounts, books published in the aftermath of the Palomares accident and information supplied by officers of the Department of State.

NOTES

1. Madrid tel. 839, Jan. 17, 1966, Confid-Nofor. Def 18 Madrid Post Files (Hereinafter cited MPF). On the release of information to the press, cf. Madrid tel. 846, Jan. 17, 1966, Confid., Def 17, MPF. Detailed accounts of the initial actions of the embassy staff are in Tad Szulc, The Bombs of Palomares (NY, 1967), pp. 54-62 and Flora Lewis, One of Our H-Bombs Is Missing (NY, 1967), pp. 63-68. Both are based on interviews conducted shortly after the acident.

2. Tel. 839 from Madrid, Jan. 17, 1966, Confid. op. cit.

3. Deptel. 851 to Madrid, Jan. 22, 1966, Secret, Def 18.1, MPF. Unnumbered Department of Defense tel. to the Embassy in Madrid, Jan. 22, 1966, ibid. Cf. Madrid tel. 838, Jan. 21, 1966, Def. 17, ibid.

4. Madrid tels. 855 and 857, Jan. 19, 1966, both Secret. Madrid 859, Jan. 20, 1966, Secret, all Def 17, MPF. DOD officials at Palomares initially attempted to place a veil of secrecy around all aspects of the accident to avoid exposure of the nuclear weapons on board the B-52. Szulc, whose presentation of the activities of the Embassy is consistently favorable, is highly critical of U.S. military efforts at press control and later DOD public affairs programs. He enjoyed a good relationship with Embassy personnel and his criticisms of the military public relations effort, in addition to reflecting a reporter's pique with the efforts at a news blackout, apparently magnified Embassy frustrations with the DoD handling of its on-site press briefings. Bombs of Palomares, pp. 114-15, 123, 168-69, 214-15. Lewis, while critical of the DOD public relations effort more accurately places most of the blame for the lack of information on the Spanish Government and notes U.S. Embassy irritation with Spain's efforts at censorship. One of Our H-Bombs, pp. 101-02, 176.

Sculz, Bombs of Palomares, pp. 215-16, reprints part of one of the press conferences which vividly present the press relations problems created by efforts to avoid admitting that a nuclear weapon was missing:
Reporter: "Tell me, any sign of the bomb?"
USAF Spokesman: "What bomb?"
Reporter: "Well, you know, the thing you're looking for..."
USAF Spokesman: "You know perfectly well we're not looking for any bomb. Just for debris."

Reporter: "All right, any signs of the thing which you say is not the bomb?"
USAF Spokesman: "If you put it that way, I can tell you that there is no sign of the thing that is not the bomb."
Sculz adds: "And so it went for days, for weeks." The New York Times (March 4, 1966.) greeted the March admission that a bomb was in fact missing with the caustic comment that it took the United States only 40 days to acknowledge the truth. 52. In spite of disagreements over public relations matters and other irritants, the level of cooperation between Embassy and on-site DOD teams was so satisfactory that Ambassador Duke wrote a three page letter to Secretary of the Air Force Harold Brown, praising the performance of General Wilson, the commander of the clean-up operation. Duke to Brown, May 10, 1966, Def. 18.1, MPF.

AFRRI
SPECIAL REPORT

DoD nuclear mishaps

H. L. Reese

AFRRI SP86-2

DEFENSE NUCLEAR AGENCY
ARMED FORCES RADIOBIOLOGY RESEARCH INSTITUTE
BETHESDA, MARYLAND 20814-5145

#634

APPROVED FOR PUBLIC RELEASE; DISTRIBUTION UNLIMITED

The following information concerning U.S. nuclear weapon accidents has been collected from materials released by the Department of Defense (DoD) in 1977, 1980, and 1981, and also from several media references. This publication is intended to be a source document in the course "Medical Effects of Nuclear Weapons," which is sponsored by the Armed Forces Radiobiology Research Institute.

The United States has never had an inadvertent nuclear detonation, even a partial one, despite the very severe stresses imposed on the weapons that might be involved in accidents. All "detonations" reported in the DoD summaries involved only conventional high explosives. Only two accidents, those at Palomares and Thule, resulted in widespread dispersal of nuclear materials.

Nuclear weapons are never carried on training flights. Most of the aircraft accidents described here occurred during logistic/ferry missions or airborne alert flights by Strategic Air Command (SAC) aircraft. Airborne alert was terminated in 1968 because of

- Accidents, particularly those at Palomares and Thule;
- The rising cost of maintaining a portion of the SAC bomber force constantly on airborne alert;
- The advent of a responsive and survivable intercontinental ballistic missile force, which relieved the manned bomber force of a part of its more time-sensitive responsibilities. (A portion of the SAC force remains on nuclear ground alert.)

Since the location of a nuclear weapon is classified defense information, it is DoD policy, normally, to neither confirm nor deny the presence of a nuclear weapon at any specific location. In the case of an accident involving a nuclear weapon, the weapon's presence may or may not be divulged at the time, depending on the possibility of public hazard or alarm. Therefore, for some of the events summarized in this publication, the presence of a nuclear weapon or material may not have been confirmed at the time. Furthermore, due to diplomatic considerations, it is not possible to specify the locations of the accidents that occurred overseas, except for Palomares and Thule.

Most of the weapon systems involved in these accidents are no longer in the active inventory. Those include the B-29, B-36, B-47, B-50, B-58, C-124, F-100, and P-5M aircrafts and the Minuteman I Missile.

With some early models of nuclear weapons, it was a standard safety procedure during most operations to keep a capsule of nuclear material separate from the weapon. Although a weapon with the capsule removed did contain a quantity of natural (not enriched) uranium with an extremely low level of radioactivity, the accidental detonation of the high-explosive element would not cause a nuclear detonation or contamination. Modern designs incorporate improved safety features, to ensure that a nuclear explosion does not occur as the result of an accident.

MANAGEMENT OF THE NUCLEAR WEAPON STOCKPILE

The management of nuclear weapons is shared by the Department of Energy (DOE) and DoD. The Secretary of Energy and the Secretary of Defense are directly responsible to the President, who retains the sole authority for weapons employment. DOE, as successor of the Atomic Energy Commission, is responsible for all research, development, test, and production of nuclear weapons. DOE is the only Government agency that is authorized by statute to engage in these activities. By law, DOE is required also to control and account for all active nuclear material, including the U.S. stockpile of war-reserve nuclear weapons. These weapons have been entrusted to DoD for employment readiness in case the President orders their use in the interest of national security. Ownership, however, is retained by DOE.

To carry out these responsibilities, the DOE organization includes a network of Government-owned laboratories, plants, and test sites in nine states, all operated by private industry or institutions under Government contract. There are three design and development laboratories, manufacturing facilities, and a field test capability.

At the policy level, DOE's Division of Military Applications (DMA) interfaces with DoD's Military Liaison Committee (MLC). DMA is DOE's primary liaison with DoD, and it provides major program guidance and direction for weapons research and development directly to the weapons laboratories. The Defense Nuclear Agency (DNA) provides some elements of the DoD liaison function with DOE. DNA is a joint service agency under the Joint Chiefs of Staff, with headquarters in Washington, DC, and its operating unit, Field Command, Defense Nuclear Agency, located in Albuquerque, New Mexico.

The MLC Chairman is the Assistant to the Secretary of Defense for Atomic Energy, and is responsible for management and control policies for all nuclear weapon functions within DoD. MLC consists of two senior officers from each Service, with the DNA Director and DOE's DMA Director acting as observers. The DoD nuclear weapon program and requirements are provided to DOE through MLC.

WEAPON SAFETY CONCEPTS

Since DOE designs, develops, and produces all nuclear weapons, it is primarily responsible for the safety features and devices within the weapons. DoD is responsible for safe and secure operations external to the weapon. Considerable overlap and interaction exist, with DoD participating in weapon design (for familiarity and to coordinate requirements) and DOE assisting in the development of safety rules for operating the total nuclear weapon system.

To understand the philosophy of nuclear weapon safety, it is important to first understand the basic nuclear physics involved. Unlike conventional explosives that derive their sensitive properties from their basic chemical makeup, a nuclear device must be specifically designed to bring about an explosion. To obtain a nuclear reaction or explosion through fission, an amount of active material sufficient to produce a continuous, self-sustaining nuclear reaction must be assembled so that a "supercritical mass" can be attained. One technique used to achieve a supercritical mass is called "implosion." In contrast to the outward burst of an explosion, implosion is an inward compression. In a nuclear weapon, high

explosive surrounds the nuclear material. A simultaneous firing of detonators mounted on the surface of the high explosive produces a shock wave that compresses the nuclear material. The important feature is the simultaneous firing of the detonators and control of the shock wave to achieve symmetrical compression of the nuclear material, and thus attain a supercritical mass.

The implosion process used to detonate a nuclear weapon, by its very nature, has a built-in safety feature. If the high explosive detonates at any single point for any reason, including fire or shock as a result of an accident, there would be no symmetrical implosion. The shock wave moving from a single point on the high-explosive surface would explode and destroy the device. This would release and perhaps scatter the active material, but would not result in a nuclear explosion.

In our latest weapons, a new, insensitive high explosive is used, which is extremely stable and will not explode on impact or in a fire. This will dramatically reduce the possibility of nuclear materials being scattered in an accident.

The current DOE safety-design concept packages the weapon-detonation subsystem into an "exclusion region." This feature follows a design philosophy intended to prevent undesired electrical energy from reaching the nuclear weapon detonator system. Included in this concept is a series of "weak links" and "strong links" to obtain predictably safe responses in abnormal environments such as fire, deep water, lightning, cruising impacts, or impact from high-velocity projectiles. The strong links are open switches that close only when the proper signals are received. The weak links are elements vital to the operation of the detonator system. These links are packaged together so that both strong and weak links experience the same environment. Safety is achieved in abnormal environments because the vital components (weak links) are designed to fail first, destroying the detonator system, before the open switches (strong links) can possibly fail to a closed position.

Associated with the exclusion region concept is the design of the strong links to respond only to unique signals. These open switches will not respond to the weapon system's electrical power sources, which might become connected through short circuits during an accident. The unique signals required can be generated by the weapon system only when intended by the human operator.

Nuclear weapons also contain environment-sensing devices that prevent firing of the detonators unless the required environment is experienced. The devices include such items as

- Pullout cables that maintain an open circuit until the cable is physically pulled from the weapon upon release from the aircraft;

- Accelerometers that maintain open circuits until they sense the acceleration or deceleration for a required period of time, as would be produced by a rocket motor or a retarding parachute;

- Barometric switch devices that remain open until they sense the pressure differential that is anticipated in desired release conditions;

- Timers that maintain open switches for a specific time interval after weapon release;

- Electromechanical switches that remain open until a positive action is taken by a human operator.

These safety features and others are designed into the weapon with stringent quality and reliability controls by DoD.

The DoD Safety Program is based on four nuclear safety standards. The standards require that, in the design, development, and employment of a nuclear weapon system, there be positive measures to

- Prevent jettisoned weapons or weapons involved in accidents or incidents from producing a nuclear yield;
- Prevent deliberate prearming, arming, launching, firing, or releasing of nuclear weapons except upon execution of emergency war orders or when directed by competent authority;
- Prevent inadvertent prearming, arming, launching, firing, or releasing of nuclear weapons;
- Ensure adequate security of nuclear weapons.

To satisfy these DoD nuclear safety standards, the Safety Program addresses safety-design engineering for each nuclear weapon system, its logistic and operational environment, and the human factors involved in the maintenance and operation of the weapon system. The various considerations of the program are listed below to give a perspective of their relationships and a feeling for the extent of the Safety Program. The program considerations include

- Requirements and design guidance for safety considerations in nuclear weapon system development;
- Safety engineering evaluation and formal certification before the system can be used with a nuclear weapon;
- Nuclear safety analysis and certification of all computer programs developed for use in the control of the nuclear weapon system;
- Engineering, operational, and logistic studies and reviews of the complete weapon system and its intended environment from storage to target, resulting in weapon system safety rules that prescribe authorized procedures and impose limitations for operation of the nuclear weapon system;
- Approved technical data and maintenance procedures that must be precisely followed in the operation or maintenance of the nuclear weapon system;
- Engineering evaluation and safety certification of all equipment used in the maintenance, movement, and operation of the nuclear weapon system;

- Reporting and analysis of accidents, incidents, and deficiencies that involve the nuclear weapon system, support equipment, and procedures;

- Safing and sealing of critical nuclear weapon system switches;

- Evaluation of all personnel associated with the nuclear weapon system to ensure their emotional stability and proper security clearance before being authorized access to a nuclear weapon, nuclear weapon system, or nuclear command and control facility;

- A "two-man" or "no lone zone" concept around the nuclear weapon and the nuclear weapon system;

- An inspection system to monitor compliance not only with the four DoD safety standards but also with all nuclear safety rules and technical data in all operations involving a nuclear weapon or nuclear weapon system.

In addition to the safety devices contained within the nuclear weapon, the weapon carrier contains devices that prevent prearming or release unless intended. Examples of these devices are

- Dual switches that force two-man consent for both prearm and launch (or release);

- Intent switches that prevent a prearm signal until manually closed by the human operators;

- A unique signal generator, activated by the prearm intent switch, that produces the unique signal required by the weapon's strong links described earlier;

- Intent switches that prevent a nuclear weapon release signal until manually closed by the human operators (separate from the prearm switches);

- Arm-inhibit switches that require a "good guidance" signal from the missile guidance system before warhead arming can occur;

- In-flight reversible mechanical locks on the weapon carriage rack that physically prevent weapon release until electrically activated by the human operators;

- A monitor system to provide the operator the arm/safe status of the nuclear weapon and lock/unlock status of the carriage rack.

Devices such as these prevented weapon arming in the Goldsboro and Palomares accidents. In early bomb racks such as those involved in the accidents at Kirtland Air Force Base, New Mexico, and at Florence, South Carolina, one means to prevent inadvertent release was the insertion of safety pins in the carriage rack. These pins were removed during takeoff and landing to permit emergency jettison. When the safety pins were removed, however, a single failure in the rack could cause an inadvertent release of the nuclear weapon, as shown by these accidents.

A cockpit-controlled, in-flight, reversible lock is now required which, when locked, prevents inadvertent weapon release even though the normal release force is applied. This design allows safe takeoff and landing with the rack in the locked position. The device is designed to fail to the locked position, and also requires an independent positioning of intent switches by two crew members in multiplace aircraft before the rack holding the weapon can be unlocked.

RADIOACTIVE MATERIALS IN NUCLEAR WEAPON ACCIDENTS

Nuclear weapons contain three principal types of radioactive materials: plutonium, uranium, and tritium. Other types of radioactive materials may also be present in lesser and varying amounts, depending on the type and age of the weapon. For accidental contamination, the initial public health risks and protective/corrective actions are the same as those for contamination by particles of plutonium, uranium, and tritium (see below).

The risks to the public from radioactive contamination caused by a nuclear weapon accident are not like fallout from a nuclear bomb blast, and are not like contamination from a major nuclear power plant accident. However, contamination from a nuclear weapon accident could be serious and could require both immediate and long-term protective and corrective cleanup measures. The potential harm to the public and the environment can be controlled best by an effective response to the accident and by providing the public with timely information and instructions about protection from contamination.

Public instructions and appropriate actions will depend on the severity of the accident, the type of material involved, and the length of time between occurrence of the accident and initiation of protective action.

ACCIDENT SEVERITY FACTORS

If nuclear weapons are involved in an accident and the condition of the weapon is not known, the potential for contamination must be assumed. Besides the immediate response around the accident site, protective measures (possible evacuation) for the general public may be necessary within 1 day.

Instructions on basic protective measures should allow time to respond to the accident, to determine the condition of the weapon, and to disseminate supplementary information and instructions to the public.

If damage to a nuclear weapon is known but the weapon is still structurally intact, any potential contamination would be limited to the immediate area of the accident site, and would probably be of very short duration (a few minutes). Keeping the public clear of the accident site and providing information to relieve unwarranted fears (prevent panic) should be sufficient for public protection.

If a nuclear weapon accident results in severe structural damage (scattering of small chunks of the warhead), fire (melting and burning of the warhead), or detonation of the conventional (chemical) high explosive, then more widespread contamination is probable and larger scale protective actions will be necessary. In this case, information and instructions provided to the public will depend on the type of radioactive material and the time since the accident.

PLUTONIUM

Contamination by plutonium particles dispersed by conventional (chemical) explosion or burning of a weapon would pose the most serious health hazard to the public, and could impact the environment over a wide area.

Plutonium is both a poison and a radiation hazard. The radiation given off consists of "alpha particles" (like very fast moving helium atoms), which do not have sufficient energy to penetrate buildings, most clothing, or even the outer skin. Therefore, short-term exposure (up to a few days) to contamination outside of the body will pose only a small health risk.

Plutonium radiation is considered a serious health risk if small "dust-like" pieces are inhaled or ingested and remain as deposits in the body. Even a very small quantity (equivalent to a single piece of dust) inside the body could cause concern as a health risk over the long term. No immediate "radiation sickness" symptoms are expected from this type of contamination.

Unless it is possible to immediately (within minutes) evacuate the area around the accident site and several miles downwind, the best initial public response will probably be to stop outside activity, seek shelter in well-sealed buildings (with little or no use of outside air for heating or cooling), and delay evacuation until the dust cloud has passed and particles have had time to settle out of the air. Besides being medically sound, this procedure will reduce casualties that result from panic and will least affect the critical and essential services.

Any evacuation of the public that does take place must be in a controlled manner, thereby reducing the risk of resuspension of the contaminant and the risk of collateral injury to the civilian population. Any person evacuating an area should breathe through a filter (such as a common dust mask or even several layers of a wet handkerchief), and move with care to avoid stirring up the dust. If resources and time permit, evacuation should include the use of protective outer clothing that can be cleaned for reuse or discarded.

The best direction and timing for travel can be specified for population centers or zones in the area. Factors such as population density, transportation, and facilities in the contaminated area must be considered in deciding whether and when to move the public out of an area.

Whether evacuation is immediate or delayed, panic of the population may result in some injury, death, or property damage. Every effort should be made to state the problem in a way that will inform the public, keep the problem in context, and avoid confusion.

The determination of cleanup requirements and techniques will involve extensive surveys and coordination with experts in several government agencies (Federal Emergency Management Agency, Environmental Protection Agency, DOE, DoD, etc.). Cleanup efforts may extend over several months, and monitoring requirements over several years.

URANIUM

Contamination by uranium fragments or small particles dispersed by a conventional (chemical) explosion or by the burning of a weapon is primarily a chemical health hazard (heavy metal poison similar to the lead poisoning associated with some paints), not a radiological hazard. The short-term risk to health occurs only if a relatively large quantity of uranium is deposited inside the body by inhaling or ingesting the dust. A short-term public hazard from radiation (alpha particles) from uranium is very unlikely. Determination of any long-term radiation (or chemical) hazard will require detailed and extensive surveys.

It is unlikely that uranium contamination, even though dispersed over a wide area, would add significantly to the overall exposure that man normally receives from radioactive materials found in most environments.

TRITIUM

The radiation given off by tritium is a low-energy "beta particle," which is stopped by the outer layers of skin. Thus external exposure is not a hazard. Contamination by tritium gas would pose a health hazard only in a closed or confined space. Tritium released by a weapons accident will dissipate and be diluted so rapidly in open air that no internal hazard would result. Monitoring (air sampling) of the immediate site of the accident is sufficient to assure prevention of exposure to accident-response personnel. Tritium from a weapons accident will not affect the public or the environment.

CLEANUP AFTER A NUCLEAR WEAPON ACCIDENT

An accident that causes a nuclear weapon to structurally break apart, burn, or chemically detonate will contaminate an area of indeterminate size with potentially hazardous materials. These materials may include plutonium, uranium, or high explosive.

The cleanup of explosive and chemical hazards will be relatively straightforward, but the decontamination of any radioactive materials will depend on technically sophisticated surveys and risk assessments.

DETERMINATION OF CONTAMINATION LEVEL

An initial estimate of the size and shape of the contaminated area and of the level of contamination within the area can be provided within a few hours by computer models. This information can be used to determine the actions necessary to protect the public and the scope of the cleanup problem. Then the determination of actual cleanup requirements and preferred techniques will depend on the material involved, field survey measurements of actual contamination levels, and careful assessment of any associated potential health risk.

Cleanup requirements may be minimized if contamination levels are low, or if the contaminating material is trapped and therefore not a hazard to plants, animals, or man. If contamination levels are high and/or the material is a health risk to man, then cleanup requirements may be quite stringent over an extensive area. The cleanup of scattered plutonium would probably present the greatest difficulty.

THE CLEANUP PROCESS

If initial estimates of the contamination level and subsequent field survey measurements indicate radiological contamination in the soil above a screening level of 0.2 microcuries/square meter (or above 1 fCi/m^3), then a careful assessment of health risks is necessary and cleanup may be necessary. Below this screening level, cleanup actions may not be necessary.

SUMMARY OF ACCIDENTS INVOLVING U.S. NUCLEAR WEAPONS, 1950-1980

An "accident involving a nuclear weapon" may be defined as an unexpected event involving a nuclear weapon or nuclear weapon components that results in any of the following:

- Accidental or unauthorized launching, firing, or use by U.S. forces or supported allied forces of a nuclear-capable weapon system that could create the risk of an outbreak of war;
- Nuclear detonation;
- Nonnuclear detonation or burning of a nuclear weapon or radioactive weapon component, including a fully assembled nuclear weapon, an unassembled nuclear weapon, or a radioactive nuclear weapon component;
- Seizure, theft, or loss, including jettison, of a nuclear weapon or radioactive nuclear weapon component;
- Public hazard, actual or implied.

Accidents involving U.S. nuclear weapons from 1950 to 1980 are summarized in the following paragraphs.

1. 13 February 1950 / B-36 / Pacific Ocean, Off Coast of British Columbia

A B-36 aircraft was en route from Eielson AFB to Carswell AFB on a simulated combat profile mission. The weapon aboard the aircraft had a dummy capsule installed. After 6 hours of flight, the aircraft developed serious mechanical difficulties, making it necessary to shut down three engines. The aircraft was at 12,000 feet altitude. Icing conditions complicated the emergency, and level flight could not be maintained. The aircraft headed out over the Pacific Ocean and dropped the weapon from 8,000 feet into the ocean. A bright flash occurred on impact, followed by a sound wave and a shock wave. Only the weapon's high-explosive material detonated. The aircraft was then flown over Princess Royal Island, where the crew bailed out. The aircraft wreckage was later found on Vancouver Island.

2. 11 April 1950 / B-29 / Manzano Base, New Mexico

A B-29 aircraft departed Kirtland AFB at 9:38 p.m. and approximately 3 minutes later crashed into a mountain on Manzano Base, killing the crew. Detonators were installed in the bomb on board the aircraft. The bomb case was

demolished, and some high-explosive material burned in the gasoline fire. Other pieces of unburned high explosive were scattered throughout the wreckage. Four spare detonators in their carrying case were recovered undamaged. Contamination did not occur, and there were no recovery problems. The recovered components of the weapon were returned to the Atomic Energy Commission. The capsule of nuclear material was on board the aircraft but had not been inserted into the weapon for safety reasons. A nuclear detonation was not possible.

3. 13 July 1950 / B-50 / Lebanon, Ohio

A B-50 aircraft was on a training mission from Biggs AFB, Texas, flying at 7,000 feet on a clear day. The aircraft nosed down and flew into the ground, killing 4 officers and 12 airmen. The high-explosive portion of the weapon aboard detonated on impact. There was no nuclear capsule aboard the aircraft.

4. 5 August 1950 / B-29 / Fairfield-Suisun AFB, California

A B-29 carrying a weapon, but no capsule, experienced two runaway propellers and landing-gear-retraction difficulties on takeoff from Fairfield-Suisun AFB (now Travis AFB). The aircraft attempted an emergency landing, crashed, and burned. Fire was fought for 12-15 minutes before the weapon's high-explosive material detonated. Nineteen crew members and rescue personnel, including General Travis, were killed in the crash or the resulting detonation.

5. 10 November 1950 / B-50 / Over Water, Outside the United States

Because of an inflight aircraft emergency, a weapon containing no capsule of nuclear material was jettisoned over water from an altitude of 10,500 feet. A high-explosive detonation was observed.

6. 10 March 1956 / B-47 / Mediterranean Sea

The aircraft was one of a flight of four scheduled for nonstop deployment from MacDill AFB to an overseas air base. The takeoff from MacDill and the first refueling were normal. The second refueling point was over the Mediterranean Sea. In preparation, the flight penetrated solid cloud formation to descend to the refueling level of 14,000 feet. The base of the clouds was 14,500 feet, and visibility was poor. The aircraft never made contact with the tanker. An extensive search failed to locate any trace of the missing aircraft or crew. No weapons were aboard the aircraft, only two capsules of nuclear weapon material in carrying cases. A nuclear detonation was not possible.

7. 27 July 1956 / B-47 / Overseas Base

A B-47 aircraft with no weapons aboard was on a routine training mission and making a touch-and-go landing, when the aircraft suddenly went out of control. It slid off the runway and crashed into a storage igloo containing several nuclear weapons. The bombs did not burn or detonate; they were in storage configuration. No capsules of nuclear materials were in the weapons or present elsewhere in the building. There were no contamination or cleanup problems. The damaged weapons and components were returned to the Atomic Energy Commission.

8. 22 May 1957 / B-36 / Kirtland AFB, New Mexico

The B-36 aircraft was ferrying a weapon from Biggs AFB, Texas, to Kirtland AFB. At 11:50 a.m., MST, as the aircraft approached Kirtland at an altitude of 1,700 feet, the weapon dropped from the bomb bay, taking the bomb bay doors with it. Weapon parachutes were deployed but apparently did not fully retard the fall because of the low altitude. The impact point was approximately 4.5 miles south of the Kirtland control tower and .3 mile west of the Sandia Base reservation. The high-explosive material detonated, completely destroying the weapon, and making a crater approximately 25 feet in diameter and 12 feet deep. Fragments and debris were scattered as far as 1 mile from the impact point. The release-mechanism locking pin was being removed at the time of release. (It was standard procedure, at that time, to remove the locking pin during takeoff and landing, to allow emergency jettison of the weapon if necessary.) The recovery and cleanup operations were conducted by Field Command, Armed Forces Special Weapons Project. Radiological survey of the area disclosed no radioactivity beyond the lip of the crater, at which point the level was 0.5 milliroentgens. There were no health or safety problems. A nuclear capsule was on board the aircraft but had not been inserted into the weapon for safety reasons. A nuclear detonation was not possible.

9. 28 July 1957 / C-124 / Atlantic Ocean

Two weapons were jettisoned from a C-124 aircraft off the east coast of the United States. The C-124 aircraft was en route from Dover AFB, Delaware, when a loss of power from the number one and number two engines was experienced. Maximum power was applied to the remaining engines, but level flight could not be maintained. At this point, the decision was made to jettison cargo in the interest of safety of the crew and aircraft. Three weapons and one nuclear capsule were aboard the aircraft, and nuclear components had not been installed in the weapons. The first weapon was jettisoned at 4,500 feet altitude. The second weapon was jettisoned at approximately 2,500 feet altitude. No detonation occurred from either weapon. Both weapons are presumed to have been damaged from impact with the ocean surface, and to have submerged almost instantly. The ocean varies in depth in the area of the jettisons. The C-124 landed at an airfield in the vicinity of Atlantic City, New Jersey, with the remaining weapon and the nuclear capsule aboard. A search for the weapons or debris had negative results.

10. 11 October 1957 / B-47 / Homestead AFB, Florida

The B-47 departed Homestead AFB shortly after midnight on a deployment mission. Shortly after lift-off, one of the aircraft's outrigger tires exploded. The aircraft crashed in an uninhabited area approximately 3,800 feet from the end of the runway. The aircraft was carrying one weapon in ferry configuration in the bomb bay and one nuclear capsule in a carrying case in the crew compartment. The weapon was enveloped in flames, and it burned and smoldered for approximately 4 hours, at which time it was cooled with water. Two low-order high-explosive detonations occurred during the burning. The nuclear capsule and its carrying case were recovered intact and only slightly damaged by heat. Approximately one half of the weapon remained. All major components were damaged but were identifiable and accounted for.

11. 31 January 1958 / B-47 / Overseas Base

A B-47 with one weapon in strike configuration was making a simulated takeoff during an exercise alert. When the aircraft reached approximately 30 knots on the runway, the left rear wheel casting failed. The tail struck the runway, and a fuel tank ruptured. The aircraft caught fire and burned for 7 hours. Firemen fought the fire for the allotted 10-minute fire-fighting time for the high-explosive contents of that weapon, and then evacuated the area. The high explosive did not detonate, but some contamination did occur in the immediate area of the crash. No contamination was detected after removal of the wreckage and the asphalt beneath it and after washing down of the runway. One fire truck and one fireman's clothing showed slight alpha contamination before washing. Following the accident, exercise alerts were temporarily suspended and B-47 wheels were checked for defects.

12. 5 February 1958 / B-47 / Savannah River, Georgia

The B-47 was on a simulated combat mission that originated at Homestead AFB, Florida. While near Savannah, Georgia, the B-47 had a mid-air collision with an F-86 aircraft at 3:30 a.m. Following the collision, the B-47, with a weapon aboard, attempted to land three times at Hunter AFB, Georgia. Because of the condition of the aircraft, its airspeed could not be reduced enough to ensure a safe landing. Therefore, the decision was made to jettison the weapon rather than expose Hunter AFB to the possibility of a high-explosive detonation. A nuclear detonation was not possible since the nuclear capsule was not aboard the aircraft. The weapon was jettisoned into the water several miles from the mouth of the Savannah River (Georgia) in Wassaw Sound off Tybee Beach. The precise impact point of the weapon is unknown. The weapon was dropped from an altitude of approximately 7,200 feet at an aircraft speed of 180-190 knots. No detonation occurred. After jettison, the B-47 landed safely. A 3-square-mile area was searched by divers and underwater demolition team technicians using galvanic drag and hand-held sonar devices. The weapon was not found. The search was terminated on 16 April 1958. The weapon was considered to be irretrievably lost.

13. 11 March 1958 / B-47 / Florence, South Carolina

At 3:53 p.m., EST, a B-47E departed Hunter AFB, Georgia, as number three aircraft in a flight of four en route to an overseas base. After level off at 15,000 feet, the aircraft accidentally jettisoned an unarmed nuclear weapon that impacted in a sparsely populated area 6.5 miles east of Florence, South Carolina. The bomb's high-explosive material exploded on impact. The detonation caused property damage and several injuries on the ground. The aircraft returned to the base without further incident. No capsule of nuclear materials was aboard the B-47 or installed in the weapon.

14. 4 November 1958 / B-47 / Dyess AFB, Texas

A B-47 caught fire on takeoff. Three crew members successfully ejected; one was killed when the aircraft crashed from an altitude of 1,500 feet. One nuclear weapon was on board when the aircraft crashed. The resultant detonation of the high explosive made a crater 35 feet in diameter and 6 feet deep. Nuclear materials were recovered near the crash site.

15. 26 November 1958 / B-47 / Chennault AFB, Louisiana

A B-47 caught fire on the ground. The single nuclear weapon on board was destroyed by the fire. Contamination was limited to the immediate vicinity of the weapon residue within the aircraft wreckage.

16. 18 January 1959 / F-100 / Pacific Base

The aircraft was parked on a revetted hardstand in ground alter configuration. The external load consisted of a weapon on the left intermediate station and three fuel tanks (both inboard stations and the right intermediate station). When the starter button was depressed during a practice alter, an explosion and fire occurred when the external fuel tanks inadvertently jettisoned. Fire trucks at the scene put out the fire in about 7 minutes. The capsule was not in the vicinity of the aircraft and was not involved in the accident. There were no contamination or cleanup problems.

17. 6 July 1959 / C-124 / Barksdale AFB, Louisiana

A C-124 on a nuclear logistics movement mission crashed on takeoff. The aircraft was destroyed by fire, which also destroyed one weapon. No nuclear or high-explosive detonation occurred; safety devices had functioned as designed. Limited contamination was present over a very small area immediately below the destroyed weapon. This contamination did not hamper rescue or fire-fighting operations.

18. 25 September 1959 / P-5M / Pacific Ocean Off the Washington Coast

A U.S. Navy P-5M aircraft assigned to Naval Air Station, Whidbey Island, Washington, crashed in the Pacific Ocean about 100 miles west of the Washington-Oregon border. It was carrying an unarmed nuclear antisubmarine weapon containing no nuclear material. The weapon was not recovered.

19. 15 October 1959 / B-52 / KC-135 / Hardinsburg, Kentucky

The B-52 departed Columbus AFB, Mississippi, at 2:00 p.m., CST. The aircraft assumed the number two position in a flight of two. The KC-135 departed Columbus AFB at 5:33 p.m., CST, as the number two tanker aircraft in a flight of two scheduled to refuel the B-52's. Rendezvous for refueling was accomplished in the vicinity of Hardinsburg, Kentucky, at 32,000 feet. It was night; the weather was clear, with no turbulence. Shortly after the B-52 began refueling from the KC-135, the two aircraft collided. The instructor pilot and pilot of the B-52 ejected, followed by the electronic warfare officer and the radar navigator. The copilot, navigator, instructor navigator, and tail gunner failed to leave the B-52. All four crew members in the KC-135 were fatally injured. The B-52's two unarmed nuclear weapons were recovered intact. One had been partially burned, but did not result in dispersion of nuclear material or other contamination.

20. 7 June 1960 / BOMARC / McGuire AFB, New Jersey

A BOMARC air defense missile in ready storage condition (permitting launch in 2 minutes) was destroyed by explosion and fire after a high-pressure helium tank exploded and ruptured the missile's fuel tanks. The warhead was also destroyed by

the fire, although the high explosive did not detonate. Nuclear safety devices functioned as designed. Contamination was restricted to an area immediately beneath the weapon and an adjacent elongated area approximately 100 feet long, caused by drain-off of fire-fighting water.

21. 24 January 1961 / B-52 / Goldsboro, North Carolina

During a B-52 airborne alert mission, structural failure of the right wing resulted in two weapons separating from the aircraft during aircraft breakup at 2,000-10,000 feet. One bomb parachute deployed, and the weapon received little impact damage. The other bomb fell free and broke apart upon impact. No explosion occurred. Five of the eight crew members survived. A portion of one weapon, containing uranium, could not be recovered despite excavation in the waterlogged farmland to a depth of 50 feet. The Air Force subsequently purchased an easement requiring permission for anyone to dig there. No detectable radiation and no hazard exist in the area.

22. 14 March 1961 / B-52 / Yuba City, California

A B-52 experienced failure of the crew compartment pressurization system, forcing descent to 10,000 feet altitude. Increased fuel consumption caused fuel exhaustion before rendezvous with a tanker aircraft. The crew bailed out at 10,000 feet except for the aircraft commander, who stayed with the aircraft to 4,000 feet and steered the plane away from a populated area. The two nuclear weapons on board were torn from the aircraft on ground impact. The high explosive did not detonate. Safety devices worked as designed to prevent nuclear contamination.

23. 13 November 1963 / Atomic Energy Commission Storage Igloo / Medina Base, Texas

An explosion involving 123,000 pounds of high-explosive components of nuclear weapons caused minor injuries to three Atomic Energy Commission employees. There was little contamination from the nuclear components, which were stored elsewhere in the building. The components were from the disassembly of obsolete weapons.

24. 13 January 1964 / B-52 / Cumberland, Maryland

A B-52D was en route from Westover AFB, Massachusetts, to its home base at Turner AFB, Georgia. The crash occurred approximately 17 miles southwest of Cumberland, Maryland. The aircraft was carrying two weapons, which were in a tactical ferry configuration (no mechanical or electrical connections had been made to the aircraft, and the safing switches were in the "SAFE" position). Before the crash, the pilot had requested a change of altitude because of severe air turbulence at 29,500 feet. The aircraft was cleared to climb to 33,000 feet. During the climb, the aircraft encountered violent air turbulence, and aircraft structural failure then occurred. Of the five air-crew members, only the pilot and copilot survived. The gunner and navigator ejected, but died of exposure to subzero temperatures after successfully reaching the ground. The radar navigator did not eject and died upon aircraft impact. The crash site was an isolated mountainous and wooded area. The 14 inches of new snow covered the aircraft wreckage, which was scattered over an area of approximately 100 square yards. The weather during the recovery and cleanup operation involved extreme cold and

gusty winds. Both weapons remained in the aircraft until it crashed, and were relatively intact in the approximate center of the wreckage area.

25. 5 December 1964 / LGM 30B (Minuteman ICBM) / Ellsworth AFB, South Dakota

The LGM 30B Minuteman I missile was on strategic alert at Launch Facility L-02, Ellsworth AFB, South Dakota. Two airmen were dispatched to the Launch Facility to repair the inner zone security system. In the midst of their checkout of the inner zone system, one retrorocket in the spacer below the Reentry Vehicle (RV) fired, causing the RV to fall about 75 feet to the floor of the silo. When the RV struck the bottom of the silo, the arming and fusing/altitude control subsystem containing the batteries was torn loose, thus removing all sources of power from the RV. The RV structure received considerable damage. All safety devices operated properly in that they did not sense the proper sequence of events to allow arming the warhead. There was no detonation or radioactive contamination.

26. 8 December 1964 / B-58 / Bunker Hill (now Grissom) AFB, Indiana

SAC aircraft were taxiing during an exercise alert. As one B-58 reached a position directly behind the aircraft on the runway ahead of it, the aircraft ahead brought advanced power. As a result of the combination of the jet blast from the aircraft ahead, the icy runway surface conditions, and the power applied to the aircraft while attempting to turn onto the runway, control was lost and the aircraft slid off the left side of the taxiway. The left main landing gear passed over a flush-mounted taxiway light fixture, and 10 feet farther along in its travel, grazed the left edge of a concrete light base. After another 10 feet, the left main landing gear struck a concrete electrical manhole box, and the aircraft caught on fire. When the aircraft came to rest, all three crew members aboard abandoned the aircraft. The aircraft commander and defensive systems operator egressed with only minor injuries. The navigator ejected in his escape capsule, which impacted 548 feet from the aircraft. He did not survive. Portions of the nuclear weapon on board burned. Contamination was limited to the immediate area of the crash and was subsequently removed.

27. 11 October 1965 / C-124 / Wright-Patterson AFB, Ohio

The C-124 aircraft was being refueled in preparation for a routine logistics mission when a fire occurred at the aft end of the refueling trailer. The fuselage of the aircraft, containing only components of nuclear weapons and a dummy training unit, was destroyed by the fire. There were no casualties. The resultant radiation hazard was minimal. Minor contamination was found on the aircraft, cargo, and clothing of explosive ordnance disposal and fire-fighting personnel, and was removed by normal cleaning.

28. 5 December 1965 / A-4 / Pacific Ocean

An A-4 aircraft loaded with one nuclear weapon rolled off the elevator of a U.S. aircraft carrier and fell into the sea. The pilot, aircraft, and weapon were lost. The incident occurred more than 500 miles from land.

29. 17 January 1966 / B-52 / KC-135 / Palomares, Spain

The B-52 and the KC-135 collided during a routine high-altitude-air refueling operation. Both aircraft crashed near Palomares, Spain. Four of the eleven crew members survived. The B-52 carried four nuclear weapons. One was recovered on the ground, and one was recovered from the sea on 7 April after extensive search and recovery efforts. Two of the weapons' high-explosive materials exploded on impact with the ground, releasing some radioactive materials. Approximately 1400 tons of slightly contaminated soil and vegetation were removed to the United States for storage at an approved site. Representatives of the Spanish Government monitored the cleanup operation.

30. 21 January 1968 / B-52 / Thule, Greenland

A B-52 from Plattsburgh AFB, New York, crashed and burned approximately 7 miles southwest of the runway at Thule AB, Greenland, while approaching the base to land. Six of the seven crew members survived. The bomber carried four nuclear weapons, all of which were destroyed by fire. Some radioactive contamination occurred in the area of the crash, which was on the sea ice. Some 237,000 cubic feet of contaminated ice, snow, water, and crash debris were removed to an approved storage site in the United States over the course of a 4-month operation. Although an unknown amount of contamination was dispersed by the crash, environmental sampling showed normal readings in the area after the cleanup was completed. Representatives of the Danish Government monitored the cleanup operations.

31. Spring 1968 / Atlantic Ocean

Details remain classified.

32. 19 September 1980 / Titan II ICBM / Damascus, Arkansas

During routine maintenance in a Titan II silo, an Air Force repairman dropped a heavy wrench socket, which rolled off a work platform and fell toward the bottom of the silo. The socket bounced and struck the missile, causing a leak from a pressurized fuel tank. The missile complex and the surrounding area were evacuated, and a team of specialists was called in from Little Rock AFB, the missile's main support base. About 8.5 hours after the initial puncture, fuel vapors within the silo ignited and exploded. The explosion fatally injured one member of the team. Twenty-one other USAF personnel were injured. The missile's reentry vehicle, which contained a nuclear warhead, was recovered intact. There was no radioactive contamination.

NOTE: The events outlined here involved operational weapons, nuclear materials, aircraft, and/or missiles under control of the U.S. Air Force, U.S. Navy, or the Atomic Energy Commission (the DOE predecessor agency). The U.S. Army has never experienced an event classified as an accident involving nuclear weapons. The U.S. Marine Corps does not have custody of nuclear weapons in peacetime, and has not experienced an accident involving them.

TABLE I - SUMMARY OF ACCIDENTS INVOLVING US NUCLEAR WEAPONS

ACCIDENT NUMBER	DATE	LOCATION	WEAPON CONFIGURATION			TYPE OF ACCIDENT	NUCLEAR WEAPON RESPONSE		
			ASSEMBLED WEAPONS	UNASSEMBLED WEAPONS	COMPONENTS ONLY		HE RESPONSE		CONTAMINATION
							HE BURN	HE DETONATE	
1	02/13/50	Puget Sound, WA	-	X	-	Jettison, 8000'			
2	04/11/50	Manzano Base, NM	-	X	-	Crash into mountain			
3	07/13/50	Lebanon, OH	-	X	-	Crash in dive			
4	08/05/50	Fairfield-Suisan AFB, CA	-	X	-	Emergency landing, fire			
5	11/10/50	Over water, outside US	-	X	-	Jettison			
6	03/10/56	At sea (Mediterranean)	-	-	X	Aircraft lost			
7	07/27/56	SAC Base	-	X	-	B-47 crashed into bunker			
8	05/22/57	Kirtland AFB, NM	-	X	-	Inadvertent jettison			
9	07/28/57	At sea (Atlantic)	-	X	-	Jettisons, 4500' & 2500'			
10	10/11/57	Homestead AFB, FL	-	X	-	Crash on takeoff, fire			
11	01/31/58	SAC base overseas	X	-	-	Taxi exercise, fire			
12	02/05/58	Savannah, GA	-	X	-	Mid-air collision, jettison			
13	03/11/58	Florence, SC	-	X	-	Accidental jettison			
14	11/06/58	Dyess AFB, TX	X	-	-	Crash on takeoff			
15	11/26/58	Chenault AFB, LA	X	-	-	Fire on ground			
16	01/08/59	US base, Pacific	-	X	-	Ground alert, fuel tanks on fire			
17	07/06/59	Barksdale AFB, LA	X	-	-	Crash on takeoff, fire			
18	09/25/59	Off Whidbey Is., WA	-	X	-	Navy aircraft ditched			
19	10/15/59	Hardinsburg, KY	X	-	-	Mid-air collision, impact			
20	06/07/60	McGuire AFB, NJ	X	-	-	Missile fire			
21	01/24/61	Goldsboro, NC	X	-	-	Mid-air breakup			
22	03/14/61	Yuba City, CA	X	-	-	Crash after abandonment			
23	11/13/63	Medina Base, TX	-	-	X	Storage igloo at AEC plant			
24	01/11/64	Cumberland, MD	X	-	-	Mid-air breakup, crash			
25	12/05/64	Ellsworth AFB, SD	X	-	-	Missile re-entry vehicle fell			
26	12/08/64	Bunker Hill AFB, IN	X	-	-	Taxi crash, fire			
27	10/11/65	Wright-Patterson AFB, OH	-	-	X	Transport a/c fire on ground			
28	12/05/65	At sea, Pacific	X	-	-	Aircraft rolled off elevator			
29	01/17/66	Palomares, Spain	X	-	-	Mid-air collision, crash			
30	01/21/68	Thule, Greenland	X	-	-	Crash after abandonment			
31	Spng '68	At sea, Atlantic	X	-	-	Lost weapons			
32	09/19/80	Damascus, AK	X	-	-	Missile fuel explosion			

NOTES:

1. USAF 09/19/77 press release to Richard Panter, Eye-Witness News Boston, obtained under the Freedom of Information Act, supplemented by DOD per Appendix I.

2. The term "Assembled Weapon" means either that the separable nuclear capsule was installed but was not in the bomb's pit or a sealed-pit type of weapon with the nuclear material integral with the HE subsystem. "Unassembled Weapons" means that the separable nuclear capsule was not installed in the weapon. (The USAF press release for accidents 1-13 used the term "assembled weapon" for the above plus where a capsule was on the aircraft.

3. Contamination from all accidents except 29 & 30 was low in radioactivity and highly localized in area affected.

4. In the parentheses, the first number indicates the number of weapons that had the named response, and the second number gives the total involved in the accident.

DOE 6(3)

SECRET

UNCLASSIFIED

RS7230/90/00018

Accident #29 Palomares, Spain 7/17/66:

1. A B-52 Aircraft carrying four Mk 28 Y1 Mod 2 War Reserve Weapons in an MHU-20/C Clip-in Assembly collided with a KC-135 Tanker at an altitude of approximately 30,500 feet during an overwater refueling operation. Both aircraft were destroyed.

2. The first weapon was found to be relatively intact with the loading lugs still engaged in the MB-3 Release mechanism. The tail closing plate was torn away from the rear case and the pilot chute had deployed. The bomb nose was depressed slightly and three of the fins had been torn away. The Arm-Safe Switch indicated SAFE. In accordance with rendering safe procedures, the weapon battery was removed. DOE b(3)

3. The primary of the second weapon which impacted in the village apparently underwent a low order detonation. DOE b(3)

The afterbody was fairly intact and the pilot chute had deployed. The weapon case and internal weapon components were badly broken and mangled by impact and detonation. DOE b(3)

4. The third weapon which impacted in rocky hills also experienced a low order detonation of the primary explosives. DOE b(3)

The crater measured approximately 20 feet across and six feet deep. The afterbody and parachute pack were blown approximately 100 yards from the crater. The mild detonating fuze had detonated and the pilot chute had spilled out. The main chute was out of the ruptured afterbody case but was retained in the chute cover. DOE b(3)

SSA002G

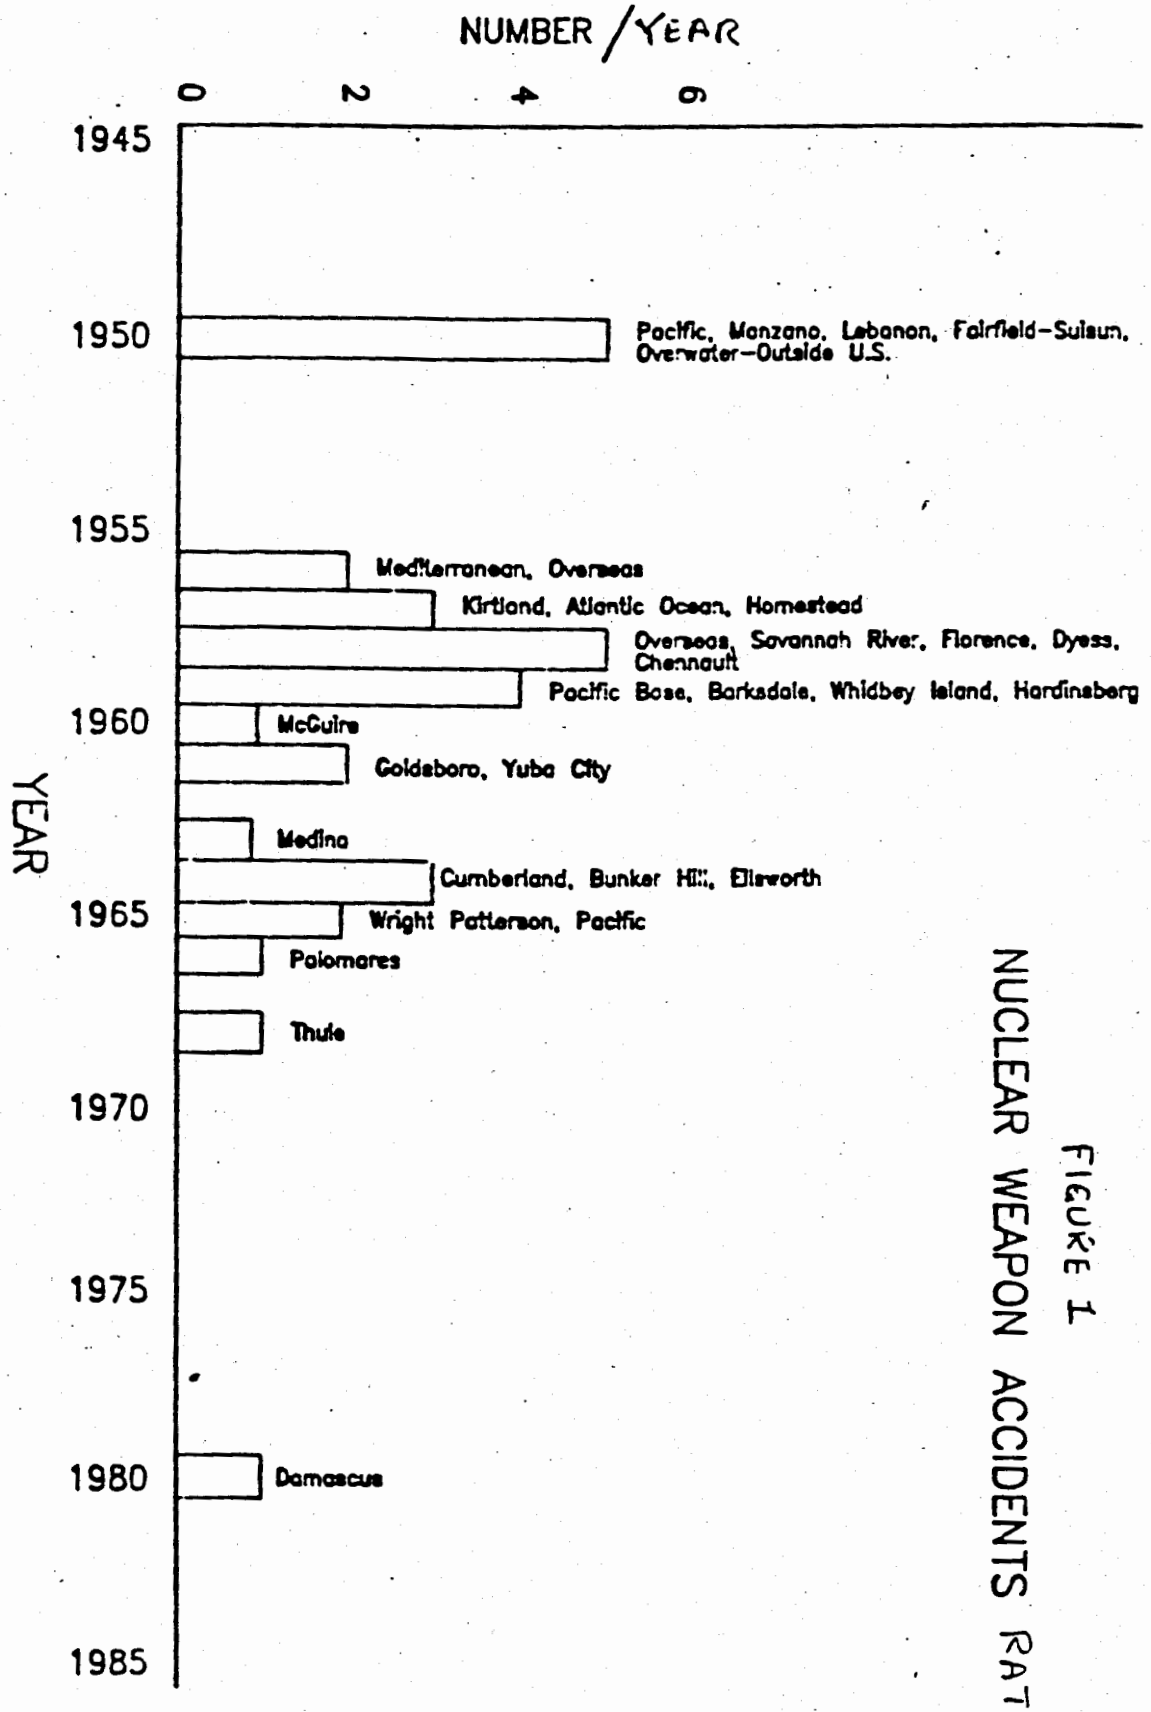

FIGURE 1

NUCLEAR WEAPON ACCIDENTS RATE

summary, of the nuclear weapons involved in the accidents since 1950:

...One of the 16 weapons (accident 4, Table I) involved in accidents with liquid hydrocarbon fuel fires (7 accidents) or missile propellant fuel fires (1 accident) experienced high-order HE detonation.

...Five of the 11 weapons involved in aircraft crashes (6 accidents) experienced HE detonation.

...Five of the ten weapons involved in accidents with free-falls (8 accidents) experienced HE detonation on impact. Free falls resulted from ejected missiles (1 accident), aircraft which broke-up in mid-air (2 accidents), jettisons (5 accidents). Neither of the two weapons involved in aircraft ditching (1 accident) or aircraft rolling off of a ship (1 accident) detonated.

...None of the three bombs involved in accidents (2 accidents) with retarded falls from high altitudes experienced HE detonation on impact.

..[redacted] DOE b(3)

In this total accident experience, there were two instances where extensive decontamination was performed: the Palomares, Spain, and Thule, Greenland accidents which involved dispersal of plutonium by detonation of the weapons' HE on impact. For the two instances where the plutonium melted as a result of the HE burning, only minor local decontamination (mostly washing and removing asphalt) was performed. None of the seven incidents involving uranium dispersal required decontamination.

SECRET
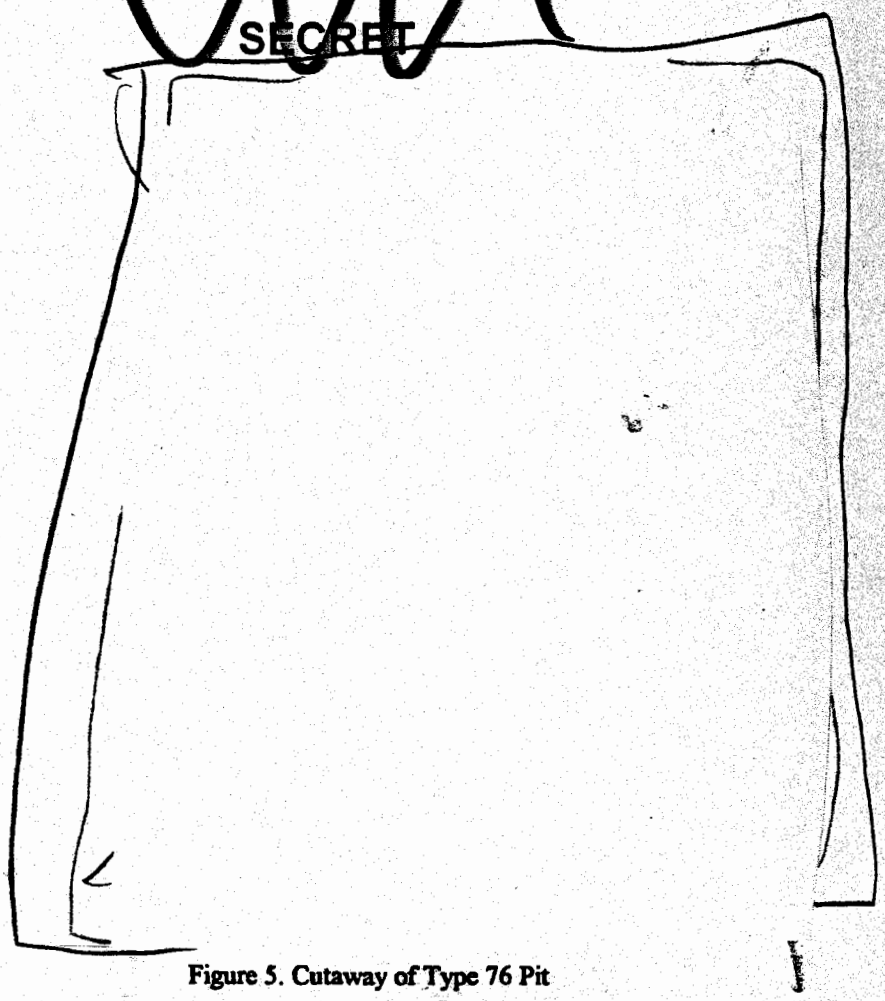
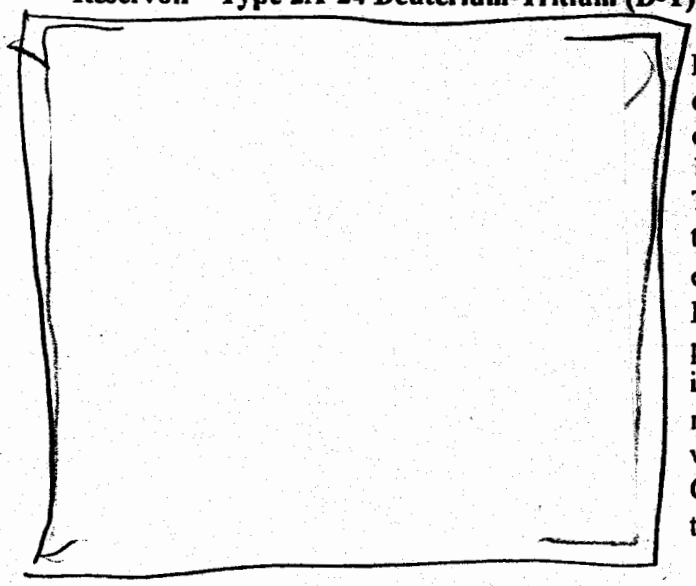
RESTRICTED DATA

DOE
D(3)





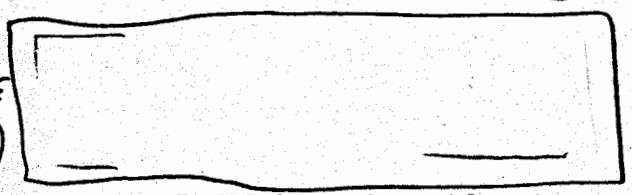


Figure 5. Cutaway of Type 76 Pit

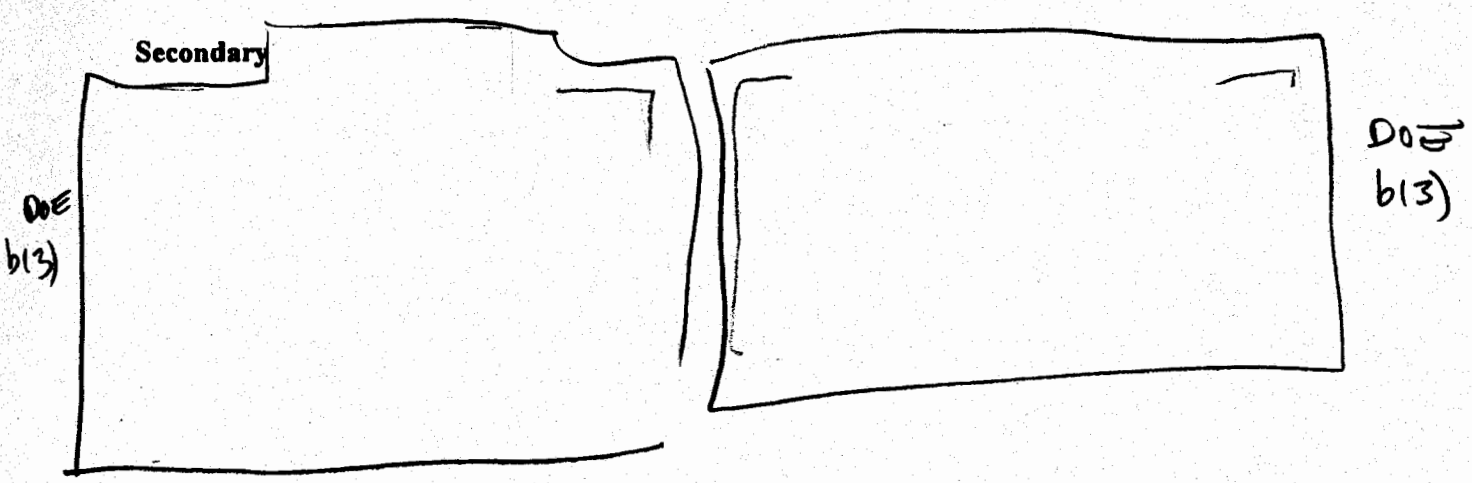
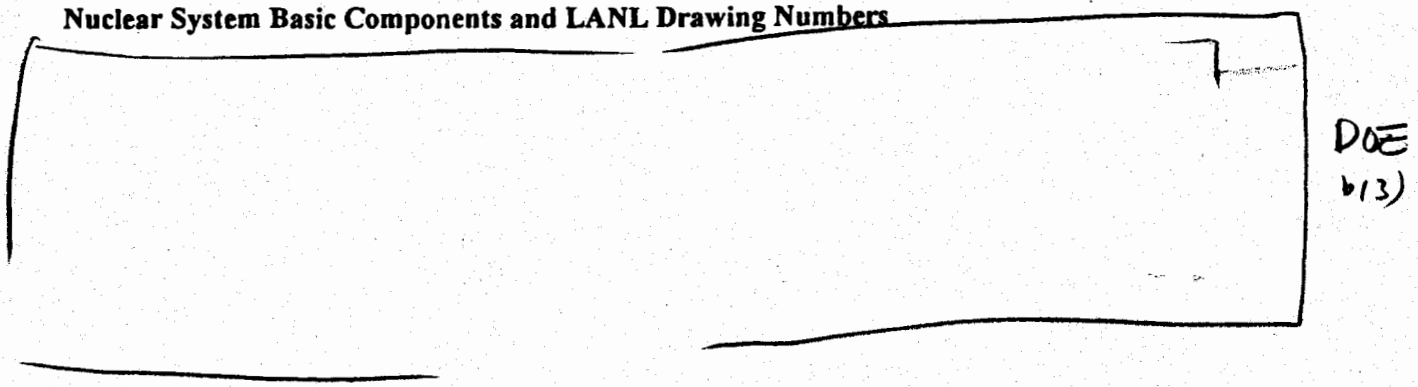
Reservoir - Type 2A-24 Deuterium-Tritium (D-T) gas reservoir and valve assembly

DOE
D(3)

Each Type 1A squib contains an electro-exploding device (EED) that initiates 25 mg of lead styphnate, which in turn initiates 175 mg of Ball Powder (black powder). The Type 1A valve assembly contains a visible thermal plug that is designed to open in a fire environment (operating temperature 104°C). If the actuator squibs fire with the thermal plug open, the gas generated by the actuators is vented to the outside and the plunger will not be forced onto the reservoir and pit tubes with enough velocity to cut the tubes. Cutting these tubes is the only way of transferring the D-T gas to the pit.



Cycle Life - The interval from the fill time to the time that the gas no longer meets the weapon yield certification because of Tritium decay. This life is used to determine the normal LLCE requirements.



Extended Cycle Life - The interval from the fill time to the time that "unacceptable" yield degradation results from Tritium decay and helium generation. This time is greater than the cycle life and less than or equal to the limit life.

Limit Life - The interval from the fill time to the time that the structural integrity of the reservoir, including an appropriate factor of safety, may be compromised, resulting in an increased probability of a Tritium leak.

Stockpile Life - The total number of years that a reservoir can be exposed to a Tritium environment. It may limit the number of times a reservoir can be refilled.

Nuclear System Basic Components and LANL Drawing Numbers

2. Unique signal is provided by the AMAC to enable the MC2929 strong-link switch (requires approximately 25 seconds).

C. Weapon release:

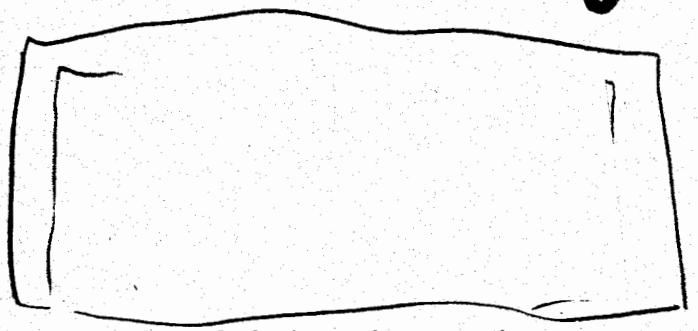
1. Pullout rods are extracted from the MC1200A Fuzing System Control Selector:

   a. Pullout switches in the main thermal battery output lines closed.
   b. Pulse generators in the MC1200A are actuated initiating the MC1262 Thermal Battery Packs (fast-rise batteries) and MC1315 Sequential Timers (parachute timers).

2. MC1262 fast-rise batteries provide 12-volt power:

   a. T_0 contacts in MC1315 timers close.
   b. MC1315s initiate the MC1264 Thermal Batteries (main batteries).

3. 28-volt power is applied to contacts in the MC1268 Interval Timer.

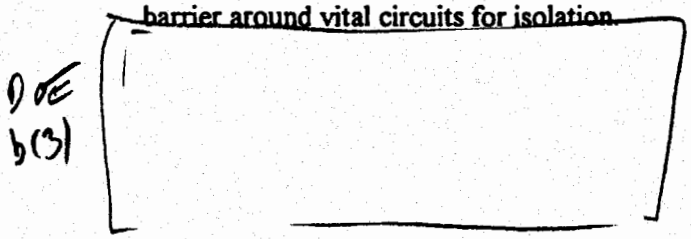


4. [redacted]

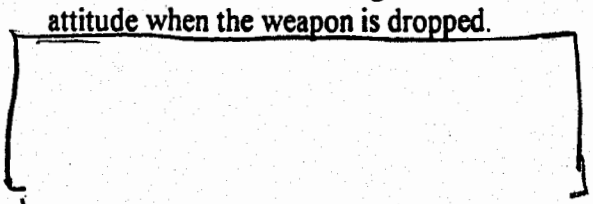
   a. MC1315 parachute timer contacts close, completing circuits between the MC1262 fast-rise batteries and the MC1060 Electric Detonators in the automatic parachute deployment system.
   b. MC1315 provides a signal to cut the retardation parachute suspension lines, and the parachute deployment sequence occurs.

      (1) Automatic deployment cover is separated from the rear case section by mild detonating fuze (MDF) system.
      (2) Automatic deployment cover deploys the pilot parachute.
      (3) Pilot parachute deploys the retardation parachute.
      (4) [redacted]

      (5) [redacted]



5. Laydown parachute drag causes the MC1268 Interval Timer (trajectory sensing device) to operate toward the armed position [redacted]



- The B53 physics package contains conventional High Explosives rather than Insensitive High Explosives.

- The B53 bomb was designed prior to the development of Enhanced Nuclear Detonation Safety (ENDS) concepts. The modification to the B53-1 utilizes a measure of ENDS, incorporating Power pack/shroud Zones and one hard-link (intent switch) and it does incorporate a barrier around vital circuits for isolation.

- The weapon contains an Environmental Sensing Device that is intended to block critical circuits until the intended use environment is sensed. The MC1268 interval timer senses a change in bomb attitude when the weapon is dropped.

Bird cage photo taken at National Atomic Museum
October 2003 by Clarke Ketter

Note: This photo not in original Sandia Site Summary.

Building 941, the older of the two "A" Structures, was constructed as a massive concrete structure, containing only four small storage rooms. Each room is approximately 10 feet wide, 13 feet deep, and 9 feet high, with the capacity to accommodate up to 30 capsules in their "critically safe" storage containers. These storage rooms are accessed through bank vault-type doors with dual combination locks (Photo 7.4). Each vault contains 24 large cubicles, each of which are 36 inches across (Photo 7.5). Nuclear capsules stored too closely together in the "A" Structures could have achieved nuclear criticality, generating a burst of neutrons. Although the capsules would not have detonated, the burst of neutrons would have presented a health hazard to maintenance personnel. The storage containers for the nuclear capsules were designed to prevent any such criticality accident from occurring. Steel braces, welded to the top, bottom, and sides of the 14 inch by 25 inch cylinders created a frame of much larger volume than the cylinder and were designed to keep the capsules at a critically safe distance. The "bird cage," or finished container assemblies, were then sealed with lead-wire seals similar to those used to prevent tampering with electrical power meters, to ensure that their contents were not disturbed between authorized maintenance activities. A bird cage is shown in Photo 2.1.

Building 908, the newer "A" Structure, may have been built during expansion of the site in 1955 or 1956. The cubicles in Building 908, used for storing bird cages, are 30 inches across and allowed for storage of more capsules in each vault than did the older design. A vault door is located only at the entryway of the four-room area.

The false upper story of the "A" Structure, in reality a solid layer of concrete, disguises the purpose of the building. The ten-foot-thick walls and massive berming of the "A" Structures were primarily designed to shield capsules stored in the vaults from external attacks, as opposed to containing accidental detonations within the building. An explosion within the structure would have been unlikely, because a sophisticated external device was required to arm the capsules. The security provided confirms the strong procedural controls established both to protect the economic value of the material and to prevent its misuse. The stored material represented a significant portion of the United States Gross National Product in the early 1950s.

Nuclear component maintenance activities always took place in the "C" Structure, not in the "A" Structure where the devices were stored; thus, no nuclear material was ever exposed in the vaults. The potential for release of radioactive material occurred only within the "C" Structure. When scheduled maintenance of nuclear capsules was required at Stony Brook, two AEC personnel were dispatched to retrieve the capsules from the "A" Structure and deliver them to the "C" Structure. Occasionally, if two AEC personnel were not available, a SNL/NM supervisor would serve as the second required person to deliver or return the capsules.

Capsules were stored and transported in their critically-safe bird cages. The lead security seals were removed in the "C" Structure. After maintenance was completed, each capsule was replaced in its bird cage, sealed in its container, and returned by AEC personnel to its respective "A" Structure. The capsules were not kept overnight in the "C" Structures (Tucker, 1994). Building 941 is currently vacant; Building 908 is being used for records storage by MMWEC.

Listing of Pages Effective With Document Change #2

The following is a list of the page numbers and respective issue dates which are effective with Document Change #2 of this specification.

3 REQUIREMENTS

3.1 Precedence

3.1.1 Precedence of this Specification and Related Documents. -- Whenever their requirements are in conflict, this specification and related documents shall take precedence in the following order:

a. The contract

b. This specification

c. Sandia Corporation drawings

d. Applicable specifications and standards

3.3.3 Fungus Inert Materials. -- Materials which are not nutrients for fungus shall be used to the greatest extent practicable.

3.3.3.1 Fungus-Nutrient Properties of Materials. -- The following materials are arranged in groups in the order of their resistance to fungus growth. Materials in Group Ia should be used in preference to those in Group Ib. Materials in Group II shall not be used unless their other desired properties cannot be obtained from materials in Group I. If materials in Group II are used, they shall be treated in accordance with 3.3.3.2. The use of materials other than those in Group I requires the prior written approval of the Sandia Corporation.

Group Ia

Ceramics
Glass
Glass-silicone
Melamines (except formaldehydes)
Metals
Mica
Monochlorotrifluorethylene
Nylon
Polyethylene (unplasticized)
Polymethylemthacrylate
Polystyrene
Polyvinylidiene chloride
Silicones (pure)

Group Ib

Cellulose acetate
Cellulose acetate butyrate
Diallylphthalate
Ethyl cellulose
Phenolics laminated with glass fibers or nylon
Phenolics (mica-,glass-, or asbestos-filled)
Phenolics (without fillers)
Polyvinyl chloride (Dioctylphthalate or dibutylphthalate plasticizers preferred)
Polyester resins
Rubber (synthetic and natural)

Group IIa

Cotton or linen cloth laminates
Phenolics filled with cotton fiber, wood or wood flour
Melamine formaldehyde
Vinyl acetate

Group IIb

Cellulose nitrate
Cork
Cotton webbing
Hair and wool felt
Leather
Paper
Regenerated cellulose
Wood and wood products

3.3.3.2 Fungus Resistant Treatments. -- If materials in Group IIa are used, they shall be coated with one coat of varnish per TT-V-119. If materials in Group IIb are used they shall be treated by a process approved by the Sandia Corporation.

3.3.4 Hygroscopic Materials. -- The water absorption characteristic of any materials used in the XMC-364 shall be the minimum for that class of material having the other desired characteristics.

3.3.4.1 Treatment of Hygroscopic Materials. -- Materials used in the XMC-364 which will absorb more than 1 per cent of their weight of water when tested in accordance with 4.2.9 shall have their surfaces coated with one coat of varnish, per TT-V-119. This requirement does not apply to insulation sleeving used on wire and cable.

3.3.4.2 Treatment of Machined Plastics. -- All machined surfaces of parts that are fabricated from plactics containing laminations or fillers, shall be coated with one coat of varnish, per TT-V-119.

3.3.5 Corrosion Resistance. -- All materials used shall be corrosion resistant or shall be treated to resist corrosion and shall cause a minimum of corrosion of other materials in the XMC-364 under the conditions specified in 3.8.

3.3.5.1 Additional Protection of Base Metals. -- Gold, nickel, chromium, rhodium, corrosion-resistant steel (12 per cent or more chromium), copper, tin, lead-tin alloys, or sufficiently thick platings of these metals are satisfactory without additional protection or treatment other than buffing or cleaning. In general, aluminum, magnesium, iron, steel, cadmium, and zinc require additional protection in accordance with 3.5.2.

3.3.5.2 Dissimilar Metals. -- Dissimilar metals shall not be used in contact unless suitably protected against electrolytic corrosion. When it is necessary that any combination of dissimilar metals be assembled, an interposing material compatible with each shall be used. Dissimilar metals are defined as follows:

a. Grouping of metals

Group I	Group II	Group III	Group IV
Magnesium alloys	Aluminum	Zinc	Copper and its alloys
	Aluminum alloys	Cadmium	Nickel and its alloys
	Zinc	Steel	Chromium
	Cadmium	Lead	Stainless steel
		Tin	Gold
			Silver

SECRET

UNCLASSIFIED

3.5.7 Wiring

3.5.7.1 Hook-Up Wire: -- All hook-up wire shall conform to JAN-C-76, except as indicated by the responsible engineer of the Sandia Corporation. The size of wire shall be compatible with the electronic circuit in which it is used. No smaller wire than #22 shall be used without the approval of the responsible engineer. All special wires which are used in high current, video circuits shall be approved by the responsible engineer before being used.

3.5.7.2 Wire Connections. -- All wire ends shall be soldered at points of electrical connections and shall be mechanically secured before soldering, except when the small size of the wire or member to which the wire attaches makes a mechanically secured connection impractical, however such small mechanical connections shall be ample to hold the wire in place before soldering. Lugs or similar devices soldered to wire ends shall be used when electrical connections are made by clamping the conductor between parts. Such connections shall not be made by clamping wire ends between parts. Lugs or similar devices shall not be clamped between a metallic and an insulating material but shall be clamped between metallic members. Lugs of either the soldered or solderless type and similar devices may be used but shall be soldered to the wire ends and shall be mechanically secured to the wire by crimping the wire upon the terminal or the terminal upon the wire before soldering.

3.5.7.3 Insulation Hazards. -- Whenever wires are run through holes in metal partitions, shields and the like, less tha 1/8 inch in thickness, the holes shall be equipped with suitable grommets for mechanical protection of insulation otherwise subject to abrasion. Panels 1/8 inch or more in thickness either shall have grommets or shall have the hole edges rounded to a radius equal to one-half the thickness of the material or equal to the diameter of the largest wire running through the hole. Care shall be exercised in the running of hook-up wire to ensure that it is not carried over or bent around any sharp corner or edge which might in time cut through the insulation. In order to prevent deterioration of the conductor by heat, care shall be taken to ensure that wiring is not exposed to local temperatures and that it cannot come in direct contact with heated parts.

3.5.7.4 Interior Cabling. -- Conductors shall be bound into a cable whenever possible and securely held by means of wraplock, cord, or other suitable means. Cables shall be securely held in place by cable clamps.

3.5.7.5 Exterior Cabling. -- Cables used to interconnect equipment outside of enclosing cabinets shall be fabricated in accordance with SCS-4.

3.5.7.6 Coding. -- All wiring shall be distinctly coded by means of numbers on each end and color coded.

UNCLASSIFIED

SECRET

3.6.6 Expected Life. -- The XMC-364 shall be capable of 46 operations in accordance with 4.2.1 without degradation of performance specified in 3.7 under the conditions of 3.8. Any of the first 45 operations may occur during or after the storage periods indicated in 3.8.3. The probability that the 46th operation shall be a malfunction shall not exceed 1 in 200 operations. The probability of malfunction occuring in any of the operations prior to the 46th operation shall also be 1 in 200 operations.

3.6.7 Safety. -- The XMC-364 shall be designed to provide maximum safety for maintenance and operating personnel. Adequate markings shall be located on equipment as warnings of mechanical, electrical, and nuclear radiation safety hazards as near the hazardous points as possible.

3.6.8 High Voltages. -- The XMC-364 or any of its components that is operative when separated from the XMC-364 shall either be designed so that operating or maintenance personnel cannot intentionally or accidentally contact voltages that are dangerous to life, or be suitably marked to warn personnel of the location of such voltages.

3.6.9 Convenience. -- The XMC-364 shall be designed to afford maximum accessibility for the replacement, adjustment and testing of its components without the necessity for disconnecting or removing interposed electrical or mechanical parts.

3.6.10 Interference. -- The XMC-364 shall comply with the requirements of MIL-I-6181 governing generation of and susceptibility to radio frequency interference voltages and fields.

3.7 Performance Requirements

3.7.1 Primary Power

a. The XMC-364 shall operate from a 400 cps ± 5 per cent power source at 115-v ± 10 per cent.

b. The XMC-364 shall operate to its intended use, in any position after a 30 second warm up period. The XMC-364 power load shall not exceed 140 watts except during short surges. Two such short surges shall be allowed in a 30 second period; the time between surges shall be a minimum of 10 seconds. A short surge shall not exceed 225 watts peak and its duration shall not exceed 3 seconds before falling off to one half of the peak of the surge. Power as a function of time requirements are shown in Figure 1. At time A the XMC-364 is turned on; at time B auxiliary equipment used with the XMC-364 is turned on. Time B shall occur at least 5 seconds before time C. The XMC-364 shall operate to its intended use after time C. Time B shall follow time A by a minimum of 10 seconds.

c. No fuses shall be used in the primary power circuit for protective purposes.

d. The XMC-364 shall not malfunction or operate prematurely to its intended use in accordance with 1.1 from signals generated in the primary power supply.

e. A regulator is required to maintain the specified voltage. The voltage regulator shall be capable of the output requirements as given in Figure 1. Regulation during short surges is not required to the accuracy indicated in (a) above. The output voltage of the regulator will nominally be 90 volts ± 1 per cent. All circuits in the XMC-364 which operate directly from the AC power supply shall be designed for 90 volts ± 1 per cent input.

f. The intended use of the XMC-364 shall be in accordance with 1.1. The performance of the XMC-364 shall be tested either by the initiation of a nuclear weapon, or by a measuring device which indicates the proper magnitude of the neutron yield at the proper time.

3.7.2 Output Intensity. -- The XMC-364 neutron yield and timing requirements are specified as follows:

DOE
b(3)

3.7.3 Operation. -- The XMC-364 shall be capable of the specified output when the following signals are supplied to the XMC-364 and when the following conditions exist in the XMC-364.

3.7.3.1 Initial Signal. -- The XMC-364 including the precision timer shall be capable of the specified output 30 seconds after the primary power is available and after being supplied by a suitable pulse. The initial signal shall be an electronic device which generates signals of the form shown in DS(5330)24289. One of these signals shall be used as the initial pulse. The initial pulse shall be reshaped for use as required. The initial signal shall have the following characteristics:

a. The amplitude of the initial signal shall be a minimum of 300 volts and a maximum of 750 volts.

b. The rise time of the initial signal shall be a maximum of .05 microseconds. The rise time of the signal is the time required for the amplitude of the signal to increase from 0.1 to 0.9 of its maximum value.

c. The maximum length of the pulse shall be 30 microseconds and the minimum length shall be 0.5 microseconds. The pulse length is the time interval between the two 0.1 maximum value points of the signal.

d. The output impedance of the signal generator shall not exceed 2500 ohms. A signal of less than 10-v peak amplitude shall not initiate the operating cycle of the XMC-364.

3.7.3.2 Precision Timer. -- The initial signal shall start a precision

DOE 6(3)

3.7.3.3 Source Gap Circuit. -- Upon receipt of the delayed signal from the precision timer, a 0.015 microfarad capacitor which has been charged to 17 kv ± 3 per cent shall be discharged into the source of the accelerator tube. This energy produces ions in the vicinity of the source. The discharge shall be initiated by a spark-gap.

SECRET UNCLASSIFIED

3.7.3.4 Target Pulse Delay. -- The delayed signal from the precision timer shall be delayed so that maximum yield from the XMC-364 results, and this delayed signal shall be used to fire the target spark-gap.

DOE 6(3)

delay does not include the target spark-gap delay.

3.7.3.5 Target Pulse Generator. -- Upon receipt of the delayed signal in 3.7.3.4, a 0.21 ± .03 microfarad capacitance which has been charged to 17 kv ± 3 per cent shall be discharged into the primary of a step-up pulse transformer. The output of the pulse transformer shall be such that the neutron yield in 3.7.2 is obtained. The capacitor is discharged by a spark-gap.

3.7.4 XMC-364 Components. -- The XMC-364 shall consist of the following major components.

3.7.4.1 Voltage Regulator. -- The input to the voltage regulator shall be obtained for a power supply which is capable of supplying the required power as specified in 3.7.1. The voltage regulator shall supply 90-v RMS at 400 cps ± 5 per cent with a maximum variation in voltage of ± 1 per cent. The voltage regulator shall also supply peak regulated power which is proportional to the RMS power. The power supplied shall be as follows:

1. 90-v RMS - 100 watts

2. 90-v Peak - 40 watts

The time required for the voltage regulator to smooth a stop load of 50 watts shall be a maximum of 2 seconds. The voltage regulator shall be capable of the specified output up to and after 90 days storage with no adjustments made when the regulator is removed from storage.

3.7.4.2 High Voltage Power Supply. -- The input to the high voltage power supply shall be obtained from the voltage regulator. The input shall be:

90-v peak proportional to RMS and 90-v RMS AC ± 1 per cent, 400 cycle ± 5 per cent.

The output voltage shall be used to charge the source capacitor and the target capacitor. The target capacitor, which is .21 microfarad ± 0.05 microfarad, shall be charged to a minimum of 16,500-v and a maximum of 17,500-v. The voltage shall not vary more than ± 1 per cent when set between these limits. The target capacitor shall charge to within 98 per cent of the set voltage in a maximum of 10 seconds. The maximum charging current shall be 6 ma. The source capacitor which is a .015 microfarad ± .005 microfarad shall charge to a minimum of 16,500-v and a maximum of 17,500-v. The voltage shall not vary ± 1.0 per cent when set between these limits. The source capacitor shall charge to within 98 per cent of the set voltage in a maximum of 10 seconds. 5 kv RMS ± 10 per cent at 500 microamperes shall be supplied to the accelerator tube's modified Phillips Ion Gage.

SECRET UNCLASSIFIED

SECRET

UNCLASSIFIED

3.7.4.3 Low Voltage Power Supply

3.7.4.3.1 Input. -- 90-v ± 1 per cent RMS AC, 400 cycle ± 5 per cent.

3.7.4.3.2 Output. -- The output shall include all regulated DC voltages to the precision timer, the voltage regulator, and the trigger circuits in the source gap. The voltage shall be as follows:

+ 500 volts unregulated	10 milliamperes
+ 300 volts regulated	75 milliamperes -1 per cent regulated
- 105 volts regulated	10 milliamperes - VR tube regulated

The filament power for all tubes in the XMC-364 will be obtained from a 6.3-v, 10 ampere source.

3.7.4.4 Source-Gap Circuits. -- The source-gap circuit shall include:

a. Source capacitor of 0.015 ± .005 microfarads

b. Source spark-gap

c. Source spark-gap trigger, trigger transformer

The source-gap circuit shall be in accordance with drawing DS(5330)24288.

3.7.4.5 Target Pulse Delay. -- The function of the target pulse delay is given in 3.7.3.4. The target pulse delay circuit shall be in accordance with drawing DS(5330)24288.

3.7.4.6 Target Gap Circuit. -- The target gap circuit shall consist of:

a. A 0.21 ± .05 microfarad capacitor which is charged to 17 kv ± 3 per cent negative with respect to ground.

b. A target spark-gap which when triggered discharges to 0.21 microfarad capacitor in (a).

c. A spark-gap trigger transformer which when supplied with a pulse triggers the spark-gap in (b).

DOE b(3)

3.7.4.7 Precision Timer. -- The precision timer specifications shall be in accordance with SC-5107-Sp.

SECRET

SECRET

UNCLASSIFIED

4.2.4 Humidity Test

4.2.4.1 Preconditioning. -- The XMC-364 shall be placed in a chamber which has been preheated to 130°F and has a relative humidity of 15 per cent. The XMC-364 shall remain in the chamber for a period of 24 hours. Immediately upon withdrawal the XMC-364 shall be placed in a suitable humidity chamber and subjected to five humidity cycles in accordance with 4.2.4.2.

4.2.4.2 Humidity Cycle. -- While the XMC-364 is in the chamber, the humidity shall be maintained at 90 to 98 per cent relative humidity throughout the following cycle:

a. The temperature shall be raised to 149°F within 4 hours and maintained at this point for 8 hours.

b. The temperature shall then be reduced to 86°F within 4 hours and maintained at this point for 21 hours. Between the 8th and 12th hours after stabilization at 86°F, the XMC-364 shall meet the requirements of 4.3.1.

c. The temperature shall be reduced to 68°F within one hour and maintained at this point for 4 hours.

d. The temperature shall then be raised to 86°F within one hour and maintained at this point for 5 hours.

4.2.4.3 Inspection Following Test. -- Upon completion of the humidity test, the XMC-364 shall meet the requirements of 4.2.1. Parts thereof shall be inspected for deterioration of materials, such as corrosion and water absorption, or potential deterioration because of accumulation of moisture.

4.2.5 Salt Spray. -- The XMC-364 shall be tested in a salt spray chamber in accordance with MIL-E-5272, Section 4.6 for 50 hours. Upon completion of the test the assembly shall meet the requirements of 4.2.1 and shall be visually inspected for deterioration of materials, e.g., corrosion.

4.2.6 Dust and Sand. -- The XMC-364 shall be tested in a dust chamber in accordance with MIL-E-5272, Section 4.11, Procedure I. Upon completion of the test the XMC-364 shall meet the requirements of 4.2.1.

4.2.7 Vibration

4.2.7.1 Resonant Frequencies. -- Prior to the vibration tests specified herein, the mechanical resonant frequencies of the assembly and/or its components shall be determined by cycling through the frequency ranges of 10 to 60 to 10 cps and 60 to 500 to 60 cps at low amplitude. If any serious resonant conditions (as evidenced by extreme amplitudes) are detected, the assembly and/or its components shall be redesigned to eliminate or minimize resonance. Prior to redesign the Sandia Corporation shall be consulted. Upon the written approval of the Sandia Corporation, vibration isolators (e.g., shock mounts) may be used.

UNCLASSIFIED

SECRET

4.2.7.2 Equipment Operating/Nonoperating Tests. -- The complete assembly (with its approved vibration isolators if any) shall be secured to a vibration table in the manner it will be mounted in service, and shall be vibrated in each of three mutually perpendicular planes under the following test conditions:

Condition	Frequency range(cps)	Constant Acceleration or double amplitude (g or inches)	Duration of cycle (minutes)	Duration of test (minutes)
1	3-10-3	.098	5	25
2	10-30-10	.109	5	25
3	30-60-30	.054	15	25
4	60-500-60	10 g	15	45

The assembly shall meet the requirements of 4.2.1 during the last few minutes of vibration under each condition in each of three planes.

4.2.8 Acceleration and Shock

4.2.8.1 Acceleration. -- The assembly shall be mounted on a spin table and subjected to a constant acceleration of 50 g for at least one second applied in both the fore and aft directions. The fore and aft line is defined by the mounting arrangement of the assembly with respect to and is parallel to the line of forward motion of the carrying vehicle. The assembly shall meet the requirements of 4.2.1 during the acceleration period.

4.2.8.2 Shock. -- The assembly shall be dropped 5 times from a height such as to produce an acceleration of 30 g in 11 ± 1 milliseconds in accordance with Figure 5 of USAF 7201. The assembly shall meet the requirements of 4.2.1 after this test.

4.2.9 Water Absorption Test. -- Materials which may absorb water shall be tested to determine the necessity of treatment in accordance with 3.3.4.1. Test strips of the material 1/8 inch thick 1 inch wide and 3 inches long shall be dried in an oven at 90°F for 24 hours. They shall then be immersed in water for a period of 24 hours. The strips shall be removed from the water, wiped dry, and immediately weighed. This weight shall be compared with the weight of the predried sample before immersion to obtain the water absorption characteristic (in per cent).

4.2.10 Rain Test. -- The assembly shall be tested in accordance with MIL-E-5272, Section 4.10.1. Upon completion of the test, the assembly shall meet the requirements of 4.2.1.

SECRET UNCLASSIFIED

5 PREPARATION FOR DELIVERY

5.1 Packaging. -- The XMC-364 shall be packaged to prevent damage in shipment by common carrier and ensure delivery in such a condition as to conform with all the requirements of this specification.

5.2 Marking. -- Each package shall be marked 'FRAGILE-HANDLE WITH CARE'.

A PROPOSED ZIPPER SYSTEM FOR SMALL WEAPONS (U)

B. J. Carr - 1423

ABSTRACT

The unit should be no larger than 100 cubic inches in volume and should weigh about 10 pounds. Two units, in a dual system, could be placed in an 11-1/2-inch-OD space only 3-1/2 inches thick.

Power and trigger can be supplied from an X-unit, or other 28-volt DC input supplies such as rotary choppers and transverters can be used.

A look into other possible future Zipper units of considerably smaller dimensions is discussed.

Work performed under AEC Contract AT-(29-1)-789.

Inventoried September 1960

A PROPOSED ZIPPER SYSTEM FOR SMALL WEAPONS

INTRODUCTION

With the realization of the desires for smaller nuclear warhead systems, it has become necessary to consider smaller Zipper units. DOE b(3)

A Zipper system which shows promise for these applications is described herein. DOE b(3)

The time delay is included in the system which is small and rugged; depending upon the power supply and timer unit selected, the system is capable of being relatively radiation-resistant.

REQUIREMENTS

A summary of the controlling requirements for this system analysis follows:

Applications

This Zipper is intended for use in 10- to 12-inch-small warheads used in guided missiles (NIKE AJAX, TERRIER, and possibly air-to-air missiles), a ballistic missile (LITTLE JOHN), a (high-g) rocket-assisted depth bomb (ASROC), and an atomic demolition munition (C-ADM). DOE b(3)

The criteria listed below include present information as to the extreme requirements which will be imposed on the Zipper by the above applications. Development of a miniaturized version of the XMC-825 with choice of power supplies such as a rotary-chopper converter, transverter or X-unit voltage supply may prove satisfactory.

Performance Requirements

Electrical. -- Zipper units should be capable of accepting a 28±4-volt DC, 1-ampere or less per channel power input, or X-unit voltages of 1800 to 2600 volts DC so that it will operate in 4 seconds after application of this power by triggering from an X-unit or other suitable signal.

DOE b(3)

. Actual neutron requirements are not firm and will be obtained from the nuclear laboratories when they have been definitely determined.

DOE b(3)

Environmental. -- The Zipper should be environmentally compatible with SCS-7 with the addition of the ability to withstand the following criteria.

-- Operate after the following weapon environments:

Linear Accelerations - 2000 g's for 0.1 ms,
1000 g's for 2 ms,
650 g's for 0.5 sec,
500-g shock in any direction.

-- Operate after the following weapon environments:

Linear Accelerations - 2000 g's for 0.1 ms,
1500 g's for 2 ms,
500-g shock in any direction.

-- Operate after the following weapon environments:

Linear Accelerations - 75 g's for 4.5 sec,
Angular Acceleration - 2000 rad/sec/sec for 0.01 sec.

Angular Velocity - 50 rad/sec for 100 sec.

Altitude - Operation at 90,000 feet altitude is required.

DOE b(3)

If extreme difficulty is encountered in development due to the acceleration, radiation insensitivity, and size and weight requirements, two separate Zipper developments might best be considered with less restrictive radiation, weight and size requirements on the high-g unit.

Reliability. -- Failure probability of a single-channel system not to exceed 1/100.

Dimensional Requirements

Size and Shape. -- Dual-channel unit allowable volume appears to be approximately 200 cubic inches. Actual size and packaging configuration should be coordinated with the applicable 1200 or 1800 project group, and appropriate form factors will have to be negotiated as design progresses.

Weight. -- Because of warhead application requirements, the weight of a dual-channel Zipper should be limited to 20 pounds including potting, with a lower weight preferred.

Additional information which may be of aid during the development stages of the Zipper unit follows:

SYSTEMS

Figure 1

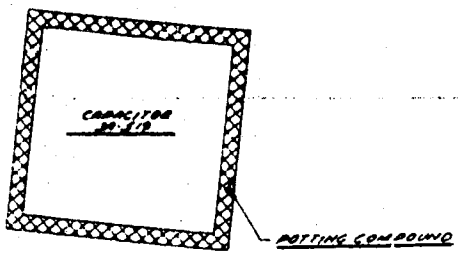
The basic system considered herein is shown in block diagram form in Figure 1. The pulsed neutron source is the same small pulsed linear accelerator which has been developed for other weapon applications. DOE 6(3)

Energy for these pulses is stored in a capacitor similar to those being developed for X-units. The energy is switched to the transformer by a switch which is triggered by the output of the timer unit. The timer itself may be electronic or explosive in nature. The input to the timer may be obtained from several points in the weapon system as may be found most adequate, such as the

FIG. 1 NEUTRON SOURCE SYSTEM BLOCK DIAGRAM

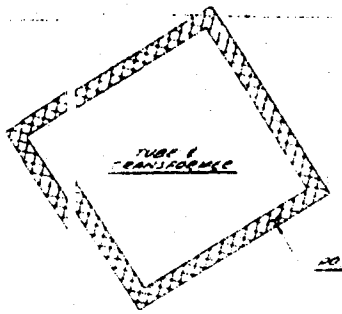
X-unit load plate, X-unit capacitor plate, an X-unit fired detonator or a crystal signal derived from the exploding HE of the nuclear system.

Power to charge the energy storage capacitor may be chosen for each specific application as desired, but the primary requirement is that the energy storage capacitor be charged to from 1800 to 2600 volts DC. Investigations will be carried out to determine if the 1800-volt minimum is realistic if its occurrence is small. Since the electronic timer delay circuit can be made so that the time delay is a function of the input voltage, there are several advantages to using voltages equal to that on the X-unit capacitor for the Zipper-operating voltage. In the case of an explosive timer, this advantage is small, and where an electronic timer with a crystal input is used, the advantages and disadvantages are not clear.



Three possible circuits for the Zipper system are shown in Figures 2, 3, and 4. The similarity of each of these circuits is that the energy storage, pulse transformer for accelerating potentials, and the neutron source tube are identical. The timers and high-voltage switch are different. Both the circuits in Figure 2 and Figure 3 are capable of several tests with no appreciable degradation to the system. The circuit in Figure 4 is a one-shot device, but special laboratory equipment can be devised which would permit the pulsed neutron portion of the unit to be tested. This unit is probably the most reliable circuit shown because it essentially precludes any field tests which might degrade its operation.

Figure 2



The time delay unit shown in Figure 2 uses an electronic timer. The time delay circuit input signal is derived from the X-unit capacitor plate.

STATUS OF DEVELOPMENT

Neutron Source Tube

DOE b(3)

They are 1-1/4 inches OD x 1-3/4 inches long and 1 inch OD and 1-3/4 inches long. Research on size requirements is being studied at UCRL (Berkeley) and at GEXR. The General Electric X-Ray Department is required to furnish breadboard units in April 1957, and will develop a suitable tube and unit for these applications.

A PIG is not desirable and efforts will be directed to removing it from the tube. The initial tube models do not use PIG's.

One transformer of the size required for these applications has been tested in oil. Considerable development of this part is necessary.

The timer circuit shown in Figure 2 has been built in breadboard form and has been tested. Preliminary data from HE experts have been found indicating that the probable accuracy of the HE timer is acceptable.

A modified SA-519 capacitor is planned for use as the energy-storage capacitor. Power supplies for use at 28 volts DC are being developed in Divisions 1469 and 1472.

A high-current, low trigger voltage cold-cathode tube is being developed in 1450. The tube is also being ruggedized to withstand high accelerations.

DOE b(3)

POSSIBLE FUTURE SYSTEMS

On a considerably longer time scale, a system which does not require a separate power supply may be practical. Possible systems are shown in

Figure 8. Here again a pulsed neutron source tube is used but energy and time delay are obtained from high explosives. Energy is transduced to usable voltage and currents by $B_aT_iO_3$ or PZT crystals and ferroelectric materials. The system operation is initiated by either an X-unit detonator or the explosive in the HE space chamber. Also possible, but more in the future, would be a system in which the HE shown in Figure 8 is the HE in the nuclear system. 1 DOE b(3)

They should be quite small, perhaps so small as 20 cubic inches for a unit. In addition, increased reliability due to decreased complexity might permit the use of a single unit in the weapons.

CONCLUSIONS

Since the time scales involved in systems such as XW-35, etc., are short, it is necessary that existing technology be capitalized upon to as great an extent as possible. Any of the systems proposed in some detail in this report require some development but the system shown in Figure 2 perhaps changes the developed art the least amount and presents at least reasonably small size and sufficiently high reliability possibilities. On the other hand, if radiation problems ruin the diodes in the proposed electronic timers, the explosive time delay system in Figure 4 may be the only usable solution. Its advantages make its use desirable but this system requires more development than the two systems using electronic timers. Subsequent to a good understanding for the radiation problem, it appears advisable to exert considerable effort on the explosive time delay system as a backup to an electronic timer.

The size of Zipper units shall be further decreased, but the proposed sizes look promising for use in near-future applications--11- to 12-inch weapons.

[redacted] DOE b(3)

. The major problems in size will be related to dielectric strength of materials to protect the circuits from voltage breakdown since the tube should be developed toward a one-shot capability. This would lower the tritium in the tube to an extremely small amount so that the PIG may not be necessary. Tube efficiency should also be increased by lowering secondary emission from the target.

FOREWORD

This report is an ambitious attempt to summarize weapons activities at Los Alamos Scientific Laboratory in a reasonably short and concise volume for the reference of staff members of the Laboratory and certain key representatives of the Armed Forces and the Atomic Energy Commission. Weapons activities here, as is well known, cover a large field with few defined boundaries. Its ramifications have led into many by-paths and it would be impossible, of course, to detail all the work which has been undertaken during the past eleven years. Moreover, the report, although it embraces the whole period of nuclear weapons development at the Laboratory, does not take the historical approach. That is, it does not chronologically define all the designs evolved and the development steps taken to achieve the end product of all Mark weapons. Its aim has been rather to elucidate as concisely as possible the underlying principles of nuclear weapons as they have been applied and empirically tested during their developmental process. It does not contain a detailed discussion of the mathematical analyses of the technological developments, engineering applications and shop construction expended upon primary models. The report is therefore neither a history of development nor a technical guide for designing nuclear weapons.

As a basic handbook on the principles of nuclear weapons development, this report should fill a variety of needs. It is recommended particularly to the attention of new staff members of the Laboratory, and for the reference use of members of the staff of the Department of Defense and the AEC who have often expressed a need for an exposition of the complex and diversified work which the Laboratory has undertaken in the interests of our national defense and security.

ACKNOWLEDGEMENT

The preparation of this report has required the coverage of both considerable range and depth of technical detail. The work could not have been completed, especially in the time available, without the generous cooperation of many members of the Laboratory staff. It is impossible to mention the names of all who contributed in one way or another, but their invaluable help is gratefully acknowledged.

In the course of collecting material, I have been greatly impressed by the excellent morale and enthusiasm that prevail throughout the Laboratory. The general scientific atmosphere is undoubtedly responsible for the important progress in weapons development summarized here. In addition, it has made the preparation of this report a pleasure and a privilege.

Chapter 1

Principles of Nuclear Energy Production

1.1 Release of Nuclear Energy

Fission and Fusion

Any nuclear reaction in which there is a net decrease of mass, i.e., in which the total mass of the products is less than that of the interacting particles, will be accompanied by a liberation of energy. Two types of reaction have been used for the large-scale release of nuclear energy. These are (a) fission, i.e., the splitting of a heavy nucleus into a pair of lighter nuclei, and (b) fusion, i.e., the combination of two very light nuclei to form a somewhat heavier one. The underlying reason why these processes are accompanied by a decrease of mass and, hence, a liberation of energy is that in each case the average net energy of attraction between the nuclear particles, i.e., the protons and neutrons, often referred to as nucleons, is smaller in the initial nucleus (or nuclei) than it is in the products of the reaction.

Mass Defect and Binding Energy

The magnitude of the net attractive energy, or binding energy, of the nucleons in any nucleus can be calculated from the masses of the various particles. Consider an isotope of mass number A and atomic number Z, so that the nucleus contains Z protons and A - Z neutrons. If m_p is the mass of a proton, m_n is the mass of a neutron, and M is the actual mass of the nucleus, as determined by the mass spectrograph or other nuclear measurements, then the mass defect (M.D.) of the particular isotope is defined by

$$\text{M.D.} = \left[Zm_p + (A - Z)m_n\right] - M. \qquad (1.1)$$

The mass defect, which may be regarded as the decrease of mass that would result if Z protons and A - Z neutrons were combined to form a given nucleus, is a measure of the binding energy of that nucleus.

Binding Energy

If the various masses are expressed in the familiar atomic mass units (amu), in which m_p is 1.00813 and m_n is 1.00897, then multiplication of M.D. by 931 gives the binding energy (B.E.) in million electron volts (Mev). This factor is based on the Einstein mass energy equation using the appropriate units of mass (amu) and energy (Mev). Consequently,

$$\text{B.E.} = 931 \left\{\left[Zm_p + (A - Z)m_n\right] - M\right\} \text{ Mev.} \qquad (1.2)$$

This gives the energy which would be released in the formation of a nucleus by the combination of the appropriate protons and neutrons or, alternatively, the energy which would be necessary to break up the nucleus into its constituent protons and neutrons.

UNCLASSIFIED

SECRET

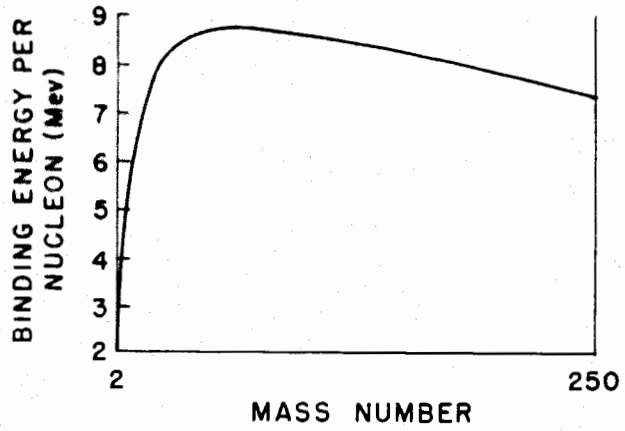

Fig. 1.1

A useful quantity is the mean binding energy per nucleon, i.e., B.E./A, where the mass number, A, is the number of protons and neutrons in the nucleus. The values of B.E./A for many nuclear species have been determined, from their known masses, and when plotted against the respective mass numbers, as in Fig. 1.1, the results are found to fall on, or very close to, a continuous curve. The significant aspect of this curve, for the present purpose, is that the mean binding energy per nucleon is less for the lightest and for the heaviest nuclei than it is for those of intermediate mass. It is this fact which accounts for the liberation of energy accompanying either the fission of heavy nuclei or the fusion of light nuclei, as can be shown in the following manner.

Calculation of Fission Energy

Uranium-235 undergoes fission in some thirty or more different ways, i.e., many different pairs of nuclei are formed. In the great majority of cases, however, the mass numbers of the fission products lie within the range from about 80 to 150, and from Fig. 1.1 it is seen that the average value of the binding energy per nucleon in this region is about 8.4 Mev. On the other hand, in the original uranium-235, the binding energy per nucleon is 7.5 Mev. Hence, the total energy which would be required to break up a uranium-235 nucleus into its 235 constituent nucleons would be 235 x 7.5 Mev, whereas for the fission product nuclei the corresponding energy would be about 235 x 8.4 Mev. In this calculation the neutrons involved in fission are neglected for simplicity, since they will have little effect on the final result. Consequently,

$$\text{Uranium-235} + (235 \times 7.5)\text{Mev} \longrightarrow 235 \text{ nucleons}$$
$$\text{Fission products} + (235 \times 8.4)\text{Mev} \longrightarrow 235 \text{ nucleons}$$

and upon subtraction and rearrangement it is seen that

$$\text{Uranium-235} \longrightarrow \text{Fission products} + (235 \times 0.9)\text{Mev}.$$

In other words, the fission of uranium-235 is accompanied by the release of 235 x 0.9 Mev, i.e., about 200 Mev, of energy.

UNCLASSIFIED

SECRET

It can be shown in an exactly analogous manner than the fusion of very light nuclei, in particular those of hydrogen and its isotopes, i.e., deuterium (D) and tritium (T), is associated with the liberation of energy, because of the difference in the mean binding energies. This is exactly the same as saying, as indicated earlier, that the mass of the products is less than that of the interacting nuclei. The difference in mass appears as energy, in accordance with the mass-energy equivalence relationship.

The Fission Process

Although fission of heavy nuclei can be brought about in a number of ways, there is only one that is of importance for the practical release of nuclear energy: this is fission initiated by neutrons. The reason is that the fission process is itself accompanied by the liberation of neutrons, so that a chain reaction with the continuous release of energy is possible. Only three isotopes, namely, uranium-233, uranium-235, and plutonium-239, need be considered here for use in a fission chain process. In the first place, although these substances are radioactive, they have relatively long half lives, so that they may be regarded as moderately stable. And, in the second place, they will undergo fission by the capture of neutrons of all energies, i.e., either fast (high energy) or slow (low energy).

The common isotope uranium-238 requires neutrons of at least 1 Mev energy to cause fission. Although most of the neutrons produced in fission actually have higher energies, they rapidly lose energy in collisions, so that they are brought below the threshold of 1 Mev for fission of uranium-238. Consequently, the maintenance of a chain reaction in uranium-238, is not possible. Nevertheless, fission of this isotope does occur and the energy released often makes an appreciable contribution to the total energy produced in nuclear weapons.

Of the three fissionable (or fissile) species mentioned above, only uranium-235 and plutonium-239 have hitherto been used in nuclear weapons. The amount of uranium-233 at present available is too small for this purpose, although it may become of considerable importance in the future. However, the general discussion of the fission chain process to be given here applies equally to all three isotopes. Such differences in behavior as do exist arise from a difference in the average number of neutrons produced when fission occurs and in the relative importance of fission and nonfission reactions.

The fission process may be regarded as producing three types of products: (a) lighter nuclei, called fission fragments, (b) neutrons, referred to as fission neutrons, and (c) energy. Thus, taking uranium-235 as typical, the fission act may be represented by

$$\text{Uranium-235} + n \longrightarrow \text{Fission fragments} + 2\text{-}3 \text{ neutrons} + \text{energy}.$$

These products will be considered in turn.

SECRET

UNCLASSIFIED

Fission Products

Some 60 or so different isotopes (fission fragments) are formed in fission, corresponding to the 30 or so different ways in which the heavy nuclei can split up into two lighter nuclei. Most of the fragments are radioactive, emitting beta and gamma radiations. On the average, each fission fragment undergoes three stages of beta decay before attaining stability, so that there are ultimately formed about 200 different isotopic species, most of which are radioactive. The mixture of fission fragments and their decay products is referred to by the general name of fission products. As just indicated, it is a very complex system, containing many radioisotopes, with half lives ranging from a small fraction of a second to a million years.

Fission Neutrons

The number of neutrons produced in fission varies somewhat with the different modes in which the nucleus splits, but the average number of fission neutrons (ν) is well defined. The results of experimental measurements are given in Table 1.1 for the three important fissile species. It should be noted that the number of fission neutrons produced by plutonium-239 is appreciably greater than that released by uranium-235. This has an important bearing on the design of atomic weapons. The energies of fission neutrons range from quite small values up to 14 Mev or more, the majority having energies of about 1 to 2 Mev.

Table 1.1 Average Numbers of Fission Neutrons*

Uranium-235	2.51
Plutonium-239	2.96
Uranium-233	2.60

The neutrons emitted in fission can be divided into two categories, namely, prompt neutrons and delayed neutrons. The former are all released within something like 10^{-12} sec of the fission process, but the latter continue for several minutes. For uranium-235 fission the prompt neutrons constitute 99.25 per cent of the total fission neutrons and for plutonium-239 they represent 99.75 per cent. Because the time scale in a nuclear explosion is very short, delayed neutrons play essentially no part in the reactions. Nevertheless, they are of great significance in connection with reactors (or "piles") in which the energy release is controlled, so that the fission rate is relatively slow.

Fission Energy

The rough calculation given earlier indicated that about 200 Mev are produced in each act of fission. Actually, both experimental measurements and more precise calculations, based on accurate values of the masses of the nuclei involved, have shown this to be a fair approximation

* Strictly true only when fission is initiated by fission spectrum neutrons.

UNCLASSIFIED SECRET

for both uranium-235 and plutonium-239. On the basis of this figure, of 200 Mev per fission, the energy theoretically available from the complete fission of 1 kilogram (2.2 lb) of fissile material, i.e., of about 2.6×10^{24} nuclei, is expressed in various units in Table 1.2.

Table 1.2 Energy Release in Complete Fission of 1 Kilogram

2×10^{13}	calories
8.4×10^{20}	ergs
6.2×10^{13}	foot-pounds
2.3×10^{7}	kilowatt-hours
7.9×10^{10}	Btu
20,000	tons TNT

It should be mentioned that not all of the energy liberated in fission is available to produce blast in a nuclear explosion. Due to the fact that some of the energy, in the form of thermal radiation and gamma rays, moves ahead of the shock wave, and for other reasons, only about 75 to 85 per cent of the fission energy contributes to the blast effect.

By comparing the available energy with that produced in the explosion of TNT, it has been estimated that the complete fission of 1 kg of uranium-235 would be as effective as 17 kilotons, i.e., 17 kt, of TNT, whereas 1 kg of plutonium-239 is equivalent to 19 kt of TNT. In other words, the energy yield per fission is equivalent to about 6.6×10^{-24} kt for uranium-235 and 7.3×10^{-24} kt TNT for plutonium-239. Although these numbers are known to be somewhat inexact, they are nevertheless used in calculations of energy yields, generally abbreviated to "yields," of nuclear weapons. Such yields are amost invariably expressed in terms of "kt," which is short for "kiloton TNT equivalent." A bomb with a yield of 20 kt is often referred to as a nominal atomic bomb, since this was roughly the energy release of the earliest (implosion) bombs.

1.2 The Fission Chain Reaction

Conditions for Chain Reaction

The condition for the maintenance of a fission chain reaction is, in essence, that for every fission caused by a neutron there should be produced another neutron capable of causing fission. Since the average number of neutrons produced in an act of fission is greater than two (Table 1.1), it would appear that a chain reaction in uranium-235 or plutonium-239 is inevitable. But this is not so, because not all the fission neutrons are available to carry on the chain, an appreciable proportion being lost in various ways. In a nuclear fission weapon, an important source of loss is leakage or escape of neutrons from the reacting system, so that many neutrons escape before being captured by a fissile nucleus. Some neutrons are also lost by parasitic capture, i.e., by capture in nonfission reactions of various kinds, either by the fissile material itself or by other nuclei.

SECRET UNCLASSIFIED

The fraction of neutrons escaping from a system in which fission is taking place can be decreased by increasing the size (or mass). Since neutrons are produced, by fission, throughout the whole volume, whereas escape takes place only from the exterior surface, it is evident that the escape probability will decrease as the volume-to-area ratio of the system is increased; this is achieved, for a given geometry, by increasing the dimensions.

Critical Size

In a very small mass of fissile material a self-sustaining chain reaction will not be possible because of the large proportion of neutrons that escape. But as the size is increased, the fraction of fission neutrons lost will decrease and ultimately a point is reached when for every neutron captured in a fission reaction another one will become available to carry on the fission chain. The system is then said to be critical, and a self-sustaining chain reaction is just possible. If a system is smaller than the critical size (or mass) it is referred to as subcritical, and if larger, it is called supercritical. In the latter case there are more neutrons available for fission at the end of each generation than were used up to cause fission at the beginning of that generation. It will be seen below that the critical mass or size is dependent on the nature of the fissile material, its shape, and several other factors.

Convergent, Stationary, and Divergent Chains

If ν is the average number of neutrons produced in each act of fission, on the average, and $\mathscr{l}$ is the average number lost, by escape and in other ways, e.g., by nonfission capture, then $\nu - \mathscr{l}$ is the number available to cause further fission; let this be represented by k, i.e.,

$$k = \nu - \mathscr{l} .$$

Thus, for every neutron causing fission in one generation, k neutrons will be available to cause fission in the next generation. Hence, in accordance with the preceding paragraph, k will be less than unity in a subcritical system; in a critical system k = 1; and in a supercritical system k will be greater than unity.

Suppose S neutrons are introduced into a fissile material and cause this number of fissions; then kS neutrons will be available for the next generation, k^2S for the next, and so on; at the end of n generations, the number of neutrons which can cause fission will be k^nS. Since, for a subcritical system, $k < 1$, it is evident that as n, the number of generations, increases, k^nS will approach zero. In other words, the number of neutrons will gradually decrease from one generation to the next; there is consequently a convergent or decaying fission chain which gradually dies out. For a system of critical size, k = 1, and then k^nS is always equal to S. The number of neutrons then remains constant from generation to generation. This is referred to as a stationary chain. Finally, if $k > 1$, as is the case for a supercritical system, k^nS increases steadily. The fission chain is then said to be a divergent or branching chain.

Prompt and Delayed Critical

In the foregoing discussion no distinction has been made between the prompt and delayed fission neutrons. As stated earlier, however, only the prompt neutrons are significant in fission weapons, and the critical size or mass is determined by the availability of the prompt neutrons, without regard to those which are delayed. This situation is often described as prompt critical. When both prompt and delayed neutrons are required to maintain the stationary chain, as in a nuclear reactor, the term delayed critical is sometimes used. Since more than 99 per cent of fission neutrons are prompt, the neglect of the delayed neutrons has little effect on the value of ν; hence, the data in Table 1.1 may still be used in essentially all calculations.

Factors Affecting Critical Mass

The critical size (or mass) is by no means a definite quantity, even for a given fissile material of specified composition. For one thing, the shape of the system has an influence on criticality, because the volume-to-area ratio varies with the geometry. The optimum condition is obtained with a sphere, for this has the largest ratio of volume to area, so that the probability of escape of neutrons is smaller than for any other shape. Thus, the critical mass of a sphere is less than that of any other geometrical form of the same material. As far as the material is concerned, it is evident that the presence of impurities will increase the critical mass of the fissile substance. Apart from the fact that the impurity may cause a loss of neutrons by parasitic capture, it adds area to the system, which increases the probability of neutron escape, without the compensating production of neutrons by fission.

It will be apparent, too, that the larger the value of ν, the smaller will be the critical size, under the same general conditions. If more neutrons are formed per fission, it will be possible to tolerate a somewhat larger loss and yet attain criticality. Hence, the critical size of plutonium-239 is less than that of uranium-235; since the densities are not very different, this is also true for the critical masses (see Table 1.3, below).

A factor which can partially compensate for a lower ν value is a smaller proportion of nonfission captures by the fissile material, since this will tend to increase the number of neutrons available for propagating the chain reaction. Although ν for uranium-233 is appreciably less than for plutonium-239, the critical masses, under equivalent conditions, do not appear to differ greatly. This is because nonfission capture in uranium-233 is relatively less than in plutonium-239.

The critical size is also dependent upon the mean free path of neutrons, i.e., the average crow-flight distance a neutron will travel before interacting with a nucleus, in a given material. If the mean free path is long, the probability that a neutron will escape from the system is also large. Consequently, under comparable conditions, the critical size will be greater than for a fissile material in which the neutrons have a shorter mean free path.

For a specified shape and composition, the size of a critical system can be decreased by surrounding it with a material which scatters neutrons back into the fissile core. By reducing the number of neutrons that escape, a smaller size (or mass) can become critical. Such a scattering material, on account of its function, is referred to, in general, as a reflector. In nuclear weapons it is called a tamper, because, in addition to decreasing the loss of neutrons by escape, it delays expansion of the exploding mass and permits a higher yield from the system undergoing fission, as will be seen later.

As is to be expected, increasing the thickness of the tamper decreases the escape of neutrons and thus makes possible a smaller critical mass of the fissile (or core) material. However, it has been shown by theoretical calculations, and verified experimentally, that when the tamper thickness reaches a certain value there is little more to be gained by a further increase of thickness (Fig. 1.2). Thus, when the thickness is about two to three neutron mean free paths in the given tamper material, its effectiveness in reducing neutron losses is within 10 per cent or so of an infinitely thick tamper.

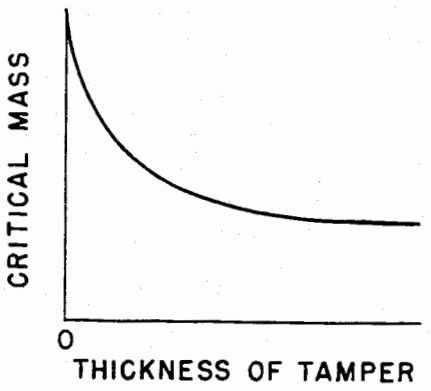

Fig. 1.2

Under precisely specified conditions, and for a given fissile (core) material, there is a definite mass that will be just critical. This is called a "crit." The critical masses of spheres of uranium-235 (94 per cent purity) and of plutonium-239 (97 per cent purity) are given in Table 1.3. In the first column are the values for a bare (untamped) sphere, whereas the values in the second column are for a thick (infinite) tamper of natural uranium metal. The effect of the tamper in reducing the critical mass of the core is very striking.

Table 1.3 Critical Masses of Spheres

Fissile Material	Bare	Tamped
Uranium-235	52 kg	17.2 kg
Plutonium-239	16 kg	5.8 kg

It may be noted that there is still another factor which affects the critical size: it is the speed (or energy) of the neutrons causing fission. The rate of the fission process is determined by the fission cross section, as will be seen later, and this varies with the neutron energy. However, as far as nuclear fission weapons are concerned, it may be tacitly assumed that only fast

neutrons, mainly with energies in the range from 0.5 to 2 Mev, are involved. Because of the relatively long slowing-down time, fission by slow neutrons would be less effective in an explosion.

1.3 Attainment of Criticality

Assembly Method (Gun-Type Weapons)

As long as a mass of fissile material is less than the critical value, i.e., it is subcritical for the existing conditions, there is no danger of a chain reaction occurring. But, if energy is to be released, e.g., in an explosion, the system must become critical and, in fact, highly supercritical, as will be seen shortly. There are two general ways, utilized in weapons, for rapidly converting a subcritical system of fissile material into one that is supercritical.

The first may be referred to as the method of assembly. Two portions of subcritical size are brought together very rapidly, so that the combined mass is supercritical. If a burst of neutrons is then introduced, a divergent fission chain will be initiated and there will be a rapid release of energy within a very short time. This is the principle used in weapons of the gun type: one subcritical portion of fissile material is shot into another subcritical portion, the combination exceeding the critical mass.

Compression Method (Implosion Weapons)

The second method of attaining criticality (or supercriticality) is based on compression of the subcritical fissile material. An approximate quantitative treatment of the relationship between the compression ratio and critical mass may be derived as follows. In accordance with the definition given above, the mean free path of a neutron is the average (crow-flight) distance a neutron travels before it interacts with a nucleus. The proportion of neutrons avoiding interaction, and which can consequently escape from the system, will evidently depend on the ratio of the dimensions, e.g., the radius of a sphere, to the mean free path. It is to be expected, therefore, that for a given fissile (core) material, under specified conditions, the critical radius will be approximately proportional to the neutron mean free path; thus, if R_c is the critical radius and λ_c is the mean free path in the core,

$$R_c \propto \lambda_c. \qquad (1.3)$$

The mean free path of a neutron is obviously inversely related to the probability of its interaction; the greater the probability of interaction, the smaller the distance the neutron will travel before it interacts with a nucleus. The probability of interaction is proportional to the number of fissile nuclei per unit volume, and hence to the density; so that, if ρ_c is the density of the core material,

$$\lambda_c \propto \frac{1}{\rho_c} . \tag{1.4}$$

The density of the material is dependent on the compression; thus, if C is the compression ratio, i.e., the volume before compression to that after,

$$C \propto \rho_c . \tag{1.5}$$

Combination of equations (1.3), (1.4), and (1.5) then leads to the result

$$R_c \propto \frac{1}{C} . \tag{1.6}$$

The critical mass M_c is related to the critical radius and the density of the material by

$$M_c = \frac{4}{3}\pi R_c^3 \rho_c , \tag{1.7}$$

and upon substituting equation (1.6) for R_c and equation (1.5) for ρ_c, it is seen that

$$M_c \propto \frac{1}{C^2} . \tag{1.8}$$

The critical mass of a given fissile material is thus inversely proportional to the square of the compression ratio. By increasing the compression the critical mass is consequently decreased.

It follows, therefore, that if a subcritical mass of fissile material is compressed it may become supercritical. [redacted] In other words, it will be highly supercritical, and the introduction of neutrons will cause a rapidly divergent fission chain to develop.

If the mass of fissile (core) material is tamped, then the result in equation (1.8) is true only if both the tamper and the core are compressed to the same extent. Actually, uniform compression is not attained throughout; it is greater near the center of the bomb, i.e., in the core, than further out, e.g., in the tamper. Even within the core itself there is a compression gradient. In general, therefore, the relationship between the critical mass and the average compression ratios of the core (C_c) and of the tamper (C_t) may be represented by

$$M_c \propto \frac{1}{C_c^{1.2}} \cdot \frac{1}{C_t^{0.8}} , \tag{1.9}$$

so that when C_c and C_t are identical, this reduces to equation (1.8). For most cases of interest in the weapons field, a good approximation is

$$M_c \propto \frac{1}{C_c^{1.7}} \quad , \tag{1.10}$$

since the conditions are such that the tamper is compressed to a smaller extent than is the core.

The use of compression to attain supercriticality is employed in weapons of the implosion type; the reason for this name will be seen later. Not only does increased compression result in a decrease in critical mass, it is also accompanied by an increase in efficiency of the energy release, as will be seen in Section 2.1. Consequently, the attainment of higher and higher compressions is one of the important objectives of weapon development.

1.4 Neutron Multiplication

Rate of Fission Reaction

No matter how it originates, an explosion involves the very rapid liberation of a large amount of energy. If the energy is to be produced by fission, then the necessary condition is a very high neutron density, since the rate of fission, and, hence, the rate of energy release, is proportional to the number of neutrons per unit volume. It is of interest, therefore, to investigate the circumstances which lead to a high neutron density.

It was seen earlier that the number of neutrons available to cause fission, for every neutron captured in a fission process, in each generation is equal to k, i.e., to $\nu - \ell$, where ν is the average number of neutrons produced per fission and ℓ is the average number lost by escape and nonfission capture. This means that for every n neutrons present at the beginning of a generation, there will be nk present at the end, so that the gain of neutrons is n(k - 1) per generation. The rate of gain, dn/dt, may then be obtained, roughly, upon dividing the actual gain by the average time, τ, between successive fission generations; hence,

$$\frac{dn}{dt} = \frac{n(k-1)}{\tau}. \tag{1.11}$$

This result will be strictly correct only if the delayed neutrons play no significant part in maintaining the fission chain. As seen above, this condition is applicable to nuclear fission weapons.

The quantity k - 1, which is the excess number of available neutrons per fission, may be

represented by f*, i.e.,

$$f = k - 1 = \nu - \ell - 1 \tag{1.12}$$

and then

$$\frac{dn}{dt} = n\frac{f}{\tau}. \tag{1.13}$$

It is customary to use the symbol α for the quantity f/τ, i.e.,

$$\alpha \equiv f/\tau, \tag{1.14}$$

so that

$$\frac{dn}{dt} = \alpha n. \tag{1.15}$$

Thus, the rate of increase in the neutron population (or neutron density) is dependent upon α, and this should be made as large as possible.

It is seen from equation (1.15) that α is a rate constant or specific rate. In nuclear weapons work it is frequently called the multiplication rate or merely "alpha." Its value depends on the conditions existing at any time. According to equation (1.15), if α is negative, i.e., $\alpha < 0$, then dn/dt will be negative and the number of neutrons will decrease with time. Since α is equal to f/τ, and τ is always positive, this condition will arise when f is negative. From equation (1.12) this means that k - 1 is negative, or $k < 1$, i.e., when the system is subcritical. Hence, is agreement with previous conclusions, the fission chain in a subcritical system will eventually die out because of the steady decrease in the neutron population. If α is zero, i.e., $f = 0$ and $k = 1$, the system is critical, and, by equation (1.15), the neutron density will remain constant. Finally, if α is positive, so that $f > 0$ and $k > 1$, the system is supercritical and there will be a steady increase in the neutron population.

If equation (1.15) is written in the form

$$\frac{dn}{n} = \alpha dt,$$

*In LASL reports, the symbol f has a significance which is somewhat different from that given here. It is a purely nuclear property of the fissile material, for neutrons of a specified energy, giving the excess neutrons per collision in a system from which neutrons do not escape. Thus,

$$f = \frac{\sigma_f}{\sigma_t}\left(\nu - 1 - \frac{\sigma_c}{\sigma_f}\right),$$

where σ_f, σ_c, and σ_t are the fission, nonfission capture, and total cross sections, respectively. The accepted values of f are 0.35 for uranium-235 (oralloy) and 0.69 for plutonium.

and α is supposed to remain constant, this expression can be readily integrated between the time limits of zero, when the number of neutrons present is n_o, and t, when the number has increased to n. The result is

$$n = n_o e^{\alpha t}, \tag{1.16}$$

where e, as usual, is the base of natural logarithms. Thus, if α is known, the neutron population at any time t can be calculated, relative to the value at an arbitrary zero time. It can be seen from equation (1.16) that $1/\alpha$ is the time period during which the number of neutrons increases by a factor e; consequently, $1/\alpha$ is often referred to as the e-folding time, i.e., the time in which there is an e-fold increase in neutron population.

Conditions for Nuclear Explosion

In order to achieve a nuclear explosion there must be a very rapid release of a large amount of fission energy. The rate of the fission process is proportional to the neutron density and so the conditions for an explosion can be realized if both α and n in equation (1.16) are large. Since n depends upon α, the value of the latter is essentially the determining factor. In general, the magnitude of α largely determines the efficiency of a nuclear fission explosion. It is of interest, therefore, to consider how α may be made as large as possible.

By the definitions of equations (1.12) and (1.14),

$$\alpha \equiv \frac{\nu - \ell - 1}{\tau}, \tag{1.17}$$

so that to increase α, it is necessary that $\nu - \ell - 1$ should be large and τ small. The value of ν is a specific property of the fissile material and, for a given substance, cannot be altered. The relative neutron loss, ℓ , can be decreased by making the system highly supercritical, e.g., by assembly or compression, as already described, or by means of a tamper. However, once the fission chain has been started ℓ remains roughly constant, as long as the volume of the system does not change appreciably. If the volume increases, then the neutron loss increase and α decreases, correspondingly. The importance of this effect of volume change will be seen later.

The significant factor in the determination of α is, consequently, the generation time, τ. This is approximately equal to λ, the fission mean free path of the neutrons in the core material, divided by the speed, v, of the neutrons causing fission, i.e.,

$$\tau \approx \frac{\lambda}{v}, \tag{1.18}$$

so that the ratio λ/v should be made as small as possible. It should be noted that the fission mean free path in equation (1.18) is not the same as the mean free path for all interactions used earlier. The λ used here is the average distance a neutron travels before it is captured in a fission reaction.

The fission mean free path is equal to $1/N\sigma_f$, where N is the number of fissile nuclei per cm^3 and σ_f is the fission cross section.* Hence, from equation (1.18),

$$\tau \approx \frac{1}{N\sigma_f v}, \qquad (1.19)$$

so that the generation time is inversely related to the product $\sigma_f v$.

*For the present purpose, the cross section may be regarded as the effective area of a nucleus for a particular reaction (or reactions). It is usually expressed in barns, i.e., 10^{-24} cm^2 units.

It is evident, therefore, that in order to achieve a nuclear explosion, fission should be brought about by fast neutrons, as far as possible.

According to equation (1.19), the generation time for neutrons of given energy (or velocity) is inversely proportional to the number (N) of fissile nuclei per cm^3. It follows, therefore, that τ is inversely proportional to C_c, the core compression; thus,

$$\tau \propto \frac{1}{C_c} . \qquad (1.20)$$

Consequently, the generation time can be decreased, and the value of α increased, by compression of the core material.

In addition to the effect of compression on τ, it also causes a marked decrease in ℓ, as indicated above, so that f is increased appreciably. It follows, therefore, from equation (1.14 that compression of the core will greatly increase α because of the simultaneous increase in f and decrease in τ.

Further, leakage of neutrons must be kept as low as possible in the exploding system. Finally, increased compression is a highly favorable factor, since it reduces leakage and shortens the generation time. Compression also increases the efficiency of the explosion, as will be seen in the next chapter.

Thus for fast-neutron fission, α is about 10^8 sec^{-1} in a supercritical system and τ, the generation time, is roughly 10^{-8} sec (or about 1 shake). Experimental determinations (see Chapter 6) give values for α in very good agreement with this calculation. It is the common practice to express the results in reciprocal shakes, i.e., 10^8 sec^{-1} units, so that in the example given above $\alpha \approx 1$ $shake^{-1}$.

Explosion Time

It will be noted, incidentally, that $1/\alpha$, the e-folding time, is of the same order as τ, the generation time. Consequently, $1/\alpha$ is frequently identified with the generation time, and αt is then the number of generations which have elapsed during the time interval t. It is thus possible to write equation (1.16) in the approximate form

$$n \approx n_o e^g, \tag{1.21}$$

where g is the number of generations in which the neutron density increases from n_o to n. In other words, the neutron population increases roughly by a factor of e per generation, i.e., by a factor of 10 in every 2.3 generations.

Before a fissioning system can explode, i.e., before the material commences to move outward, a certain energy density must be attained.

The fission chain reaction then gradually dies out, because the increasing rate of neutron escape causes α to decrease and eventually to become negative.

Obviously, to obtain a high efficiency, the expansion of the core must be delayed as much as possible, and this is an important function which must be fulfilled by the tamper.

Spontaneous Fission

The fission processes discussed so far have been those involving the deliberate introduction of neutrons. These reactions can also be brought about by extraneous neutrons, such as those present in cosmic rays or resulting from the action of alpha particles, emitted by uranium or plutonium, on certain impurities. In addition, there is the possibility of completely spontaneous fission of certain nuclei, without the intervention of neutrons. It is important to point out, however, that such spontaneous fissions are, nevertheless, accompanied by neutron emission and the latter are capable of causing further fissions.

The spontaneous fission rates, expressed as the number of nuclei undergoing fission per hour per gram of material, of some isotopes of uranium and plutonium are given in Table 1.4. Since two to three neutrons are liberated per fission, the rate of neutron emission is obtained upon multiplication of the fission rates by the appropriate number. The spontaneous fission rates of uranium-233, uranium-235, uranium-238, and plutonium-239 are fairly small, but those

Table 1.4 Spontaneous Fission Rates

Isotope	Fission/hour/gram
Uranium-233	< 0.7
Uranium-234	<30
Uranium-235	1.3
Uranium-238	24
Plutonium-238	1.1×10^7
Plutonium-239	35
Plutonium-240	1.6×10^6

of plutonium-238 and -240 are considerable. The former of these two isotopes is of no significance in the production of weapons, but some plutonium-240 is almost invariably present in plutonium-239 and its high spontaneous fission rate is of serious consequence in connection with fission weapons.

UNCLASSIFIED

1.5 Production of Weapon Materials

Uranium-235

The two important fissile materials, namely, uranium-235 and plutonium-239, are both produced from natural uranium but by entirely different procedures. Ordinary uranium contains about 0.7 per cent of uranium-235 to 99.3 per cent of uranium-238, and a trace (0.006 per cent) of uranium-234. The uranium-235 is separated by diffusion (through porous barriers) of the vapor of uranium hexafluoride (UF_6), made from natural uranium. The hexafluoride of the lighter isotope diffuses more rapidly than does that of the heavier species, and by the use of several thousand diffusion stages an enrichment of 93.5 per cent, i.e., a material containing an isotopic proportion of 93.5 per cent of uranium-235, can be obtained. The highly enriched uranium hexafluoride is then converted into the tetrafluoride (UF_4) by heating with hydrogen or methane. The uranium tetrafluoride is reduced to metal by means of calcium plus some iodine to act as a "thermal booster." Reaction between iodine and part of the calcium starts at about 400°C; the heat generated raises the temperature sufficiently for rapid reduction of the tetrafluoride by calcium to take place

Plutonium-239

The element plutonium occurs in nature as virtually insignificant traces, at best. Consequently, the plutonium-239 used in weapons is obtained artifically by a series of nuclear reactions resulting from the exposure of uranium-238 to slow neutrons in a nuclear reactor or "pile." A nuclear reactor is a device in which a fission chain reaction is taking place in a controlled manner. If a material of low mass number, called a moderator, is present, in addition to fissile material, the fission neutrons will be slowed down, and such a system is, in a sense, a source of slow neutrons.

In a reactor, uranium-238 captures neutrons to form a higher isotope, uranium-239, with the emission of gamma radiation; thus

$$_{92}U^{238} + {}_{0}n^{1} \longrightarrow {}_{92}U^{239} + \gamma,$$

where the subscripts give the atomic numbers, i.e., number of protons, and the superscripts indicate the mass numbers, i.e., total number of neutrons and protons in each case. The uranium-239 is radioactive, with a half life of 23 min, emitting a beta particle. Representing the latter by $_{-1}\beta^{0}$, since it carries a negative charge and has essentially no mass, the radioactive decay process may be written as

$$_{92}U^{239} \longrightarrow {}_{-1}\beta^{0} + {}_{93}Np^{239},$$

UNCLASSIFIED

SECRET

UNCLASSIFIED

the product being an isotope of a new element, atomic number 93, called neptunium (Np), of mass number 239. Neptunium-239 is also radioactive, half life 2.3 days; it emits a beta particle according to the reaction

$$_{93}Np^{239} \longrightarrow {}_{-1}\beta^{0} + {}_{94}Pu^{239},$$

so that the product, atomic number 94, mass number 239, is plutonium-239. This is an alpha emitter with a fairly long half life--about 24,000 years--and hence it is relatively stable.

It may be mentioned that the decay product of plutonium-239 is the fissile uranium-235, its half life being about 9×10^{8} years. Hence, as far as fission is concerned, plutonium will undergo only relatively minor changes over a period of several hundred years. The same is true, of course, to an even greater extent, for uranium-235.

As the plutonium-239 accumulates in a reactor, it also begins to capture neutrons, the rate of capture being proportional to the neutron density and to the concentration of plutonium-239 nuclei. The process is

$$_{93}Pu^{239} + {}_{0}n^{1} \longrightarrow {}_{94}Pu^{240} + \gamma$$

with plutonium-240, an alpha emitter of half life about 6500 years, as the product. The two isotopes of plutonium cannot be separated from each other in the chemical process used for the extraction of plutonium from the fission products and the unchanged uranium discharged from a production reactor. Hence, plutonium-239 is always associated with a certain proportion of plutonium-240, the amount increasing, up to a limiting value, with the exposure time of the material in the reactor, and also with the neutron density.

The amount of plutonium-240 present in the uranium fuel elements, as they are called, increases, up to a limiting value of about 35 per cent, with the time spent in the reactor and with the reactor power. Consequently, the quality of plutonium, as regards its plutonium-240 content, is frequently described in terms of megawatt-days of exposure in the reactor per ton of uranium fuel, i.e., in MWD/T units. Actually, the unit is not too precise because the reactor power is not uniform throughout its volume, so that the plutonium-240 content corresponding to a given average MWD/T value depends on the location of the fuel element in the reactor. However, because many fuel elements ("slugs") are processed simultaneously, this tends to average out sufficiently well for practical purposes.

UNCLASSIFIED

At the present time essentially all the plutonium in the United States is made at Hanford, Wash., in reactors employing natural uranium, in the metallic form, with graphite as the moderator for slowing down the neutrons. The uranium-235 present maintains the fission chain, while the uranium-238 captures some of the neutrons. This leads, ultimately, to the formation of plutonium-239, as seen above. In the new production plant being built at Savannah River, S.C., natural uranium will be the fuel, as at Hanford, but the moderator will be heavy water, i.e., water highly enriched in the heavier isotope, deuterium.

Code Names

There are a number of code names and symbols frequently employed in connection with nuclear weapons work. Uranium metal enriched in the uranium-235 isotope, originating in Oak Ridge, is often called oralloy, an abbreviation of "Oak Ridge alloy." It is represented by the symbol Oy, followed by a number in parentheses indicating the percentage enrichment; thus Oy(93.5) indicates a material containing 93.5 per cent of uranium-235 and 6.5 per cent of uranium-238 and other isotopes. Until recently, this was the only form of enriched material in general use and it is this composition which is frequently referred to as oralloy or Oy, without qualification. However, some applications of a less enriched product, Oy(37.5), are now being made.

The corresponding code name tuballoy, symbol Tu, is used for uranium metal, in the normal isotopic proportions, i.e., 99.3 per cent uranium-238. It is based on the designation Tube Alloys Limited applied to the British wartime atomic energy project. The metal obtained from the depleted uranium residues of the gaseous diffusion plants, containing more than 99.3 per cent of uranium-238, is sometimes called "Q" metal.

The names mentioned above are generally used for specific materials. A (declassified) code system of another kind is frequently employed to represent particular isotopes. The last numerals of the atomic number and of the mass number are combined to give a two-digit symbol that is characteristic of the particular species. Thus, uranium-235, mass number 92, is referred to as "25"; uranium-238 is "28"; and plutonium-239, atomic number 94, is "49".

*Up to 1000 MWD/T, at least, the percentage of plutonium-240 is roughly proportional to the exposure.

Production of Neutrons

In an atomic weapon, the chain reaction is initiated by the introduction of neutrons into the highly supercritical system. Consequently, the methods for producing neutrons may be briefly reviewed. Two main procedures will be considered here, others will be mentioned in Section 1.6.

One of the simplest methods for obtaining neutrons is by the action of alpha particles of sufficient energy on certain light elements, notably beryllium. The reaction may be represented by

$$_2He^4 + {}_4Be^9 \longrightarrow {}_6C^{12} + {}_0n^1,$$

recalling that the alpha particle is identical with a helium nucleus. For laboratory purposes, radium is a very convenient source of alpha particles, but for several reasons it is not practical for use in nuclear weapons. The alpha-particle source employed is the radioelement polonium-210. This has the advantage of being relatively simple to make and, unlike radium, neither plutonium itself nor its radioactive decay products emit gamma radiation. Polonium-210 is produced by exposure of bismuth to neutrons in a nuclear reactor, when the reaction

$$_{83}Bi^{209} + {}_0n^1 \longrightarrow {}_{83}Bi^{210} + \gamma$$

occurs. The bismuth-210 is a beta-emitter, with a half life of 5 days, and so it soon decays to form polonium-210; thus,

$$_{83}Bi^{210} \longrightarrow {}_{-1}\beta^0 + {}_{84}Po^{210}.$$

The use of polonium-210 has, however, three drawbacks. Its half life is only 138.4 days, so that the neutron source has a short stockpile life and requires frequent replacement. In addition, the polonium constitutes a health hazard and special precautions must be taken in fabrication. Finally, its production requires neutrons which could otherwise be used for making plutonium. There is consequently considerable interest in the development of neutron sources which do not involve polonium.

DOE b(3)

1.6 Thermonuclear Reactions

Limitations of Energy Release

It should be apparent from the earlier discussion that the energy release of a nuclear fission weapon is limited by the mass of fissile material which can be included in it and yet retain a subcritical system. It should be remembered, of course, that the critical mass depends on the geometry of the system. Consequently, if desired, a large mass of fissile material can be made subcritical by fabrication into a form in which it has a large exposed area, e.g., a spherical shell.

DOE b(3)

Fusion Reactions

Nuclear reactions of the fusion type were first attained in the laboratory by using charged particles, e.g., protons (hydrogen nuclei), deuterons (deuterium nuclei), or tritons (tritium nuclei), which were accelerated in a cyclotron, Van de Graaff generator, or similar device. In this manner, the nuclear particles acquire sufficient energy to permit them to react with other light nuclei. Since this energy is merely kinetic energy, it is not different from that which a nucleus would acquire as a result of raising its temperature. Thus, assuming a Maxwell-Boltzmann distribution of energy among the nuclei, it is found that the mean kinetic energy corresponding to a temperature of T^{o} Kelvin is $8.6 \times 10^{-11} T$ Mev. Consequently, it is to be expected, and has been confirmed by experiment, that nuclear reactions can be brought about by the use of high temperatures. Such processes are referred to as thermonuclear reactions.

The thermonuclear reactions which have been achieved so far involve only the heavier isotopes of hydrogen, i.e., deuterium and tritium.* This is because the necessary kinetic energies are lower, and, hence, so also are the requisite temperatures, than for other nuclear processes.

As a first approximation, the minimum interaction energy may be regarded as that required to overcome the electrostatic repulsion forces operating between the interacting nuclei. If Z and Z' are the respective positive charges, i.e., atomic numbers, and r is the distance

*The descriptions given here refer only to thermonuclear processes achieved by man; these and other such reactions take place in various heavenly bodies and constitute their energy sources.

between the nuclei, the coulombic repulsion energy is $ZZ' e^2/r$, where e is the value of the electronic charge. This energy will be least for reactions between hydrogen nuclei, since Z and Z' are then both unity; the repulsion energy which must be overcome is consequently e^2/r.

If electrostatic repulsion were the determining factor, the energy required for the above reactions would be roughly 0.1 Mev; this would correspond to the extremely high temperature of about 10^9 °K. However, for various reasons, which are explicable in terms of quantum mechanics, it has been found that the reactions involving deuterium and tritium will take place at an appreciable rate at energies of the order of 1 to 10 kev, i.e., 10^{-3} to 10^{-2} Mev.

DOE (3)

Three thermonuclear reactions are of particular importance. These are represented below, together with the amount of energy released as calculated from the masses of the nuclei involved:

$$_1D^2 + {}_1D^2 \longrightarrow {}_1H^1 + {}_1T^3 + 4.0 \text{ Mev}$$

$$_1D^2 + {}_1D^2 \longrightarrow {}_0n^1 + {}_2He^3 + 3.3 \text{ Mev}$$

$$_1D^2 + {}_1T^3 \longrightarrow {}_0n^1 + {}_2H^4 + 17.6 \text{ Mev}$$

The D-D and D-T reactions have possible applications in two different directions to be described shortly.

Thermonuclear Energy Release

Since the energy liberated in these reactions is several Mev in each case, whereas they can be initiated, at least, by energies of from 1 to 10 kev, it is apparent that a kind of thermonuclear chain is possible. Thus, if the energy liberated in the reaction between a quantity (or volume) of deuterium nuclei can be used to raise the temperature of other such nuclei, then further D-D reactions will result, and a self-sustaining thermonuclear propagation will be possible. As in the case of the fission chain, this will be accompanied by the continuous release of energy. Whereas in the fission reaction the chain is maintained by neutrons, the thermonuclear propagation is maintained by thermal energy.

*It has become the practice in thermonuclear work to express the temperature in terms of the equivalent kinetic energy. Thus, reactions involving deuterium and tritium are said to take place at "temperatures of 1 to 10 kev."

It may be remarked that in many respects thermonuclear propagation (or burning) is analogous to the process which takes place in an internal combustion engine. The spark initiates the reaction between a quantity of oxygen and gasoline; the energy generated then raises the temperature of adjacent material to such an extent that reaction can occur, and so on.

Thermonuclear Neutron Production

It will be observed that one of the D-D reactions and the D-T reaction, referred to above, yield neutrons as a product. In the latter case, the energy of the neutrons is about 14 Mev, as may be readily calculated on the basis of conservation of momentum between the neutron and the helium nucleus formed in the process. Neutrons produced by these thermonuclear processes have been used to initiate the fission chain or to introduce a burst of neutrons at a later stage in order to maintain and enhance the progress of the fission reaction.

It should be noted that the D-D reaction which leads to the formation of H and T will be followed by interaction between the tritium and any unchanged deuterium nuclei that may still be present. This D-T reaction will, of course, result in the production of additional neutrons.

Thermonuclear Weapons

One of the reasons for the interest in thermonuclear weapons has been indicated earlier. The energy release of a fission weapon is limited by safety considerations which make it necessary to maintain the fissile material, before detonation, in a subcritical state. Deuterium and tritium, on the other hand, can be safely held in large volumes, and the amounts that could be included in a weapon would be determined only by practical considerations. Consequently, the energy yield of a weapon utilizing the deuterium and tritium reactions would be limited only by the quantity of material that could be used. Thus, weapons of extremely high yields are feasible at a considerably lower cost than is possible for equivalent fission weapons.

Tritium is made in nuclear reactors and its production involves the capture of a neutron by a lithium nucleus, as will be explained shortly. The same neutron could be used to produce plutonium, and so each tritium atom formed represents the loss of an atom of plutonium. In a reactor using natural uranium as fuel there will inevitably be some plutonium production, and so, even if it were desirable, the available neutrons could not be used exclusively for tritium production. Consequently, this isotope will be expensive and not too common. There is a possibility that lithium could be used, in place of cadmium, as a central absorber to make the neutron flux (and heat liberation) in a nuclear reactor more uniform. In this event, tritium would be produced by means of neutrons which are otherwise wasted.

A further matter of significance may be mentioned: tritium is radioactive, and its half life is only about 12.5 years. Hence, in addition to being somewhat of a health hazard, it decreases in amount at an appreciable rate. The beta-decay product is helium-3, and this can react with

deuterium to yield a fairly large amount of energy, i.e.,

$$_1D^2 + {}_2He^3 \longrightarrow {}_1H^1 + {}_2He^4 + 17.6 \text{ Mev},$$

but the higher charge of the helium nucleus makes this reaction less probable than the D-T reaction. However, when neutrons are available, e.g., from a D-D or D-T reaction, the tritium may be regenerated by the reaction

$$_2He^3 + {}_on^1 \longrightarrow {}_1T^3 + {}_1H^1.$$

In a nuclear reactor, one neutron can be made to yield one plutonium atom or one tritium atom. But whereas fission of a plutonium atom liberates about 200 Mev, a thermonuclear reaction with tritium rêleases only 18 Mev. It would thus seem, at first sight, that use of tritium in a weapon would be a highly uneconomic procedure. The justification lies, however, in the fact that a relatively small amount of tritium may be made, in various ways, to help initiate a D-D reation in a large quantity of the much less expensive and more readily available deuterium.

Production of Deuterium and Tritium

Deuterium oxide (heavy water) is present to the extent of about 1 part in 6500, i.e., 0.015 per cent, in ordinary water. In spite of this very small proportion, enrichment of water in deuterium is not too difficult, and heavy water of 99 per cent purity is now produced on the industrial scale. Large quantities are required to supply the need for a moderator in the Savannah River, S.C., plant for plutonium and tritium production.

Three main processes have been used to achieve a partial separation of the hydrogen isotopes in water: these are (a) isotopic (chemical) exchange, (b) distillation, and (c) electrolysis. In the isotopic exchange process, hydrogen gas or a gaseous compound of hydrogen is made to react with liquid water. As a result of the somewhat different reactivities of the two isotopes, there is a partial separation between the liquid and gaseous phases. The large-scale production process now operated by AEC contractors, utilizes the reaction between hydrogen sulfide gas and water. The exchange reaction results in a relatively higher proportion of deuterium in the liquid phase than in the gas. By utilizing a countercurrent flow of gas and liquid in several stages, considerable enrichment in deuterium can be achieved in the liquid.

The distillation method for separating the isotopes of hydrogen depends on the fact that heavy water has a slighly higher boiling point, i.e., lower vapor pressure, than light water. Consequently, a partial separation can be achieved by fractional distillation, preferably under reduced pressure.

UNCLASSIFIED

SECRET

When a slightly acid or alkaline solution in water is electrolyzed, the hydrogen gas liberated at the cathode contains relatively more of the lighter isotope than does the water. By repeated electrolysis in stages, heavy water of a high degree of enrichment can be obtained.

Each of the three foregoing procedures has certain advantages under suitable conditions. Hence, for the production of heavy water in quantity, ordinary water is first partially enriched by the isotopic exchange process. The deuterium is further concentrated by fractional distillation under vacuum, and then it is finally brought up to about 99 per cent enrichment by electrolysis. Deuterium itself can be released from heavy water by any of the familiar chemical methods used to prepare hydrogen gas. It can then be converted into any compound that may be required, or it may be liquefied by cooling under pressure, in the usual manner, to obtain liquid deuterium.

Tritium is produced by exposure of lithium to slow neutrons in a nuclear reactor; the less abundant lithium-6 isotope then undergoes the reaction

$$ {}_3Li^6 + {}_0n^1 \longrightarrow {}_2He^4 + {}_1T^3 $$

with the formation of tritium. This isotope can be converted into compounds or liquefied, just like other forms of hydrogen. It is expected that larger quantities of tritium will become available when the reactors at the Savannah River plant commence operation.

SECRET

Chapter 2

Efficiency of Fission Weapons

2.1 Determination of Efficiency

Definition of Efficiency

The efficiency (ϕ) of any weapon may be defined as the ratio of the energy actually developed when it explodes, i.e., the energy yield, to the total energy available, i.e.,

$$\phi = \frac{\text{energy yield}}{\text{energy available}} \tag{2.1}$$

In other words, it is the fraction of the energy available which is actually released in the explosion. In the case of a fission weapon this is equal to the ratio of the number of nuclei which actually undergo fission to the total number of fissile nuclei present.

In designing a fission weapon it is essential to be able to estimate its yield from theoretical considerations. But the calculation of the efficiency is very complicated, involving a detailed hydrodynamic treatment of the core material and tamper during the main period of energy release, i.e., in the interval between about the 50th and 55th generations after initiation of the fission chain. With the availability of high-speed electronic computers, such as the IBM 701 and the MANIAC, progress is now being made in the rapid calculation of the efficiency of any proposed fission weapon. However, the procedures are tedious and not necessarily complete, so that other, partially empirical, methods for determining efficiencies are still in general use.

Detailed Calculation Procedure

The following description is intended as a brief outline of the detailed method for calculating weapon yields (or efficiencies); its purpose is merely to give a general indication of the procedure used. The bomb assembly is divided, somewhat arbitrarily, into a finite number of concentric shells, and the time behavior of each shell, or "mass point," is determined by numerical calculations using equations describing the processes of neutron production, material acceleration, and heat flow. The initial time for purposes of these calculations, at which significant physical effects may be assumed to begin, is taken as that after the 50th generation. Up to this time the mass points are essentially stationary, and very little energy has been liberated. The subsequent changes with time, as the system expands, are treated by calculating the neutron density, position, and physical properties of the mass points at time $t + \Delta t$ in terms of those existing at time t. For convenience, different time intervals Δt may be taken for different purposes.

Starting with the initial radii, masses, and nature of the fissile material for the several mass points, the values of α and of the neutron distribution at the zero time can be determined

by some form of neutron transport theory. Then, making use of this alpha and the familiar equation (1.16), for the time rate of increase of neutron population, the neutron distribution after the interval Δt can be evaluated.

The next step is to determine the acceleration of the mass points by hydrodynamic calculations; this gives the velocity at Δt, from which the new radii of the mass points can be obtained. Finally, the temperature distribution is calculated from the heat flow equation, taking into account the energy produced by fission, the work done by the mass points in their outward motion, and the transfer of energy by radiation.

These calculations complete one cycle, since the new neutron densities, radii, and temperatures of the mass points are now known. From the temperatures, the new physical properties are determined. The whole procedure, starting with alpha and the neutron distribution, is repeated over and over until the bomb has completely exploded and the rate of energy release by fission has fallen almost to zero. Upon summing the number of fissions which have taken place, the total energy yield can be obtained. This includes the energy released by fission after the system has expanded and become subcritical. Although chain propagation is no longer possible, interaction of the many neutrons and fissile nuclei still present will result in a considerable energy production; this may amount to some 30 per cent of the total yield.

The Bethe-Feynman Formula

The formula for the efficiency of a nuclear explosion derived by Bethe and Feynman is admittedly approximate since it involves a number of simplifying assumptions. It is based largely on the following arguments. As a result of the energy liberated in fission, very large pressures are developed in the core, and the core-tamper interface consequently receives a large outward acceleration. This causes highly compressed tamper material to pile up just ahead of the expanding interface, in an effect referred to as the "snowplow" phenomenon, because of its similarity to the piling up of snow in front of a snowplow. The inertia of the compressed tamper will delay expansion of the core, so that a considerable pressure gradient will build up from the center of the core to its outer surface.

Further, as a result of the delayed expansion, it may be supposed that the volume of compressed core remains essentially constant during the first 50 or so generations following initiation of the fission chain. After this interval, almost the whole of the bomb energy is released within an extremely short period, during which time the core expands rapidly until it becomes subcritical. Although there is an appreciable energy release in this state, as seen above, the liberation of energy may be regarded as over when the dimensions are just critical. It will be assumed, in the subsequent treatment, that during the very short period while the energy is being released, none escapes from the system. It may be remarked that most of the

UNCLASSIFIED SECRET

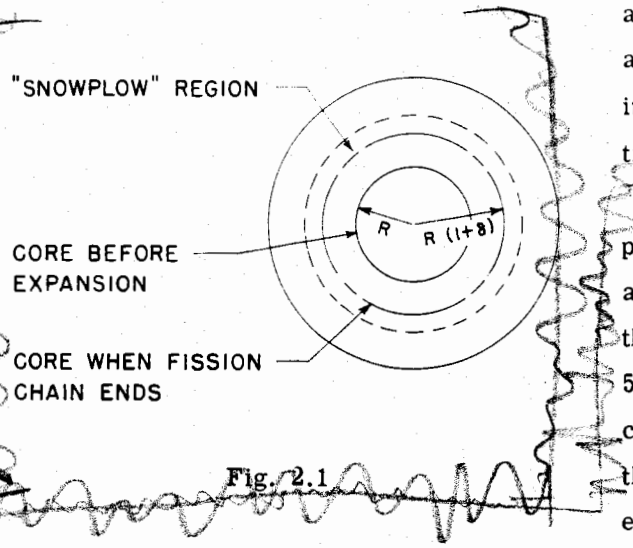

Fig. 2.1

approximations and assumptions involved are applicable when the efficiency is small, and it is for this condition that the Bethe-Feynman treatment is justifiable.

Let R be the radius of the core at the point of maximum supercriticality; then, in accordance with the postulate made above, this will remain unchanged until about the 50th generation after initiation of the fission chain. Subsequently, the energy content of the system becomes so large that mechanical effects begin and the core starts to expand. Suppose that when the core has expanded by a fraction δ, so that the radius is $R(1 + \delta)$, the system is just critical (Fig. 2.1). Beyond this point the core material will be subcritical; the fission chain will end and there will be, according to an earlier assumption, essentially no further release of energy.

Consider a thin shell of material in the core, of volume dV and thickness dr; the cross-sectional area of the shell is then dV/dr. If dP is the pressure difference on the two sides of this shell, caused by the fission energy liberated, the net outward force, F, to which the shell is subjected, i.e., pressure x area, is then

$$F = dP \frac{dV}{dr} = \frac{dP}{dr} dV \ , \qquad (2.2)$$

where dP/dr is the pressure gradient in the given shell. As a reasonable approximation, it may be supposed that the pressure gradient is constant throughout the core, so that it is possible to write

$$\frac{dP}{dr} \approx \frac{P}{R} \ , \qquad (2.3)$$

where P is the total difference in pressure from the center of the core to the outer surface. Hence, from equations (2.2) and (2.3),

$$F \approx \frac{P}{R} dV \ . \qquad (2.4)$$

The time required for the core to expand from radius R to $R(1 -$ [illegible] distance of $R\delta$, is about five generations. However, as a rough approximation this [illegible] taken as $1/\alpha$, where α is the multiplication rate when fission is initiated, as described in 1.4.

UNCLASSIFIED SECRET

Hence, the mean outward acceleration of the core material, and of the shell dV, may be expressed as $R\delta\alpha^2$. The mass of the shell is $\rho_c dV$, where ρ_c is the core density, and, hence, by Newton's second law of motion, i.e., force = mass x acceleration, the force acting on the shell is given by

$$F \approx R\delta\alpha^2 \times \rho_c dV \ .$$

Upon comparing this result with equation (2.4), it is seen that

$$P \approx \rho_c R^2 \alpha^2 \delta \ . \tag{2.5}$$

At the existing temperatures the core material will be in the gaseous state, and if, as postulated, the loss of energy from the system during the initial expansion is negligible, it may be considered as a gas undergoing an adiabatic process. The total energy of such a gas, which may be regarded as equal to the energy of the core, is then

$$E = \frac{PV}{\gamma - 1} \ , \tag{2.6}$$

where γ is the ratio of the specific heats of the gas. Using equation (2.5) for P and writing M/ρ_c for the volume of the core, M being the mass, equation (2.6) becomes

$$E \approx \frac{MR^2\alpha^2\delta}{\gamma - 1} \ . \tag{2.7}$$

If ϵ is the energy released in the complete fission of unit mass of core material, i.e., about 0.017 kt per gram for uranium-235 and 0.019 kt per gram for plutonium-239, then the total energy available in the core is $M\epsilon$, and the efficiency, by equation (2.1), should be $E/M\epsilon$, where E is given by equation (2.7). However, this is not strictly correct, for in the derivation of this equation no allowance has been made for the depletion of the core material as fission proceeds. For low efficiencies this is, of course, not important, but a distinction will, nevertheless, be made by writing ϕ' for the value obtained using equation (2.7), so that

$$\phi' = \frac{E}{M\epsilon} \approx \frac{R^2\alpha^2\delta}{(\gamma - 1)\epsilon} \ , \tag{2.8}$$

where ϕ' may be related to the true efficiency, ϕ, by a relationship such as

$$\phi = \frac{\phi'}{1 + 1.2\,\phi'} \ , \tag{2.9}$$

sometimes referred to as the depletion correction.

If the tamper density, ρ_t, is not very different from that of the core, then, within a

moderate range of efficiencies, approximate allowance for the effect of the tamper may be made by a factor proportional to $(\rho_t/\rho_c)^n$, where n is less than unity. The limited applicability of the correction may be seen from the fact that it fails completely when there is no tamper, i.e., when ρ_t is zero. However, upon introducing this correction factor, with n = 0.5, into equation (2.8), the result is

$$\phi' \propto \frac{1}{(\gamma - 1)\epsilon} \quad R^2\alpha^2\delta \sqrt{\frac{\rho_t}{\rho_c}} \ . \tag{2.10}$$

The first factor on the right side is a constant, k, so that equation (2.10) reduces to

$$\phi' \approx kR^2\alpha^2\delta \sqrt{\frac{\rho_t}{\rho_c}} \ , \tag{2.11}$$

which is one form of the Bethe-Feynman formula. [redacted] Since the total mass of fissile material is known, the actual energy release can also be evaluated.

DOE b(3)

By comparison with experimental determinations, to be described in Chapter 6, it has been found that while the Bethe-Feynman formula is a useful qualitative guide, it is not always quantitatively correct. For example, the so-called constant, k, varies with the yield and with the composition of the core material, e.g., either plutonium alone, oralloy alone, or combinations of both in various proportions. Hence, normalization procedures must be adopted when using equation (2.11). As an increasing amount of information has become available, it has been found possible to adjust the value of k, and also to make other semi-empirical corrections. Carefully applied, the Bethe-Feynman approximation has been used successfully to design bombs having a wide range of energies. For complex assemblies or where fine distinctions are sought, however, more exact methods of calculating efficiencies are used, e.g., the detailed procedure described earlier or the crits method given below.

Effect of Size and Compression on Efficiency

From an examination of equation (2.11) a number of general conclusions can be drawn concerning the factors affecting the efficiency of a nuclear explosion. In the first place, since the efficiency increases as R^2, it would be advantageous for the core to be large at the time of initiation of the fission chain. This can be achieved in practice by bringing together subcritical masses which are designed to contain a large total amount of fissile material. Thus, for a given compression (or for no compression), the efficiency would be expected to be

greater the larger the mass of the core material. This expectation has been confirmed in numerous tests.

Although compression will result in a decrease in R, this will be more than compensated for by the considerable increase in α^2, for the reasons given in Section 1.4. In addition, the effect of compression on δ must be taken into account; the more highly compressed the core material at the time of initiation, the further will be the distance the surface will travel before the supercritical system becomes just critical. Thus, increased compression should result in a marked increase of efficiency; that this is the case is shown very simply by comparing the yield from a gun-type weapon, in which there is no compression, with that of an implosion weapon.

The effect of increasing the compression in an implosion weapon is indicated by the data in Table 2.1 which are based partly on experiment and partly on calculation.

Table 2.1 Effect of Compression on Efficiency

Average Compression		Efficiency
Core	Tamper	(per cent)

Calculation of Efficiency by the Crits Method

Consider a system containing a mass M of fissile material under a compression C_c; let M_c be the critical mass of the material under these conditions with a specified tamper. Then the number of crits or critical masses, N, present is given by

$$N = \frac{M}{M_c} \qquad (2.12)$$

According to equation (1.8), however, M_c is proportional to $1/C_c^2$, and so if M_{co} is the critical mass of the uncompressed material, i.e., when $C_c = 1$, with the same tamper, in the assembled

SECRET

UNCLASSIFIED

form, it follows from equation (2.12) that

$$N = \frac{MC_c^2}{M_{co}} \qquad (2.13)$$

From the general discussion of the Bethe-Feynman formula it was seen that increasing either the mass of fissile material or of the core compression results in an increase of efficiency. It is evident, therefore, from equation (2.13) that the efficiency of a weapon will increase with the number of crits present at the explosion time. This qualitative result is of considerable interest, but a more quantitative development is possible, e.g., by expressing α and δ as empirical functions of the number of crits.

The method used to calculate efficiencies by the crits method is to consider a specific core material, e.g., either oralloy or plutonium, and a given tamper. The efficiencies for various masses of core and a certain compression, which may be unity, are then calculated in any convenient manner, e.g., by the Bethe-Feynman formula. From the results, a curve expressing the variation of efficiency with the number of crits can be drawn. According to the arguments presented above, this curve should apply to all core-tamper systems of the same type, i.e., with the same core material (plutonium or oralloy) and the same ratio of the compressions (or densities) of core and tamper.

Since, for any core of mass M and compression C_c, the number of crits is given by equation (2.13), the efficiency of the corresponding fission weapon can be obtained directly from the curve. A different curve is used, of course, for each core material. Variations in the ratio of core-tamper compressions and in the neutronic thickness of the tamper are taken into account in estimating the critical mass. For composite cores, containing both plutonium and oralloy, semi-empirical adjustments are required to make the crits method applicable to such systems.

The crits method has been found to provide a rapid and reliable procedure for calculating efficiencies. Its main advantage over the Bethe-Feynman formula lies in the fact that the difficult and uncertain neutron theory calculations of α and δ for each case are avoided. The basic curve showing the variation of the efficiency with the number of crits is determined by applying the Bethe-Feynman formula to a simple system for which this formula is known to be reliable.

UNCLASSIFIED

SECRET

2.2 Factors Affecting Efficiency

Effect of Impurities on Efficiency

It was seen in Section 1.2 that the presence of impurities in the fissile material results in an increase in the critical mass. Hence, the number of crits present in a given mass of fissile material will decrease as the proportion of impurity increases. As seen above, a decrease in the number of crits means a decrease of efficiency. Consequently, the efficiency of a weapon will suffer appreciably if nonfissionable impurities are present. For this and other reasons, as will shortly be evident, it is desirable that the fissionable material be as pure as possible. Some indication of the effects on the energy yield of plutonium-240 as an impurity will be given below (Table 2.4).

Effect of Predetonation on Efficiency

The time at which the fission chain is initiated is of paramount importance in determining the yield of a given weapon.

DOE b(3)

There is a certain probability that the fission chain will be initiated during this period by a background neutron, but the chance that this will occur at optimum compression is very small. Consequently, it is essential that a neutron source, such as described in Section 1.5, be included to initiate the chain reaction at the proper time.

DOE b(3)

The effect of predetonation* can be illustrated by reference to Fig. 2.2, in which the ordinates are either the number, N, of critical masses, i.e, crits, or α, the multiplication

*The term "predetonation" as used at LASL refers to initiation before maximum supercriticality. Preinitiation, used by some workers, would be a more appropriate term, but there appears to be little prospect of its general adoption.

UNCLASSIFIED

SECRET

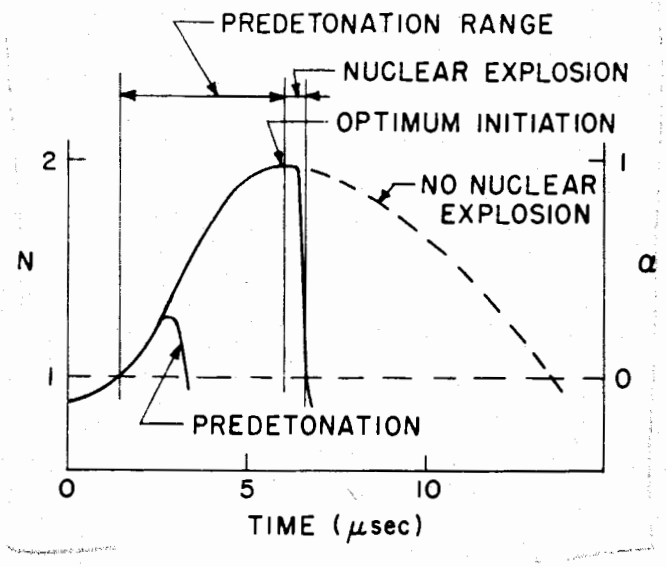

Fig. 2.2

rate, and the abscissae are elapsed time from the beginning of the assembly of a gun-type weapon or compression of an implosion weapon. The numerical values given for N and α are not exact and are intended merely as an indication of the changes which occur. The times, on the other hand, are fairly representative of an implosion weapon. The horizontal dotted line represents the situation for a system that is just critical, i.e., $N = 1$, $\alpha = 0$. Actually, the curves for N and for α as functions of time are somewhat different, and the maxima do not necessarily coincide. However, for the present qualitative discussion, a single curve is adequate.

At zero time the fissile material is subcritical, i.e., $N < 1$, and α is negative, but as compression (or assembly) occurs the value of N increases and α becomes positive, i.e., the system becomes supercritical. If, for some reason, there were no nuclear explosion, the fissile material would suffer decompression, due to its elasticity, after reaching the compression maximum, as indicated by the broken line in Fig. 2.2. In the case of a gun weapon, the parts may fly apart due to the impact.

The optimum yield will obviously be obtained if initiation occurs at the maximum of the curve, i.e., when N has its maximum value. It is at this instant, a few microseconds after compression starts, that the chain should be initiated by the special neutron source. In this event, the whole nuclear explosion will be over in 0.25 to 0.75 μsec, as stated in Section 1.4.

If a neutron entered the core in the period between that at which $N = 1$, $\alpha = 0$ and the maximum of the curve, i.e., while the system is supercritical but before maximum supercriticality is attained, an explosion would occur, but since N would not be as large as is possible, the efficiency will be low. Thus, in order to attain the highest efficiency, predetonation must be avoided. The same will also be true, of course, for postdetonation, i.e., initiation after the maximum of compression has been passed.

The variation of yield with time of initiation may be calculated by any of the methods given above for the determination of efficiency. All that is necessary is to introduce the values of N, α, ρ, etc., which are appropriate to the explosion time in each case. The values

UNCLASSIFIED

SECRET

of ϕ will, of course, pass through a maximum, corresponding to the instant of maximum supercriticality.

Oralloy: Neutron Background and Predetonation Probability

In view of the loss of efficiency that would result from predetonation, it is necessary to consider the question of background neutrons, due to spontaneous fission and to the action of alpha particles on light nuclei. Nuclear reactions of the latter type are referred to as (α,n) reactions.

Because of the relatively low rates of spontaneous fission of both uranium-235 and -238, the number of neutrons due to this cause in oralloy is very small. Further, as a result of the very long half lives of both these isotopes, the rate of alpha particle emission is very low. The third naturally occurring isotope, uranium-234, has a half life of 2.35×10^4 years, and so emits alpha particles at an appreciable rate. This isotope is present to the extent of about 1.1 per cent in oralloy. However, the rate of neutron liberation in oralloy as a result of (α,n) reactions with light elements is not very large.

The total background neutron production in oralloy does not exceed about 2 neutrons/sec per kg.

If P_1 is the probability that a background neutron will be available in the fissile material during the period that the core is supercritical, and P_2 is the probability that this neutron will be able to start a fission chain, then the probability, P, of predetonation is given by

$$P = 1 - e^{-P_1 P_2} \approx P_1 P_2 \quad , \tag{2.14}$$

the approximate form being applicable when $P_1 P_2$ is small.

It should be pointed out that P_2 is a function of time and that both P_1 and P_2 depend, to some extent, on the position of the neutron and other variables. For the present purpose, which is to draw general conclusions only, specific values will be assigned to both P_1 and P_2. A neutron may either escape from the system altogether, or be captured in a nonfission reaction, or produce fission. Although the probabilities of these three processes are by no means equal, it will be postulated here that P_2 has an average value of 0.3 over the predetonation period, in all cases.

DOE b(3)

DOE b(3)

DOE b(3)

[redacted]

Tamper and Initiator Background

DOE b(3)

[redacted]

Plutonium: Neutron Background

With plutonium the situation as regards background neutrons is very different from that with oralloy. Not only is the spontaneous fission rate of plutonium-240 (an inevitable impurity)

high, but, in addition, the moderately short half life of plutonium-239 means a considerable rate of alpha-particle emission which can lead to neutron production by (α, n) reactions.

DOE b(3)

The elements which have appreciable cross sections for (α, n) reactions are those with mass numbers of about 30 or less.

DOE b(3)

DOE b(3)

It should be noted that the amounts refer to each individual element if it alone is present. If there are several present, as will usually be the case, then if c_i is the concentration of the element i in parts per million, the sum of the c_i/q_i values for all the elements must not exceed unity, where q_i for each element is that given in Table 2.2.

Predetonation Probability with Plutonium

DOE b(3)

It is of interest to mention here that when the nuclear fission bomb was first planned, it was designed as a gun-type weapon, since it was felt that this would provide a simple and reliable method for rapidly attaining supercriticality. However, when plutonium became available in quantity, and the high background rate of neutron production due to spontaneous fission of plutonium-240 was discovered, a complete change of outlook was necessary. It was then that consideration was given to the much more difficult problem of converting a subcritical mass of fissile material to the supercritical system by compression in an extremely short interval of time by means of an implosion.

The chief difficulty anticipated in the design of an implosion weapon was the production of a shock wave having reasonably good spherical symmetry, so as to provide uniform and, hence, virtually instantaneous compression of a subcritical sphere of fissile material. When this problem was solved, by the methods to be described later, the smaller predetonation probabilities and the higher efficiencies attainable resulted in a concentration of attention upon weapons of the implosion type.

The smaller the permissible proportion of plutonium-240 in the fissile material, the shorter will be the exposure time, expressed in MWD/T, of the fuel elements in the production reactors (see Section 1.5). Consequently, material of low plutonium-240 content, i.e., with a low neutron background, will be both scarce and costly. It is desirable, therefore, in the design of implosion weapons to determine if plutonium of higher MWD/T value can be utilized.

UNCLASSIFIED

Effect of Background Neutrons and Material Dilution on Yield

The estimates of predetonation probabilities due to the presence of plutonium-240 have been intended only to give an indication of their orders of magnitude.

in Chapter 4.

In addition to the yield loss from predetonation, i.e., the predetonation probability, which is statistical in nature and can be determined only as an average loss for a large number of bombs, there is another loss which occurs for each individual bomb. This is usually referred to as material dilution, and is due to the dilution of the plutonium by the less reactive 240-isotope.

The values are relative to the efficiency for plutonium containing none of the 240-isotope.

Chapter 3

General Design of Fission Weapons

3.1 Implosion Weapons

Components of Implosion Weapons

In brief, an implosion weapon is designed to provide the greatest possible symmetrical compression of the fissile (core) material and, at the proper time, i.e., as close as possible to maximum compression, to introduce neutrons which will initiate a fission chain reaction. The necessity for symmetry in the compression arises from the fact, considered at the end of the preceding chapter, that any appreciable asymmetries lead to a decrease of efficiency and, hence, in yield of the explosion.

The general principle whereby the foregoing requirements are achieved can be explained by means of Fig. 3.1; this is a scale drawing of a section through the original form of the implosion bomb which was detonated at the Trinity test and at Nagasaki in 1945, and in the Bikini tests of 1946.

DOE (6)

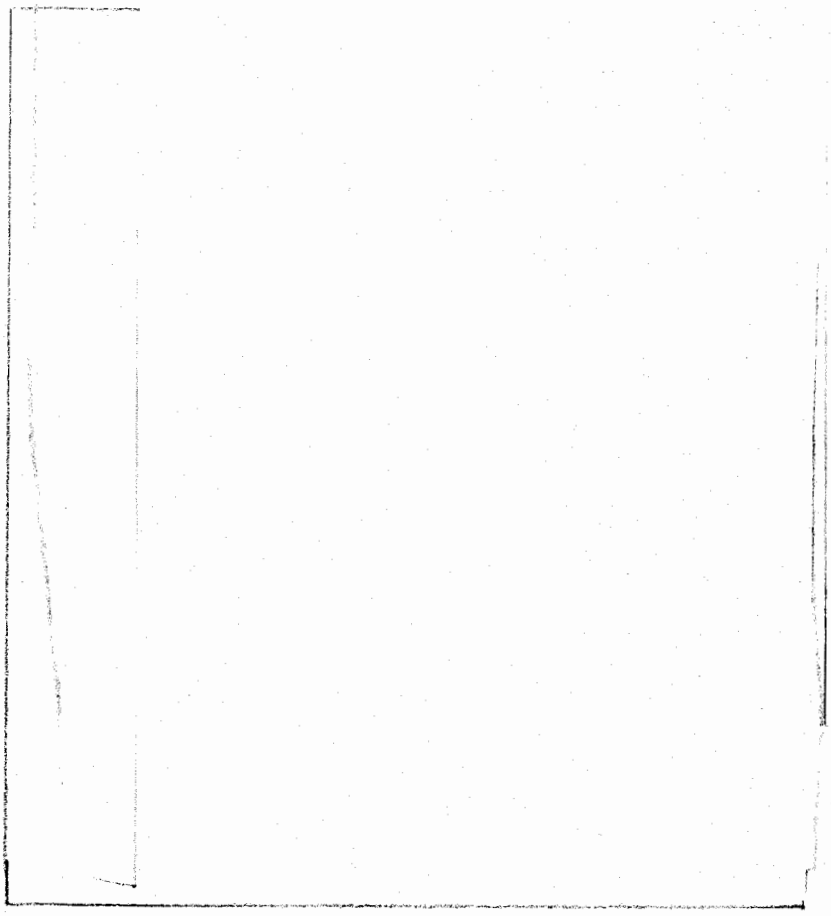

Fig. 3.1

The purpose of the lenses, as will be explained shortly, is to convert the usual divergent detonation (or explosion) wave arising from an explosive charge into an inward-traveling, spherical,

SECRET

UNCLASSIFIED

convergent (or implosion) wave. In order to insure maximum symmetry of the implosion wave the spread of firing times over the surface of the sphere must be very small.

This is largely because it appears that when only a limited space is available, it is better utilized in other ways, as will be explained later.

The implosion shock wave travels through the tamper and then strikes the core of the fissile material. As a result of the steadily decreasing volume into which the shock moves, there is a greatly increased concentration of shock energy, and a corresponding increase in compression, as the wave travels toward the center. The highest compression is thus attained in the core where it is needed. As the core is compressed in this manner the previously subcritical mass becomes supercritical and a divergent fission chain can be maintained. When the shock wave arrives at the center of the core, it brings about activation of the neutron source or initiator. Consequently, neutrons are introduced into the core and the fission chain is initiated at a time close to the instant of maximum compression. As already seen, maximum compression is a reasonable criterion for optimum energy yield.

DOE b(3)

UNCLASSIFIED

The large uncertainties indicated are due to differences in the results obtained by the two standard methods for determining bomb yields (see Chapter 6).

DOE b(3)

DOE b(3)

It is of interest to give some idea of the time scale in a fission bomb explosion. The elapsed time between firing the detonators and the initiation of the fission chain by the central neutron source is called the transit time.

Fig. 3.2

Principle of the Lens System

The fundamental laws underlying the propagation of detonation waves are analogous to those

DOE b(3)

UNCLASSIFIED

applicable to acoustical and optical waves. In fact, the laws of geometrical optics can be used to describe the behavior of detonation waves. Just as light waves are refracted when they travel from one medium to another in which the speed of light is different, so a detonation wave can be made to undergo refraction by using two explosives with different detonation velocities. The ratio of these velocities, as with light, is called the index of refraction of the system.

A properly designed combination of an inner portion consisting of a slow explosive, i.e., one having a moderately slow speed of detonation, and an outer portion of a faster explosive is able to produce a convergent (or implosion) wave (see Section 4.3).

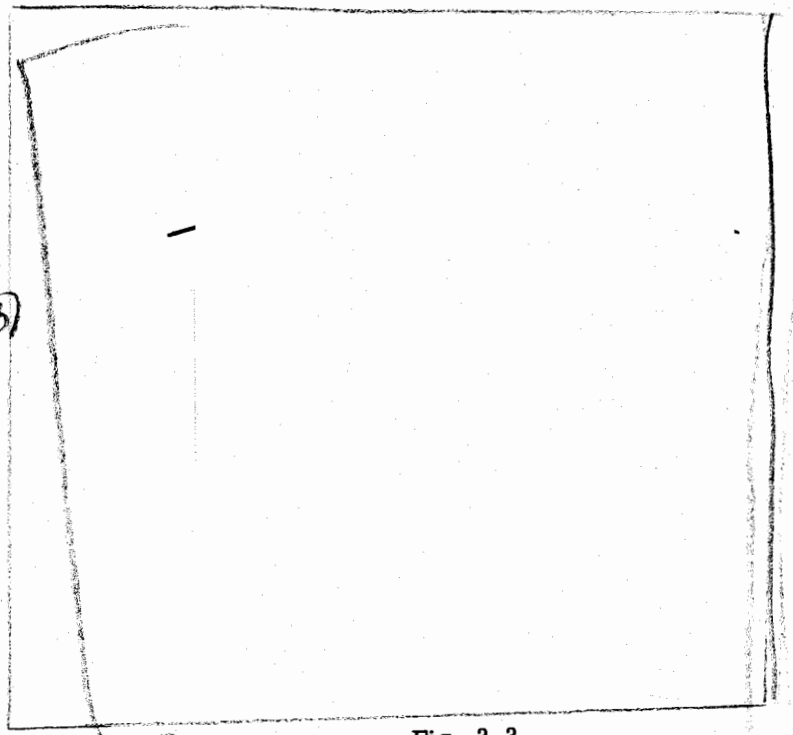

Fig. 3.3

The fast component surrounds the slow one, and its lower surface is concentric with the desired implosion wave. The combined system can act as a lens to produce spherical convergence of a detonation wave to a desired focus.

If a detonation is started at the apex of the slow component, the detonation wave will travel faster over its surface, where it is in contact with the fast component, than in its interior. As a result there will be a lag in the front of the detonation wave within the slow component, as indicated by the dotted lines in Fig. 3.3; this shows a number of successive positions of the detonation wave as it moves toward the center of the bomb. If the lens is properly designed, this wave will be concentric with the bomb and hence with the sphere of fissile material located at its center. If the convergent detonation waves from the various lenses reach the inner surface of the lens system simultaneously, they will join together to form a complete spherical implosion wave. This will then travel without appreciable change in form, but with increasing energy, through the uniform HE inner charge.

3.2 General Design Modifications

UNCLASSIFIED

b(3)

b(3)

When the shock wave produced by the detonation of the HE inner charge enters the tamper, the latter moves forward, with the attached pusher, through the air space with increasing velocity. As a result, when the tamper reaches the core, it strikes the latter a tremendous, hammer-like blow. More energy is thereby transferred to the core, which is consequently more highly compressed than would be the case in the absence of a free run.

Fig. 3.4

b(3)

Composite Cores

b(3)

UNCLASSIFIED

b(3)

SECRET

b(3)

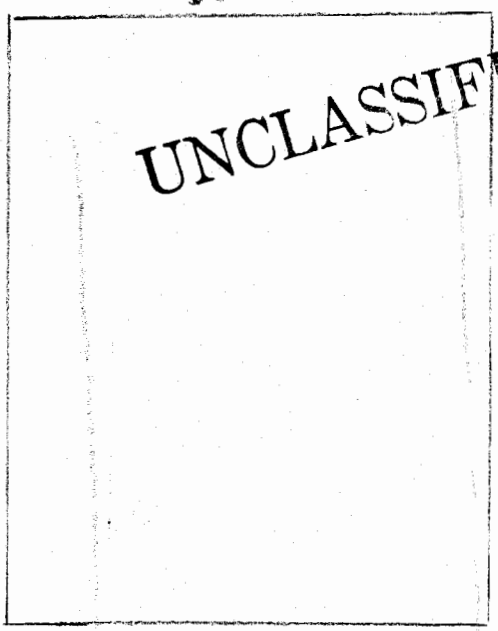

Fig. 3.5

This results from the fact that plutonium produces, on the average, about 2.9 prompt neutrons per fission, whereas uranium-235 yields about 2.5 neutrons. Because its chances of escape are less, a neutron originating in the center of the fissile core has a greater probability of causing fission than one produced in the outer portions. The over-all fission rate and energy yield are thus markedly dependent on the fission rate near the center of the core. Since plutonium produces more neutrons pe fission than does oralloy, it will have a higher α value, i. ., a high multiplication rate. Consequently, in a spherical co e consisting of a plutonium center and an oralloy outer region, the neutron density in the latter will be appreciably greater than if the core consisted entirely of oralloy.

3.3 Design of Implosion Bombs

b(3)

The HE System

The design of an implosion bomb involves a combination of theoretical hydrodynamic calculations, performed with the aid of computing machines, empirical relationships, based on previous experience, and experimental tests of various components and assemblies. It is not necessary to treat the problem in detail here, and a general outline of the approach used will be sufficient.

b(3)

b(3)

UNCLASSIFIED

Fig. 3.9

b(3)

In actual practice, some variation is possible, as will be seen in Chapter 4.

Pusher and Tamper

The next component to consider is the pusher. As stated earlier, this serves to smooth out asymmetries in the implosion wave, and it may provide some additional tamping by scattering neutrons back into the core.

In the HE systems now in general use, the irregularities in the implosion front are relatively small.

UNCLASSIFIED

b(3)

General Considerations

As indicated at the outset, the first step in the design of a new weapon, using accepted principles, is to make machine and other calculations based upon hydrodynamic theory and empirical data obtained in various tests and experiments. If the general results of these calculations appear promising, then the individual components are designed and tested individually and finally in various assemblies. The details of design and testing will be discussed in subsequent chapters.

It has been assumed, so far, that established and proven concepts are used in weapon design. From time to time, however, new ideas are proposed or old ones are revived.

b(3)

They are, of course, subjected to both theoretical and experimental tests before

b(3)

UNCLASSIFIED

a decision is made concerning their value and possible incorporation in new weapons. Some of these new principles will be examined below.

UNCLASSIFIED

3.4 Gun-Type Weapons

Components of Gun-Type Weapons

The design of gun-type weapons is a much simpler problem than is the case for implosion weapons. The principle of the gun-type design may be understood from Fig. 3.10.

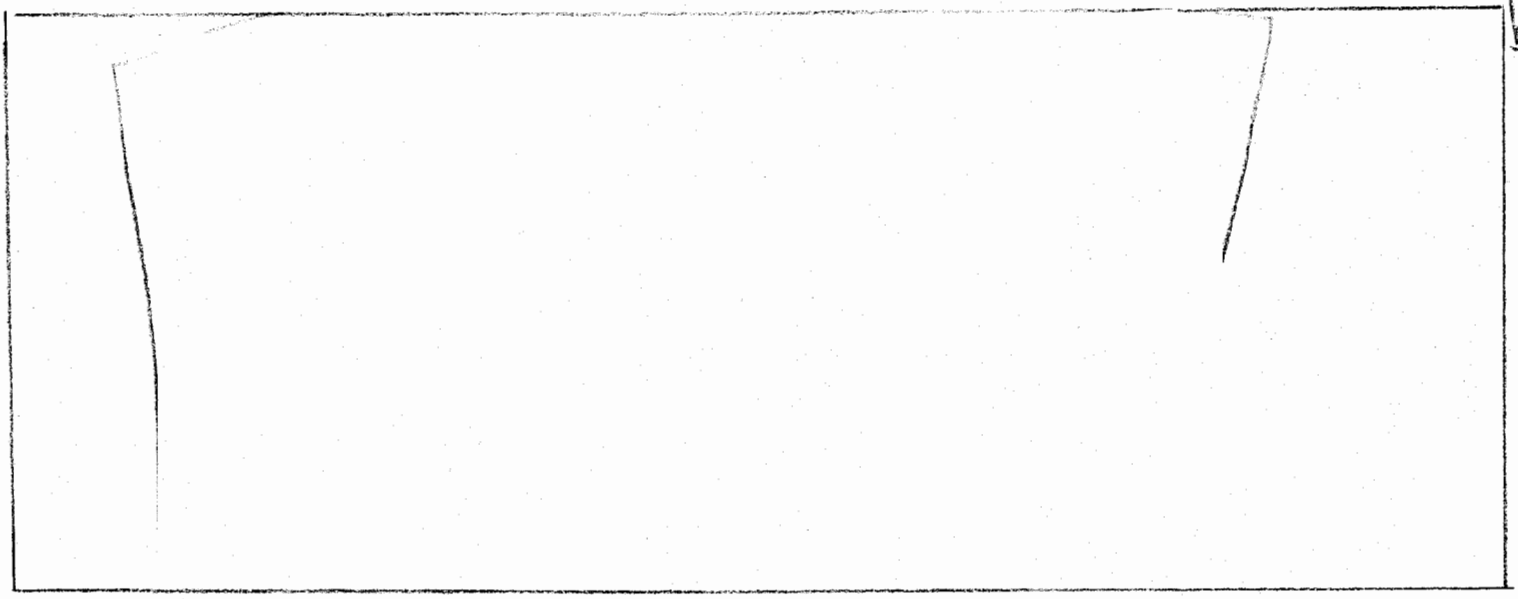

Fig. 3.10

In order to explode the weapon, the detonator, at the left end of Fig. 3.10, is fired and this causes ignition of the propellant. When it is completely seated, the impact activates the polonium-beryllium initiator and neutrons are injected very close to the instant of maximum supercriticality. The fission chain is initiated and the weapon explodes.

UNCLASSIFIED

b(3)

The tamper in the gun-type weapon serves two functions which are the same as in implosion weapons, i.e., neutronic and inertial tamping.

b(3)

The efficiency of a gun-type weapon is considerably less than that of an implosion weapon employing the same amount of fissile material. The absence of compression in the gun-type weapon is the primary reason for this difference.

b(3)

While the fundamental design principles of the gun-type weapon have remained essentially unchanged, a number of improvements have been introduced and proposed. These will be referred to in Chapter 5, where the constructional details of various forms of this weapon are described.

Design of Gun-Type Weapons

Because of their lower efficiency and, apparently, limited range of energy yield, as compared with implosion bombs, the design of gun-type weapons has not received great attention.

b(3)

SECRET

UNCLASSIFIED

This fissile material produces more neutrons per fission than does uranium-235 (see Table 1.1) and loses less in non-fission captures, and so it would give a higher efficiency.

Other factors, such as the nature of the tamper, which affect the efficiency of the chain reaction and the range of an artillery shell, are also being investigated. As a result, there has been a revival of interest in gun-type weapons for various special purposes.

3.5 Uranium-233 in Fission Weapons

Properties of Uranium-233

Although uranium-233 is as yet obtainable only in relatively small quantities, its nuclear properties are of interest in connection with fission weapon design. It is produced in reactors, by neutron capture in thorium, followed by two moderately rapid stages of beta decay. The uranium-233 is then separated from the thorium by chemical methods. Thus, the production of uranium-233 is somewhat similar to that of plutonium, and it may be inferred that its cost would be approximately the same. However, the problem of spontaneous fission in plutonium, due to the presence of the 240-isotope, is virtually negligible in uranium-233 (see Table 1.2).

Experiments with uranium-233 have shown that its critical mass in spherical form, either bare or with an infinite tuballoy tamper, is approximately the same as for plutonium (see Table 1.1). The higher density of uranium, however, makes the critical volume somewhat less. Although the number of neutrons produced per fission in uranium-233 is not much greater than in the 235-isotope (oralloy), the ratio of the fission cross sections is about 1.6 in favor of the former. Further, the neutron loss due to nonfission capture is less in uranium-233. As a result, this material has interesting possibilities for use in fission weapons.

The neutron background in uranium-233 is due almost entirely to (α, n) reactions with light element impurities; the spontaneous fission rate, including that of other uranium isotopes present, is very small. Since uranium-233 has a much shorter half life (1.62×10^5 years) than uranium-235, the rate of alpha-particle emission is greater. Hence, for the same light element

SECRET

UNCLASSIFIED

impurities as in oralloy, the background is estimated to be 35 to 50 neutrons/sec per kg, as compared with a total of 2 neutrons/sec per kg for oralloy. Nevertheless, the former value is very much less than for 200 MWD/T plutonium, which has a background of 16,000 neutrons/sec per kg.

Chapter 4

Components Design and Testing: The HE System

4.1 Introduction

In the preceding sections, the general fundamental principles involved in the design and operation of nuclear weapons have been discussed. The present chapter and the next one will be devoted to a description of some detailed aspects of the design, production, and testing of the various components of weapons of different types. Before proceeding with this, however, it will be worth while to review certain historical phases in the development of implosion bombs.

The outer diameter (60 inches) of the earliest implosion weapons was determined by the size of a B-29 bomb bay.

b(3)

After the development of the first stockpile bombs, the Mark 3 and Mark 4, both now obsolete, two directions were considered in which improvement in design appeared possible. First, to decrease the size without any great loss in yield and, second, to increase the yield for a given size.

b(3)

* Because of its size, the first implosion bomb was called the "Fat Man" (or FM), in contrast with the first gun weapon, which was thinner and longer; the latter was called the Little Boy (or LB).

b(3)

4.2 The Detonator System

UNCLASSIFIED

General Design Principles

In order to obtain a spherically symmetrical implosion, it is necessary that the maximum possible simultaneity be attained in the firing of the detonators which initiate the explosion wave in the lenses. Consequently, it was necessary to design special detonators and a suitable firing system that would give an extremely small spread in firing time.

The principles developed for the detonator systems of the earlier bombs are still used, although there have been marked improvements as regards weight, size, efficiency, and over-all design. The actual firing is performed by passing an electrical pulse of relatively high energy through a short, thin wire, called a bridge wire. As a result of the sudden and large increase of temperature, the wire vaporizes extremely rapidly and produces a shock wave.

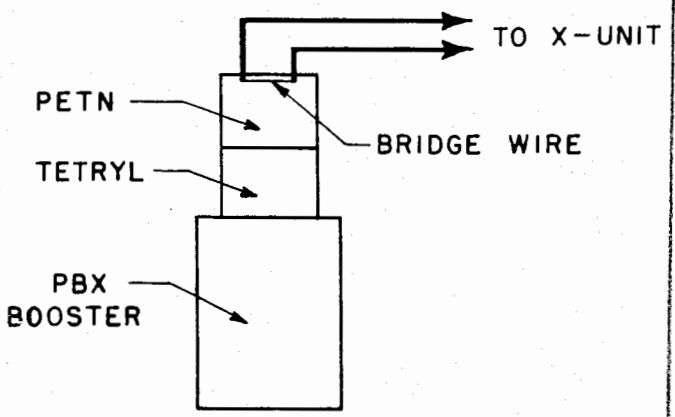

Fig. 4.1

UNCLASSIFIED

The X-Unit

The electrical firing system is called the X-unit; its action depends on the charging of a bank of condensers to a high voltage, and then discharging them at firing time through the detonator bridge wires, in parallel, by means of a triggered spark gap or a mechanical switch.

*Increase in packing density increases the energy yield (or power) of an explosive, but makes it less sensitive to detonation.

Detonator Types

UNCLASSIFIED

b(3)

UNCLASSIFIED

As a result of field tests by the military, it was found that the 1E22 detonator would not withstand rough handling. Consequently, some constructional changes have been made to provide additional mechanical strength. The new form is being called the 1E25 and it is proposed for use in conjunction with ring lenses in the TX-13 bomb which is not yet in production.

b(3)

As a result, the 1E23 was produced.

b(3)

A section through the middle of a 1E24 detonator is shown in Fig. 4.3.

b(3)

Fig. 4.3

UNCLASSIFIED

b(3)

UNCLASSIFIED

Since simultaneity is an important requirement of a set of detonators, special care is taken to insure uniformity in the composition and density of the explosive materials. The dimensions of these substances in the detonator and of the bridge wire must be exact, within close tolerances. The necessity for careful control of all components involves numerous inspections at all stages of production.

Detonator Testing

Prior to assembly, the parts of a detonator are gaged and the head, containing the electrical connections, is examined radiographically to detect internal faults, as will be described shortly. When assembled, the detonator is inspected visually, important external dimensions are gaged, and the resistance of the bridge wire is measured. A selected number of detonators are then subjected to destructive testing.

Three types of firing tests are performed; these are determination of (a) simultaneity, (b) transit time, and (c) threshold (or minimum) voltage required to detonate the bridge wire. The detonators are manufactured in lots of about 1250 under conditions which should make them as nearly identical as possible. Of each lot, 132 are selected at random for destructive testing: 112 for simultaneity, 10 for transit time, and 10 for threshold voltage. This number is regarded as being large enough to represent a good sample.

Simultaneity is investigated by the rotating mirror camera method (RMC)* which will be explained with the aid of Fig. 4.4. A set of 28 detonators and two bare bridge wires are placed horizontally, in a direction perpendicular to the plane of the paper. The purpose of the two bridge wires is to provide fiducial or reference points for timing purposes. The detonators and bridge wires are attached to a special X-unit of precision construction, so that they can be fired simultaneously. When the shock wave emerges from the detonator after firing, light is produced and this is focused by the objective lens system onto a horizontal slit, parallel to the line of detonators.

b(3)

UNCLASSIFIED

*This rotating mirror camera is also called a "smear" or "streak" camera or a Bowen-type camera; however, the original Bowen device was not a smear camera, but a high-speed framing camera using a rotating mirror.

SECRET

UNCLASSIFIED

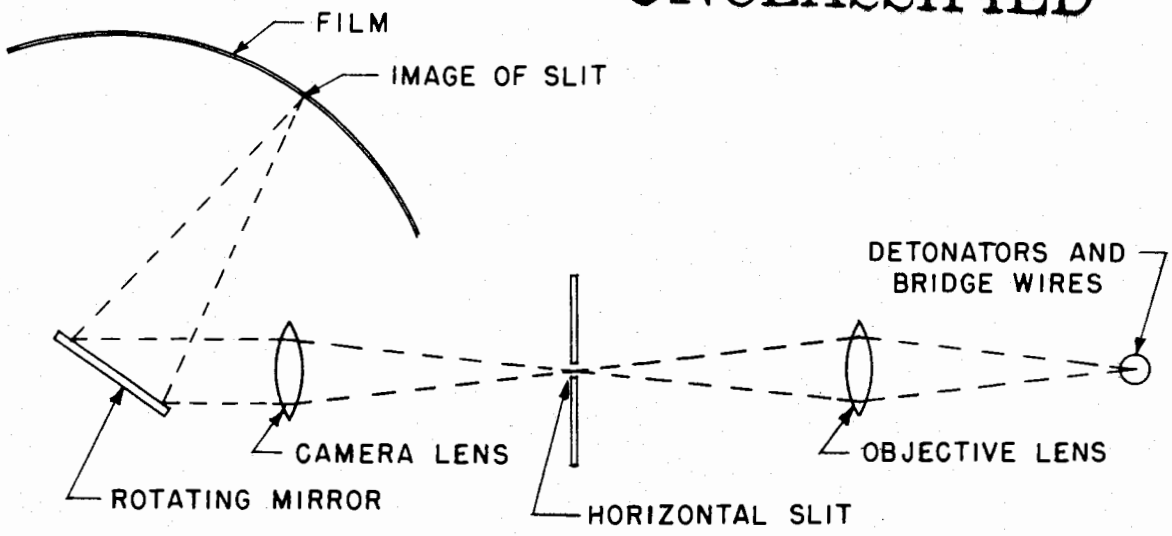

Fig. 4.4

As the mirror rotates, the first light picked up is that from the two bare bridge wires, and these leave traces (or streaks) on the film, which appear after development. There is then an interval during which the detonation waves are traveling through the 28 detonators. As each wave emerges from the face of the detonator, the light emitted produces its effect on the film. If all the detonators fired absolutely simultaneously, then all detonator streaks would start at precisely the same level on the film, and any deviations from simultaneity can be readily detected. From a knowledge of the rate of rotation of the mirror, and the distance from it to the film, displacement of the streaks on the film can be converted into intervals of time.

b(3)

The procedure described above is carried out with four groups of 28 detonators, and failure of any one of the 112 to fire, or inability to meet the simultaneity specifications given above, results in rejection of the complete lot of 1250 or so detonators. It is for this reason that the lots are not made too large, yet sufficiently large for a reasonable number to remain after removal of samples for testing.

Although the primary purpose of the rotating mirror camera procedure is to test simultaneity, it can be used to determine the time elapsing between bursting of the bridge wire and

SECRET UNCLASSIFIED

the production of shock-induced light at the detonator face. While the information obtained in this manner is useful, it is not regarded as sufficiently reproducible for use in comparing batches of detonators or finding if changes have occurred in storage. For the precise determinations of transit time the cable timing system (CTS) is employed.

In the CTS procedure only one detonator is used in each measurement, and determinations are made with 10 detonators from each lot. A schematic diagram of the circuit used is shown in Fig. 4.5. When the switch is closed, the firing condenser causes a high-voltage discharge

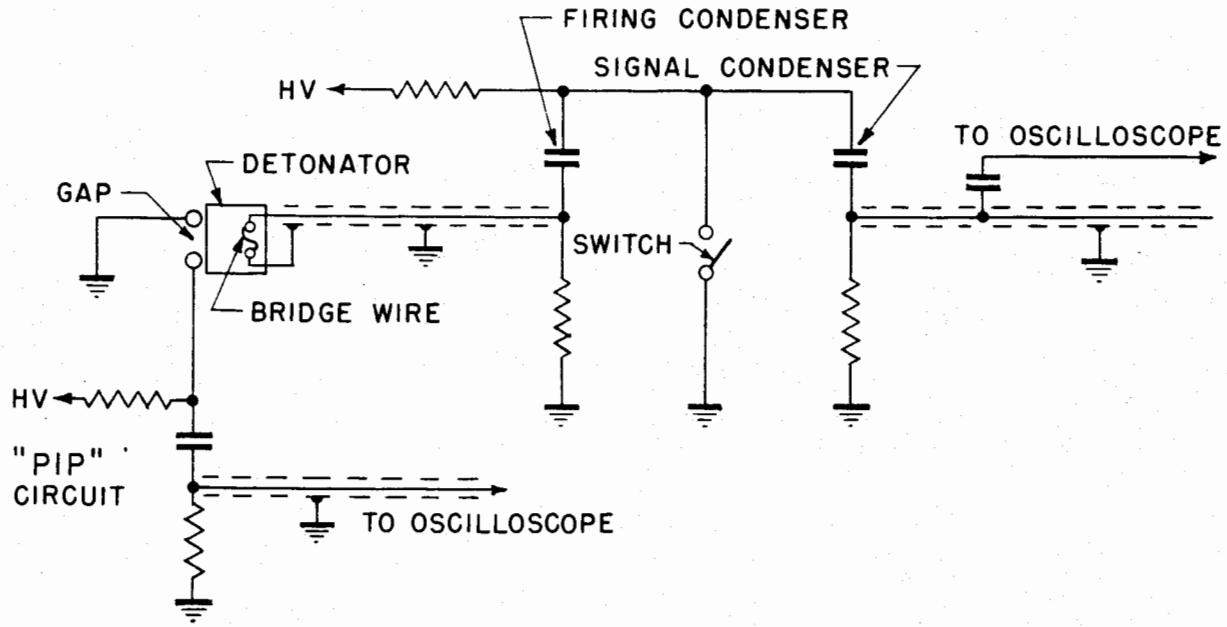

Fig. 4.5

to pass through the bridge wire of the detonator, at the left, and simultaneously, the discharge of the signal condenser, of smaller capacity, sends a signal along the coaxial cable at the right. This is recorded on an oscilloscope to indicate the time of closing the circuit. The signal continues to travel to the end of the coaxial cable and upon its return it will produce a second indication on the oscilloscope The distance between the indications represents an exact time interval which is dependent on the dielectric properties of the coaxial cable.

In the meantime, the bridge wire will have exploded and initiated the detonator. When the detonation wave reaches the front of the detonator an ionized region is formed which allows current to pass across a gap and so permits the discharge of the condenser in the "pip" circuit. As a result, a signal is sent to the oscilloscope and the record appears

somewhat as in Fig. 4.6. Since the fixed time interval is known, the transit time of the de-

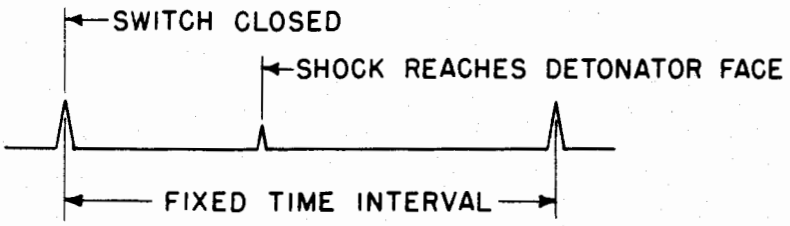

Fig. 4.6

tonator, between closing the firing switch and the appearance of the shock wave at the face, can be determined.

b(3)

It should be noted that the transit time includes the interval between closing the switch and the explosion of the bridge wire; this differs somewhat from the value obtained by the RMC method, since in the latter case the fiducial signal is provided by the exploding bridge wire.

b(3)

If the detonator fails to fire, it is replaced by another, as the bridge wire will undoubtedly have been destroyed.

b(3)

Radiographic Testing

In the radiographic testing of detonators, X-rays of relatively low voltage (40 to 120 kv) pass through the object to be examined and then fall on a radiographic film, which is subsequently developed. The procedure is, in fact, exactly similar to that employed in medical and dental radiographs. The plastic head of every detonator, which contains the bridge wire and its connections, is examined by this method for internal defects that cannot be seen or detected in any other way. Two radiographs are taken from two directions at right angles, so that the positions of various components can be determined.

SECRET

UNCLASSIFIED

b(3)

Thus, in the noncritical region some reliance is placed on the judgment of the observer.

Environmental Tests

Because detonators may be required to operate under extreme conditions of temperature, humidity, altitude, etc., as dictated by military expediency, they are subjected to a variety of so-called environmental tests. For example, they are test fired at both very low temperatures, e.g., -65°F and sometimes as low as -90°F, and at very high temperatures, e.g., 165°F, after being maintained at these temperatures for some time. The effects of short exposures to very high temperatures, to which a nuclear fission warhead in a guided missile might be exposed, are also examined. The detonators must operate at high altitudes, up to 35,000 feet,* and over a considerable range of humidities.

The effect of storage in various climates is investigated by artifical simulation of the conditions. This includes temperature cycling, equivalent to the day and night variations that might be encountered in arctic, tropic, and desert regions.

Extensive and continuous testing is performed to determine the effect of temperature and humidity on the life of a detonator in storage. This insures that stockpiled detonators have not deteriorated. Non-propagating storage cases have been designed, so that if one detonator is accidentally set off, the others in the case will not be affected.

As an aspect of the environmental testing, detonators have been subjected to gasoline fires and hot oil. Although burning occurred, there was no explosion. The effect of impact has been studied and the results show that the detonators are remarkably safe. Some tests have been made with the HE system of a Mark 7 having the projecting 1E23 detonators installed. Five complete HE assemblies were dropped from a height of 40 feet on to a thick steel slab backed

*The firing system (X-unit) will not function at substantially higher altitudes, because leakage occurs due to electrical discharges at low pressures.

UNCLASSIFIED

SECRET

by concrete. A few detonations of a low order occurred, which may have been due to the fast component (Composition B) of the lenses. The lenses and HE inner charges suffered severe mechanical damage; so also did many of the detonators but they did not explode. In a similar impact test with five Mark 12 HE assemblies, with buried (1E24) detonators, there was no indication of either detonation or burning of the detonators or HE inner charge, although mechanical damage was considerable.

HE Components of Lenses

The fast-explosive component, which has remained almost unchanged throughout the development of implosion weapons, is known as Composition B. It consists of 60 parts by weight of RDX and 40 of TNT (trinitrotoluene).* In addition to being a stable but powerful explosive, it is readily available. The detonation velocity of Composition B in rod form, i.e., the so-called "stick rate," is about 7900 meters/sec, and although explosives with higher detonation velocities are available, so that the refractive index may be increased, they have various drawbacks, with regard to stability, fabrication, handling, availability, etc., as compared to Composition B.

b(3) UCNI

UNCLASSIFIED

*In order to introduce some system into the naming of explosives, it has been proposed to refer to Composition B as cyclotol 60/40. By convention, a name ending in "ol" indicates the presence of TNT.

UNCLASSIFIED

Fabrication of Lenses

b(3)

The amount of machining done is the minimum necessary to remove extraneous material.

b(3)

UNCLASSIFIED

b(3)

A highly significant aspect of the machining method of fabrication is its great flexibility. Whereas in the so-called precision casting procedure any change in design or dimensions required new and expensive molds, many such changes can now be very rapidly made by adjustment of the cutting tools.

HE Inner Charge

The prime purpose of the HE inner charge, often abbreviated to I.C., is to transmit the spherically convergent implosion wave, produced by the lens system, with increased energy, so as to cause maximum compression of the core of the bomb. In addition, it has been found that, if of sufficient thickness, the HE inner charge serves partially to smooth out some of the local irregularities which inevitably exist in the detonation wave at the time it leaves the lens system.

Apart from the obvious requisites of uniform density and composition, and the absence of air bubbles, voids, cracks, etc., the explosive material of the I.C. should be one of high power and of good stability. In the Mark 5, 6, and 18 bombs, Composition B is used, but in the Mark 7, this has been changed to a new mixture, called cyclotol 75/25, consisting of 75 parts by weight of RDX and 25 parts of TNT. Weight for weight, this provides about 13 per cent more compressive energy than does Composition B. Cyclotol 75/25 will also be used in the Mark 12 system. [redacted]

b(3)

[redacted] This is a provisional measure, pending a final decision concerning the exact dimensions of the tamper. [redacted]

b(3)

b(3)

b(3)

UNCLASSIFIED

Improvements in the HE inner charge system may come from the introduction of a more powerful explosive or from better fabrication methods. As regards the former, a mixture called Octol, consisting of 75 per cent of the explosive HMX (cyclomethylene tetranitramine), which is related to RDX, and 25 per cent of TNT, is being considered. Because of the high density (1.91 g/cc) of HMX (as compared with 1.81 g/cc for RDX), it is possible to include a greater mass in the same volume.

b(3)

At the present time HMX is expensive and is not available in sufficiently large amounts for wide usage.

A study is being made of the possibility of adapting a plastic bonded explosive (PBX) for HE inner charges. The main advantage would be that the charges could be rapidly and economically fabricated by vacuum pressing of a molding powder consisting of RDX and a plastic. The product would be more uniform than that obtained by casting and it would have improved mechanical properties. Ultimately, precision molding might be possible, so that machining to exact dimensions would be unnecessary. Actually there are many problems still to be solved before PBX could be seriously considered as a substitute for Cyclotol (or Octol) in HE inner charges.

One of the drawbacks to the use of the regular PBX is that the polystyrene is an inert constituent and contributes essentially nothing to the explosive power. This might perhaps be overcome by means of a nitrated plastic material that would itself be an explosive. A study is being made of substances which could serve this purpose.

4.4 Testing HE Lenses and Inner Charges

Physical, Analytical, and Radiographic Tests

Both HE lenses and inner charges are manufactured from materials, supplied by outside producers, which must meet certain specifications. Standard quality control techniques are used at all stages of fabrication, and acceptance tests are applied to the finished products. The latter are thoroughly tested to insure uniformity in composition, and to determine if they have certain required characteristics. The testing procedures may be considered under four

main headings: a) physical methods, (b) analytical techniques, (c) radiographic methods, and (d) test firing. In addition, environmental tests, similar to those described for detonators, are made with samples of lens systems and inner charges.

b(3)

b(3)

Analytical techniques are destructive in nature and are concerned with a detailed examination of a number of samples obtained from different parts of a single piece. Determinations are made of density and composition to insure uniformity. These are, of course, important factors in connection with the symmetry of the spherical implosion wave.

b(3)

Radiographic methods are employed both for quality control and to determine acceptability. They are nondestructive and are consequently applied to all finished products, as well as in some intermediate stages. Because the heavy element barium is rather opaque to X-rays, radiations

b(3) UCNI

b(3) UCNI

b(3)

UNCLASSIFIED

Inner charges are examined radiographically for cavities, impurities, and defects of various kinds. The whole of the inner charge is important and so there are no noncritical regions. Since inner charges are not subjected to routine firing tests, as are lenses, the radiographic procedure acquires special significance. However, the performance (or quality) of inner charges is determined indirectly in the course of other measurements, to be described below.

The radiographic technique is primarily applicable to the detection of discrete defects having definite boundaries.

b(3)
DCNI

For a given material, this absorption will depend on the product of the thickness and density; thus, it may be possible to detect, in a nondestructive manner, gradual changes of density which cannot be observed radiographically.

Test Firing of HE Lenses

The purpose of test firings is to determine the transit time of a lens, i.e., the time for the detonation to travel from the face of the detonator to the lower face of the lens, and also to study the variations, if any, in emergence time of the shock wave at points across the face. For this test, anywhere from 2 to 10 per cent of the lenses of a given batch are selected so as to form a representative sample.

b(3)

Each gap forms part of an electrical circuit, so that when the shock front reaches the gap, the ionization produced causes a condenser to be discharged and a signal is transmitted to a rasterscope (or raster oscilloscope). This instrument gives a series of traces, each successive one below the other, over a period of time; accurate time interval pulses are superimposed on the rasterscope pattern. A schematic representation of the electrical circuit is given in Fig. 4.18.

UNCLASSIFIED

b(3)

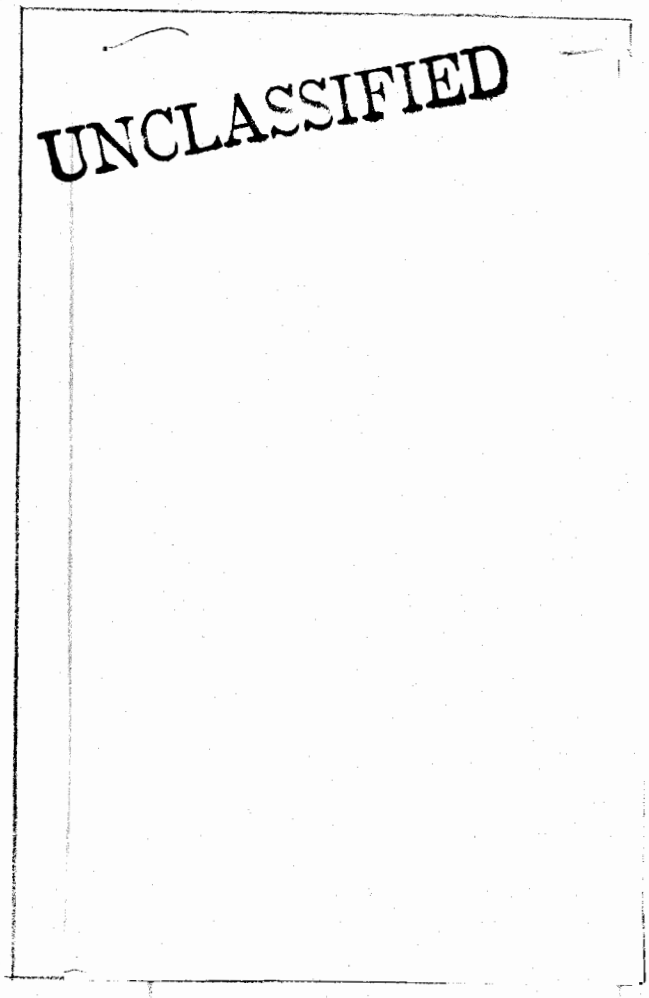

Fig. 4.17b

When the detonator is fired, the ionization due to the shock wave emerging from its base discharges one condenser, and this causes a deflection on the rasterscope trace. Then as the wave proceeds and emerges from the face of the lens, the second condenser is discharged, and a second deflection appears.

The distance between the two deflections on the trace, which is recorded by means of a camera, is then a measure of the transit time of the detonation wave through the lens. The actual transit time is obtained by making use of superimposed time pulses on the rasterscope trace. Some experimental values of transit times for various HE systems are given in Table 4.1 (below).

Simultaneously with the performance of the foregoing measurements, of transit times, the emergence times of the luminous detonation front at points across the lens face are being studied by means of rotating mirror (streak) camera. The procedure is exactly similar to that described in Section 4.2, for the testing of detonators.

b(3)

The slit shown in Fig. 4.19 is arranged so that the camera picks up the light from a strip across the middle of the face of the lens.

b(3)

If the luminosity appeared at exactly the same instant across the whole lens face, the developed film would show a dark streak with a sharp, straight boundary. Actually, because of the variations in emergence times of the shock front, the boundary shows irregularities. By magnifying the image from the film, it is possible to determine accurately the emergence times at a series of points across the lens face, with reference to the earliest emergence time. The results are then represented graphically with the time as abscissae and the

UNCLASSIFIED

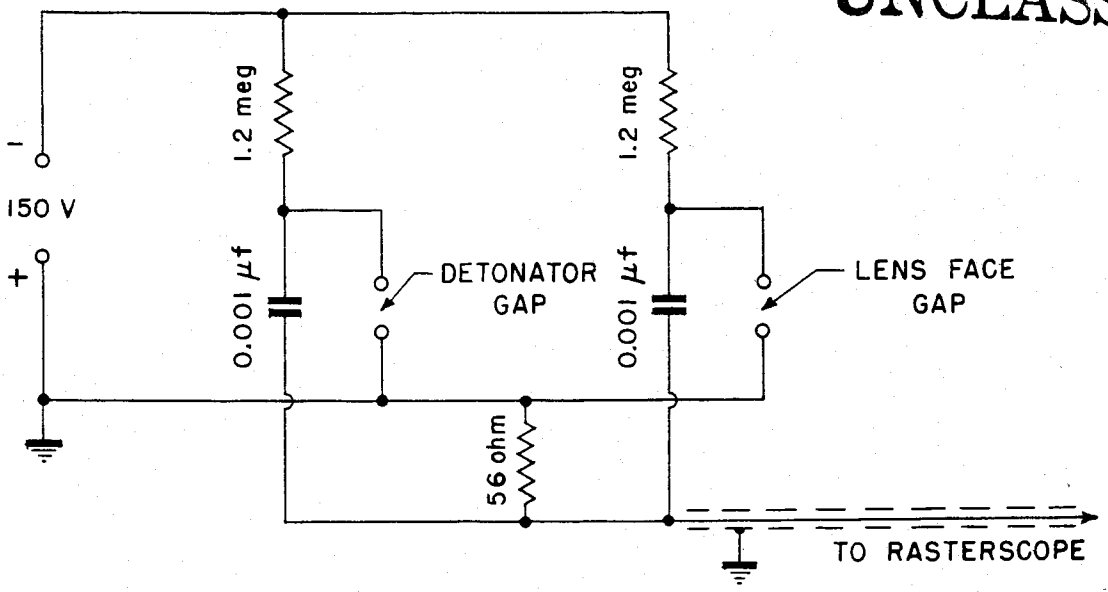

Fig. 4.18

fractional distance across the lens face as ordinates.

b(3)

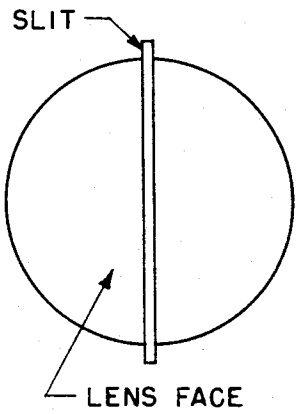

Fig. 4.19

In addition to testing lenses for simultaneity of emergence, the rotating-mirror, streak technique is of great value in the development of new lenses.

b(3)

One of the limitations of the procedure described above is that it permits of the examination of only a single strip across the lens face. Ideally, the whole area should be

b(3)

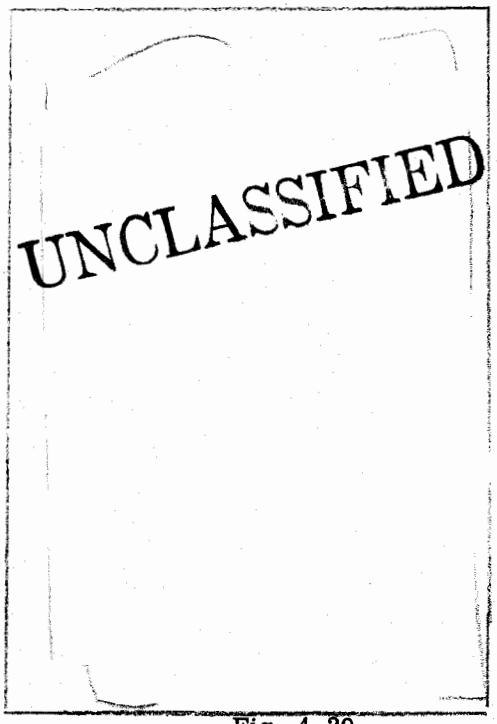

Fig. 4.20

studied, since the lens may not have axial symmetry. An approach to this ideal has been made by using a number of parallel slits, in place of a single slit, so that the whole face is essentially covered at the same time. However, the ordinary rotating mirror method cannot be used without modification because the various streaks would overlap.

[redacted] The b(

streaks obtained by the rotating mirror camera from several slits simultaneously are thus quite narrow and there is no overlap.

The technique involved in the multislit method is somewhat complicated, and so it is not generally used for lens testing. Its main application so far has been in an experimental study of the time spread, over a fairly large area, of the detonation wave as it leaves the lens and passes through various thicknesses of I.C.

Environmental Tests of Lenses and Inner Charges

As described in Section 4.2 for detonators, both lenses and inner charges are subjected to low (-90°F) and high (165°F) temperatures and also to temperature and humidity variations such as might be encountered under arctic, tropic, or desert conditions. Examination is made for significant changes in dimensions, for mechanical damage, e.g., stress cracks, and for the appearance of excessive exudation from the HE materials. Tests are being planned in which the HE system will be fired at both temperature extremes to determine the relationship between temperature and transit time.

Summary of HE Systems

For convenient reference, a summary of the characteristics of the HE systems in stockpile, in production, or which will soon be production, is given in Table 4.1.

4.5 Implosion Performance Studies

The general behavior of implosion systems has been studied by three general methods. These are (a) the pin technique, (b) the RaLa method, and (c) photography. At the present time the pin technique is the most widely used for both testing and development work, whereas the RaLa and photographic procedures are now mainly employed in the study of special problems in development and research. A technique, employing radar, for the study of the detonation wave in the inner charge system is under development.

The Pin Method

In the pin method the times are recorded at which the implosion wave or material-air surface reaches various points within a sphere. One principle used is similar to that applied in the cable timing system for detonators (Section 4.2) and in the test firing of lenses (Section 4.4). The closing of a gap, at a known position, either by ionization due to the detonation wave or by actual metallic contact, causes a condenser to be discharged. This produces a deflection on an oscilloscope (or rasterscope) trace, which can be timed very accurately.

A simplified schematic diagram of the circuit is shown in Fig. 4.21. The gap, which is closed by ionization or contact, is at the top of the figure. One point of the gap is part of the

*While in the development stage, a weapon is given a TX number; when the final design has been released and approved for stockpile this is changed to a Mark number, which is usually, although not always, the same as the TX number. Code names, such as "Thor" and "Brok," used during development, are frequently retained.

SECRET

UNCLASSIFIED

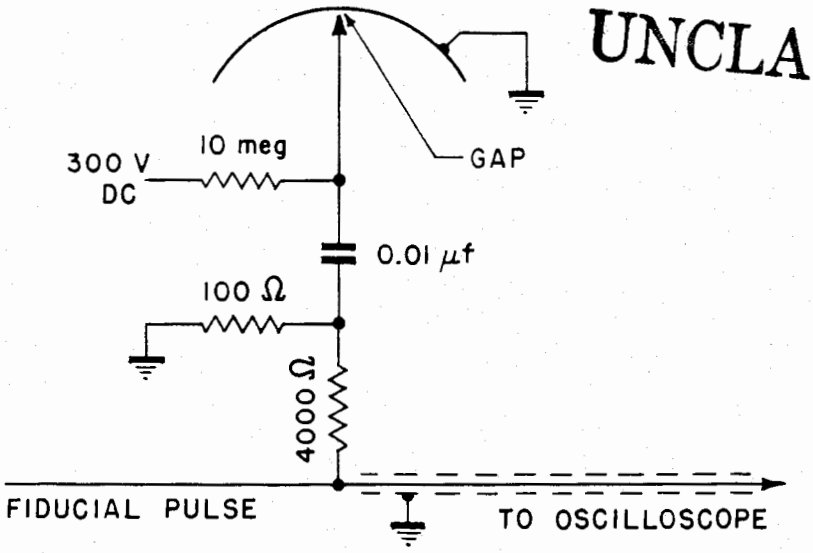

Fig. 4.21

implosion system being studied, whereas the other, indicated by the arrowhead, is a wire, often in the form of a long pin. It is from the appearance of these contactors that the name "pin method" originates. It may be mentioned that by using 300 volts to charge the condenser, no amplification of the oscilloscope pulse is necessary and consequently very rapid response is obtained.

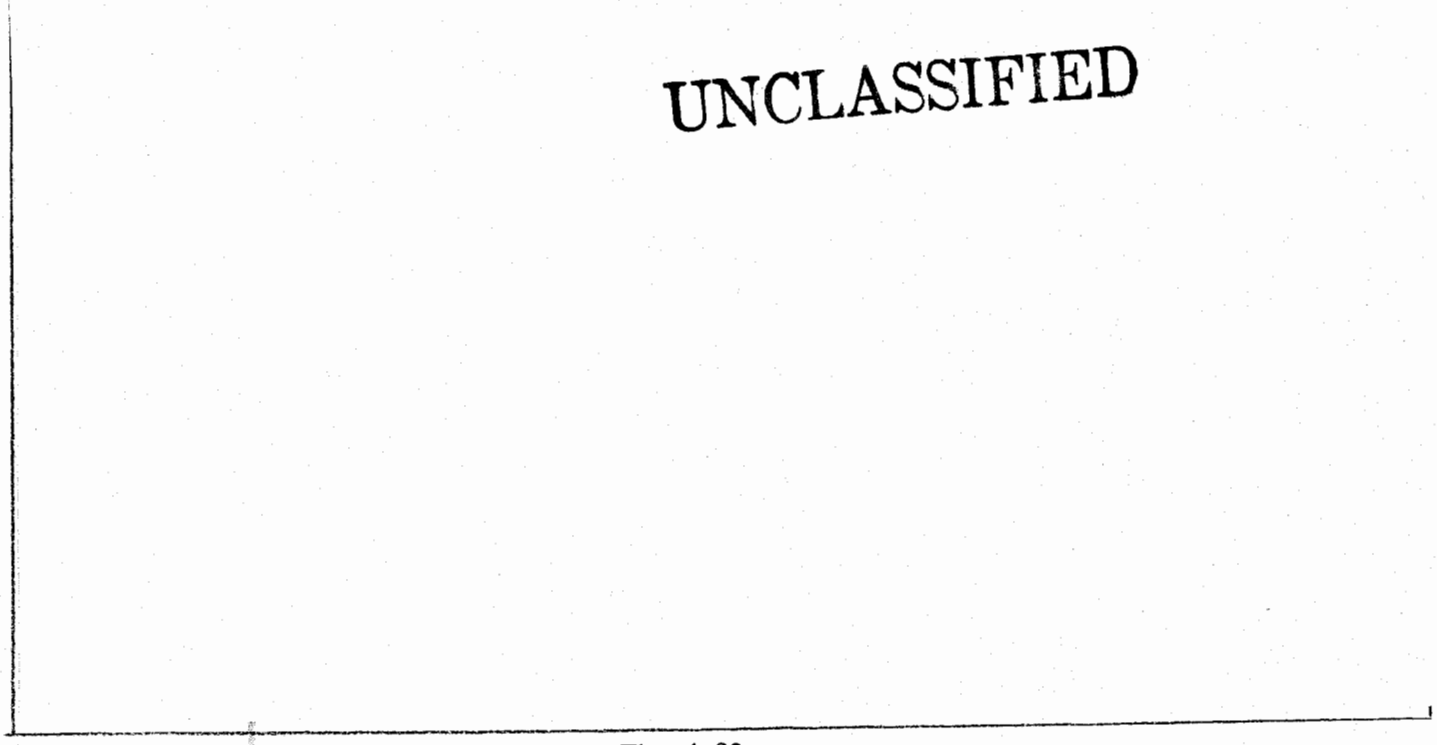
Two main types of measurements are made by the pin method. These are called (i) tamper run, and (ii) ball run, respectively. The objective of the tamper run is to determine the transit time of the shock front through the aluminum pusher and the tuballoy tamper, the velocity of the inner (free) surface of the tamper through the air (free run) space in a levitated system, and the symmetry of the implosion wave, using a given HE system (Fig. 4.22). For this purpose, insulated contactors are located at the HE-pusher (A), pusher-tamper (B), and tamper-air (C) interfaces. In addition, a number of pins (D) of five or more different lengths are fixed into a so-called pin dome of an insulating plastic; this replaces the ball containing the fissile material in the actual bomb. Connection from each of these contactors or pins is made to oscilloscopes in the recording chamber which is protected from the explosion. In this way, the time arrival of the shock front at A, B, and C can be recorded, and the subsequent movement of the tamper-air surface can be followed down to very small radii, e.g., about 2 inches.

Although a relatively small number of pins are shown in the figure, the total number used may range from 100 to 300. If these are spread over an area, they provide a good indication

SECRET

UNCLASSIFIED

UNCLASSIFIED



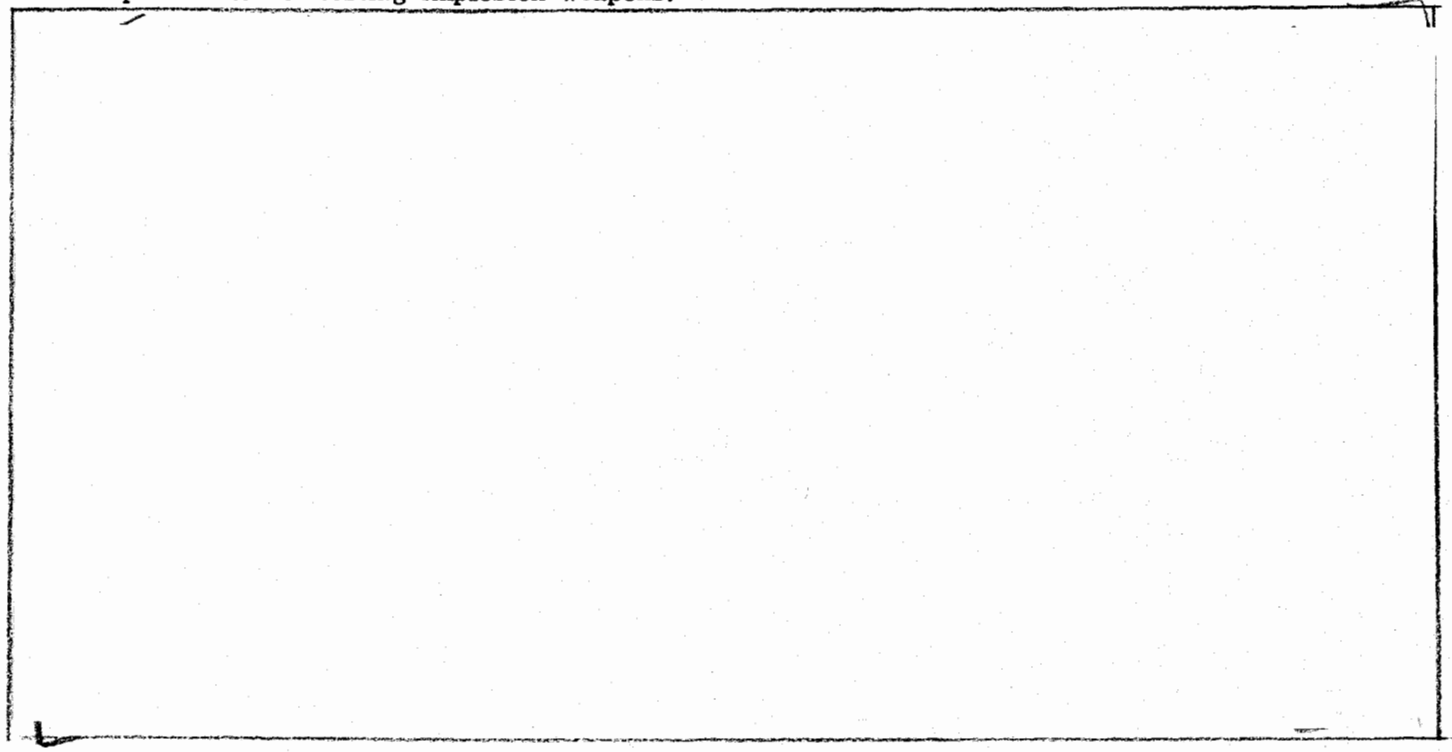


Fig. 4.22

of the symmetry of the implosion wave in that region. This is a highly important aspect of the pin method of testing implosion weapons.

UNCLASSIFIED

b(3)

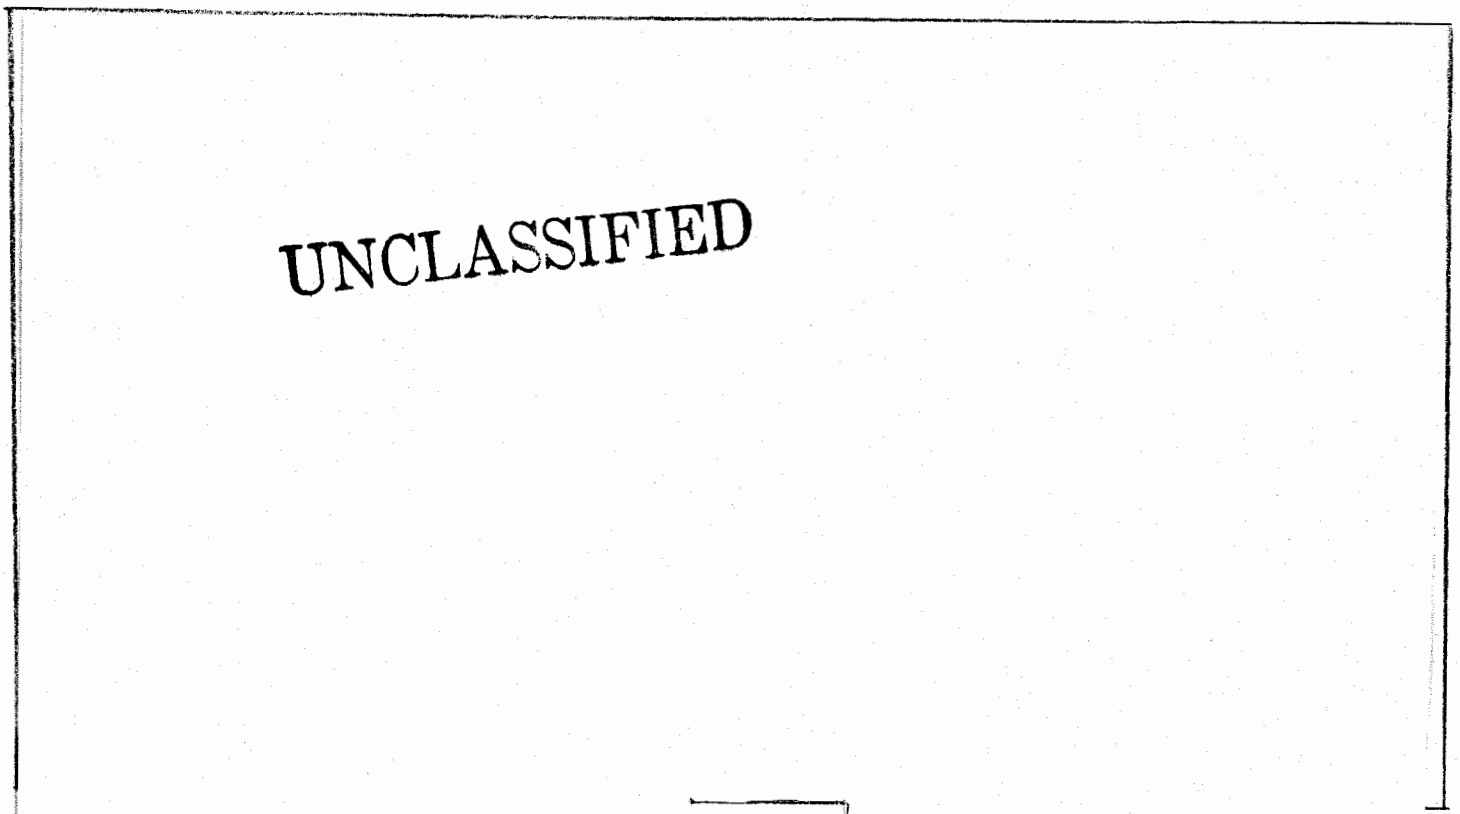

Fig. 4.23

b(3)

Asymmetry due to other causes can, of course, be studied in the same manner.

One purpose of the pin-method measurement described above is to check the actual free surface and shock velocities against those computed from hydrodynamic theory. From the transit time observations, ball time and collapse time, at which the shock wave reaches the outside of the ball and its center, respectively, can be determined.

b(3)

In addition, information is obtained concerning the effects of various factors on the symmetry of the implosion.

b(3)

UNCLASSIFIED

For this purpose, shock and material velocities are determined. The data will be used to improve hydrodynamic calculations of the expected compressions and, hence, the yield of weapons of new design.

Because of its relative simplicity and adaptability, the pin technique is extensively used for implosion studies. Nevertheless, it has some drawbacks which may be mentioned. A portion of the spherical HE and tamper system must be removed to permit insertion of signal lead wires to the pins. This upsets the symmetry of the implosion near the opening.

As a result, measurements are reliable over a limited region of the sphere. Another fact which must be borne in mind is that a highly localized disturbance may reach a particular pin. In this case, the reading obtained could be misleading, but the use of a large number of pins minimizes the probability of this occurring.

The RaLa Method

The RaLa (pronounced "Rah-lah") method was originally used in connection with weapon design to indicate the compression of the ball as a function of time in an implosion and also to study the symmetry of the latter. Its main purpose at present, however, is to obtain data for verifying calculations based on equations of state at high pressures.

SECRET

UNCLASSIFIED

The RaLa method of studying compression is based on the fact that the fraction of gamma rays absorbed (or transmitted) by the ball depends upon its compression. Consider a sphere in which the density (or compression) changes with time but remains uniform over the radius; then,

$$\text{Fraction of gamma rays transmitted} = e^{-\mu r}, \qquad (4.3)$$

where r is the radius of the sphere and μ is the mass absorption coefficient of the material for the given gamma rays.

b(3)

The oscillographs attached to the detectors give a record of the per cent transmission as a function of time (Fig. 4.24). From this the variation of compression of the ball with time can

b(3)

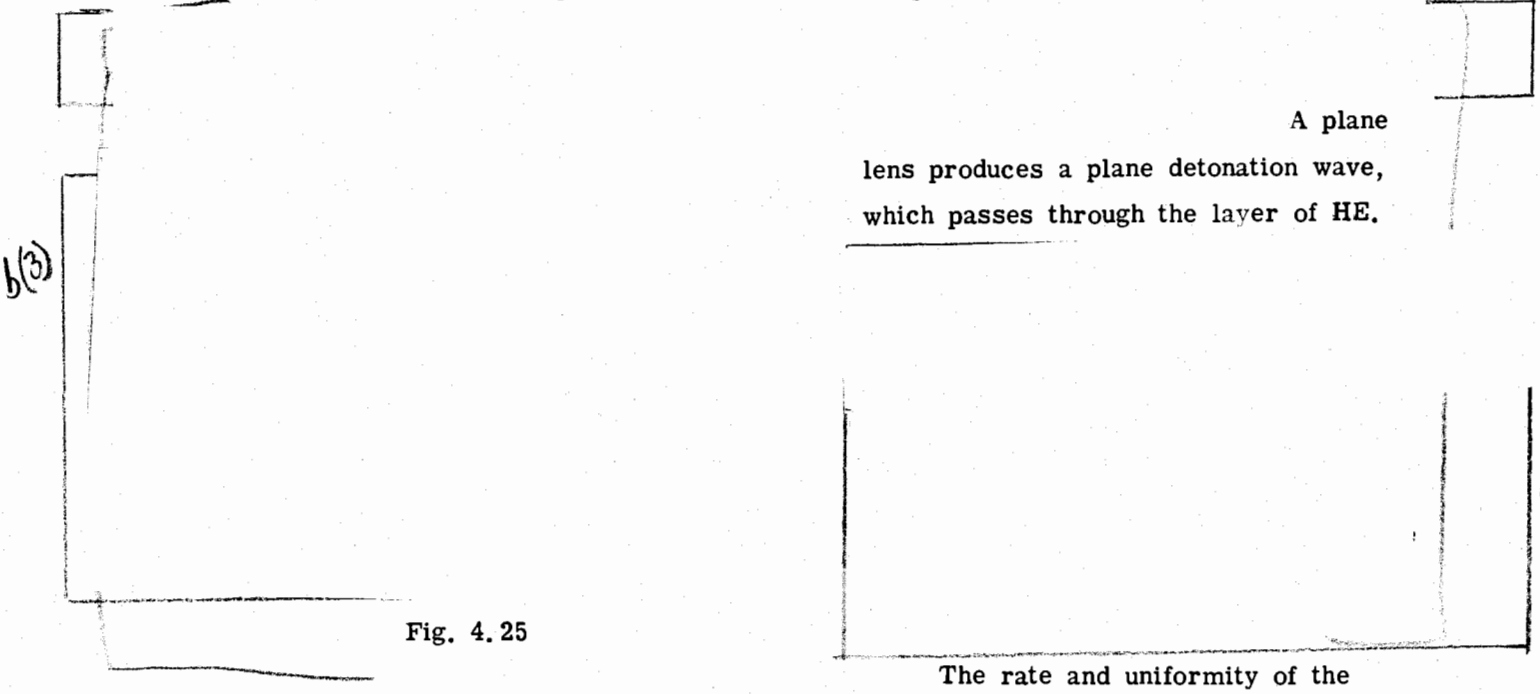
Fig. 4.24

be determined.

b(3)

By comparing the traces obtained from several detectors located around the implosion system, the symmetry of the wave can be investigated.

b(3)



UNCLASSIFIED

SECRET

Photographic Methods

In the study of implosion phenomena, photographic methods are chiefly applied to investigate the motion of metal surfaces, e.g., of the tamper or ball. In this way, the effects of perturbations in the detonation wave and in the shock wave, which may be due to the supporting structure for the ball, may be examined. Although the photographic technique is not generally employed for routine testing or design, it is used in trying out new ideas. For this purpose, a simple, rapid, and inexpensive procedure has been developed.

b(3)

A plane lens produces a plane detonation wave, which passes through the layer of HE.

b(3)

b(3)

Fig. 4.25

The rate and uniformity of the movement of the free surface is studied by drawing a rectangular grid pattern on the lower surface of the plate.

b(3)

Advanced models of this rotating mirror camera have been designed which will take pictures at rates up to 3.5 million per second. The intense illumination of short duration required for these very brief exposures is obtained by passing a shock wave, produced by a detonation in HE, through a column of argon.

The plane lens and the HE used to produce the flash in argon are fired simultaneously, and a series of photographs of the grid, either perpendicularly or at a slant angle, are taken by the high-speed camera. From the pictures made at an angle it is possible to calculate the free surface velocity of the metal plate. In addition, from an examination of the grid, preferably in a direct view, qualitative information can be obtained concerning the symmetry of the shock wave. Results secured in this manner can be confirmed, if necessary, by means of a spherical implosion system with a grid drawn on a hemispherical surface.

In addition to the procedure just described, high-speed photography is used to produce profile shadowgraphs, i.e., edge-on views, of a plate subjected to the action of a shock wave. Information concerning departure from uniformity of motion can be detected in this manner.

On the whole, high-speed photography is best suited to qualitative studies; it is particularly valuable in providing a physical picture of the effects of a shock wave produced in a given manner. If more exact quantitative data are required the rotating-mirror streak camera, described in Section 4.2, is used to amplify the observations. The multiple slit procedure, referred to in Section 4.4, can provide quantitative information concerning leads and lags in the shock front at free surfaces. The photographs obtained with the high-speed framing camera facilitate the interpretation of the streaks.

High-speed, flash photography, like the other two methods of studying implosion effects, is used to derive equation of state data for metals at high pressures for theoretical calculations. In fact, this is the main application at the present time. Fortunately, the three procedures do not duplicate one another, as each is best suited to a particular range of pressures.

b(3)

[redacted]

The photographic technique is then particularly convenient, as described above.

Radar Technique

A proposal for the use of radar in the study of the rate of propagation of the detonation wave, and the effect upon it of convergence, in the inner charge system is under development. Due to the ionization it produces, the surface of a detonation wave is a good electrical conductor and so reflects radar waves, i.e., electromagnetic waves of short wave length, about 3 cm. Because the detonation front is in motion, the frequency of the reflected radar waves differs from that of the incident waves, as the result of a type of Doppler effect. From the beat frequency arising from the combination of incident and reflected waves, the velocity of the detonation front can be determined.

Components Design and Testing: The Nuclear System

5.1 Pit and Capsule Characteristics

Pit and Capsule Defined

The portion of an implosion bomb lying within the HE system consists essentially of two components: the pit and the capsule.

b(3)

b(3)

UNCLASSIFIED

Fig. 5.1

b(3)

UNCLASSIFIED

b(3)

If the final positioning of the capsule within the pit is performed while the weapon is airborne, the process is referred to as "in-flight insertion," abbreviated to IFI.

Characteristics of Pits

b(3)

Some of the important characteristics of the pits referred to above are summarized in Table 5.1.

b(3)

Table 5.1 Characteristics of Pits

b(3)

UNCLASSIFIED

Characteristics of Capsule Balls

b(3)

b(3)

UNCLASSIFIED

For reasons connected with the limited life of the neutron (polonium-beryllium) source which initiates the fission chain, capsule balls must be disassembled from time to time and provisions for this must be made in their construction.

b(3)

The outer radii and compositions of the capsule balls are given in Table 5.2; the per cent plutonium indicates the proportion this element represents of the total fissile material.

5.2 Storage and Inspection Procedures

However, plutonium represents a very serious radiological hazard to personnel handling bomb capsules.

Capsules are therefore kept in steel carrying cases which are thoroughly dried by baking and then filled with dry air.

Safety in Storage

Safety during storage has two aspects, namely, personnel and nuclear. The main problem, as far as personnel are concerned, is the plutonium danger, referred to above. This is checked by what is called a swipe test. A piece of cleansing tissue is rubbed over the plutonium surface and then tested for alpha-particle activity by means of a suitable counter.

Although they do not represent such a serious radiological hazard as does plutonium, the swipe test is also applied to oralloy and tuballoy surfaces to determine if loose corrosion products have been formed.

Many steps are taken to insure nuclear safety. One of these, as already mentioned, is the separate storage of pits, with their HE assemblies, and capsules.

UNCLASSIFIED

b(3)

UNCLASSIFIED

A series of experiments on the neutron multiplication due to various numbers of cores spaced at certain regular intervals were made using remote control methods (see Section 5.7). As is to be expected, the over-all multiplication increases with the number of cores and with a decrease in their separation. However, provided the distance between adjacent cores exceeds a certain amount, a large number can be stored without the danger of the whole becoming critical. In actual storage practice, the minimum permissible distances between capsule cases are maintained by means of rigid partitions.

b(3)

Testing and Inspection (Surveillance) Procedures

All components of pits and capsules are subjected to rigorous testing and inspection, both at the time of manufacture, to insure that required specifications are met, and during storage, to detect possible deterioration. Although the detailed procedures vary according to circumstances, the following brief description of an acceptance inspection may be regarded as fairly typical; it is, however, merely an outline of the many operations which are performed

on the pit and capsule components and assemblies.

b(3)

In addition to visual inspection for obvious flaws, they are radiographed to detect possible internal faults.

b(3)

The ratio of gamma rays emitted to the total beta plus gamma radiation can be used as a qualitative indication of the isotopic composition of the uranium. The ratio is much less for oralloy than for tuballoy, so that the two materials may be readily distinguished. The actual amount of uranium-235 can be determined, if required for accountability purposes, by placing the core, or some portion of it, in a tamping geometry with a neutron source and observing the subcritical multiplication due to fission (see Section 5.7). Uranium-238 gives no multiplication under these conditions. The results are calibrated, in terms of the proportion of uranium-235 present, by mass spectrographic analysis.

b(3)

Periodic Inspections

b(3)

UNCLASSIFIED

b(3)

UNCLASSIFIED

Other tests may be made as required by circumstances. The checking of the initiators, which is performed at the same time, will be described below.

Capsule and core parts which are stored in dry, pressurized air with silica gel as desiccant are normally inspected only at the time of initiator replacement. But capsules stored in unpressurized cases, also with silica gel, are inspected every 90 days. They are cleaned, if necessary, and the desiccant is renewed. No matter how it is stored, any capsule or component that has been exposed to temperatures below 0°F or in the range from 120° to 150°F for more than a week is inspected. A more detailed examination, involving disassembly, is necessary if the storage temperature has exceeded 150°F for any time or if the capsules have been accidentally subjected to violent handling, e.g., dropping.

b(3)

If the pit has been stored in a humid atmosphere, or under any conditions that might lead to condensation of water, inspection is necessary. This inspection usually involves a visual examination for corrosion blisters, pitting, and warping. The opportunity is then taken to clean the pit interior.

5.3 Fabrication of Pit and Capsule Components*

Plutonium Production and Fabrication

As extracted from spent reactor fuel elements (Section 1.5) by chemical processing, plutonium is almost invariably obtained in the form of a suspension or concentrate of the nitrate in water. In order to reduce the light element impurities, and thus decrease the neutron background due to (α, n) reactions, this is further purified. The nitrate is dissolved, in batches not exceeding 320 grams of plutonium, to avoid the possibility of the solution becoming critical, and hydrogen peroxide is added to precipitate plutonium peroxide. The peroxide is removed and heated to 550°C in a mixture of hydrogen fluoride gas and oxygen to form plutonium tetrafluoride (PuF_4).

The fluoride is mixed with calcium turnings, together with some iodine as a temperature booster, and heated to a starting temperature of about 400°C in a magnesium oxide crucible by means of an induction furnace. Plutonium turnings from fabrication processes may be added at this stage. The plutonium fluoride reacts with the calcium and is thereby reduced

*The following description applies to procedures used at Los Alamos; they are similar to those employed by other producers and fabricators.

SECRET

UNCLASSIFIED

to plutonium metal; an argon atmosphere is maintained to prevent oxidation of the latter. Considerable heat is evolved in the chemical reactions which occur, and metallic plutonium, melting point 635°C when pure, drops to the bottom of the crucible and is removed as a button upon cooling. It is of interest to mention that all the foregoing processes are now performed by remote control.

Because the critical mass of plutonium is greater in the absence of water, it is permissible to operate with larger quantities in the dry stages. Thus, clean plutonium turnings or filings, obtained from metal fabrication processes, are added either to the fluorination or to the reduction stages for recovery. The metallic buttons obtained may weigh up to 750 grams.

During the reduction process gallium metal is added to form a plutonium-gallium alloy containing 1 per cent by weight of the latter element. The purpose of the gallium is to stabilize the plutonium in the delta-phase form.

UNCLASSIFIED

b(3)

b(3)

UNCLASSIFIED

If the plutonium hemispheres pass the foregoing tests they are then examined radiographically and by autoradiography. The radiographic test, using gamma rays from cobalt-60, will detect the presence of cavities, cracks, etc. If these are in excess of a certain minimum size and number, the part is rejected.

b(3)

Oralloy Production and Fabrication

As stated in Chapter 1, oralloy, in the form of uranium hexafluoride, is obtained from the gaseous-diffusion plants. It is then of sufficient purity not to require further processing before reduction to metal, by the method given in Section 1.5. Nevertheless, the material is analyzed to make sure that the light-element impurities are not excessive. The metal, which does not have such good metallurgical properties as delta-phase plutonium, is fabricated by vacuum casting followed by machining to shape.

b(3)

UNCLASSIFIED

b(3)

UNCLASSIFIED

After casting roughly into the required size and shape, the oralloy is machined to exact specifications. In the "as-cast" condition, the metal exists in the stable alpha phase, in which state its fabrication properties are not too good. From the relatively little work that has been done on uranium alloys, there is as yet no evidence that a form more amenable to fabrication can be stabilized at ordinary temperatures. Consequently, machining of castings is not the ideal method of fabrication and other procedures are being investigated (see below).

Additional problems arise in the fabrication of oralloy due to its chemical and radiological properties. Because of the rapid reaction with oxygen in the air, the chips, etc., produced are likely to ignite spontaneously. Small particles of metal will be oxidized and the resulting dust is an inhalation hazard. The operations are therefore carried out under hoods and the work is cooled to prevent ignition. Although oralloy is moderately radioactive, the manipulation of solid pieces is not especially dangerous, provided they are handled with protective gloves. The value of the material requires that great precautions must be taken to avoid losses of all kinds.

b(3)

After completion of the oralloy part it is radiographed to detect possible internal defects.

Tuballoy Production and Fabrication

Since the physical, chemical, and metallurgical properties of tuballoy are identical with those of oralloy, the procedures used for the production and fabrication are much the same. However, the handling of tuballoy is much simpler in many respects. In the first place, since there is no danger of criticality, larger masses can be melted and cast.

b(3)

The radiological hazard is appreciably less than for oralloy, and since it is less valuable, moderate fabrication losses can be tolerated.

b(3)

Because of the ease of oxidation, precautions against spontaneous ignition during machining must still be taken.

b(3)

UNCLASSIFIED

b(3)

SECRET

UNCLASSIFIED

Recovery of Plutonium and Oralloy

Because of their value as fissile materials, all residues of plutonium and oralloy are carefully collected for recovery. Plutonium in the form of metal, e.g., turnings, filings, etc., or of oxide, formed in casting, is dissolved in nitric acid with a little hydrofluoric acid. From the resulting nitrate solution (or slurry), plutonium peroxide is precipitated by hydrogen peroxide and sent to the plutonium production line. Magnesium oxide crucibles and molds and the calcium fluoride-iodide slag remaining from the metal reduction stage are dissolved in nitric acid containing aluminum nitrate. The plutonium is then recovered either by direct extraction in tributylphosphate (TBP) diluted with kerosene, or extraction after an intermediate stage involving volume reduction by precipitation of the plutonium with calcium oxalate as carrier. Organic matter such as clean-up paper, rags, etc., are first incinerated and the residual ash is then treated as just described.

Oralloy turnings and oxide residues are dissolved in nitric acid and after two stages of precipitation with hydrogen peroxide, to insure high purity, the resulting uranium peroxide is converted mainly to U_3O_8 by heat and is then reduced by hydrogen to the dioxide, UO_2. The action of hydrogen fluoride gas converts this to the tetrafluoride and the metal is finally obtained by heating with calcium. Magnesium oxide crucibles, slag, and other residues are treated in a manner similar to that used to recover plutonium. The materials are dissolved in nitric acid with aluminum nitrate and the uranium is extracted by means of TBP in kerosene.

5.4 The Fission-Chain Initiator

b(3)

The Tom Initiator

The initiators in general use produce neutrons by the (α,n) reaction upon beryllium, with polonium as the source of the alpha particles (Section 1.5).

b(3)

UNCLASSIFIED

Fig. 5.8

b(3)

UNCLASSIFIED

Fig. 5.9

b(3)

Although the efficacy of the Tom initiator has been proven in several test explosions of complete bombs, a detailed study of some of its characteristics has been made.

Fig. 5.10

b(3)

UNCLASSIFIED

*The maximum rate of neutron production is 2.8 neutrons/μsec per curie of polonium, for the (α, n) reaction with beryllium.

UNCLASSIFIED

b(3)

Although the average rate of neutron production depends on the strength of the initiator, as expressed by the number of curies of polonium present, the actual emission is random in character, due to the nature of radioactive decay.

b(3)

b(3)

UNCLASSIFIED

b(3)

Another important drawback of polonium-beryllium initiators arises from the fact that polonium is a very serious radiological hazard. A lethal dose is a millicurie, i.e., 0.001 curie, weighing only 0.2 μgram, i.e., 2×10^{-7} gram. Polonium metal oxidizes readily and the oxide easily escapes into the air. Consequently, very great precautions must be taken to prevent entry of polonium into the body, particularly by inhalation.

Testing Tom Initiators

b(3)

Two main checks are performed, both at the time of acceptance and

during storage. The purpose of the first is to determine the strength in curies so as to make sure it lies within the acceptable limits. This is done by measuring the intensity of the gamma rays by means of a Geiger, or other, counter.

5.5 External Initiators

b(3)

[redacted]

One problem in the use of an externally activated initiator is that of precise timing. For this purpose, it is necessary to know the transit time of the bomb, from the triggering of the X-unit to the time the implosion shock wave reaches the center of the core.

b(3)

[redacted]

UNCLASSIFIED

b(3)

UNCLASSIFIED

The ENS Initiator

The new external initiator, called the ENS (Experimental Neutron Source), makes use of the fact that 14-Mev neutrons are released in the T-D reaction, between tritium and deuterium nuclei. However, the energy required to make the reaction take place is here supplied by accelerating tritium ions (tritons) in an electrical field; these high-energy ions then impinge upon, and react with, deuterium nuclei.

b(3)

Fig. 5.12

UNCLASSIFIED

b(3)

The total weight of the present ENS and time-delay unit is just over 100 pounds and its volume is about 2 cu. ft.

b(3)

The neutron yield of the ENS initiator is more than sufficient to meet these requirements.

The reliability of the ENS system has been proved in numerous tests, although it has not yet been used in an actual weapon.*

b(3)

5.6 Details of Gun-Type Weapons

Introduction

As previously indicated, the gun-type bomb was the first nuclear fission weapon considered and was also the first to be used in combat.

b(3)

*A definite development program aimed at the design and production of an externally initiated implosion weapon has been started.

b(3)

Although the various components could be treated in turn, as with implosion weapons, it is more convenient, in the present case, to consider each gun-type weapon model as a whole.

Since the LB (Little Boy) bomb is now obsolete, it will be referred to very briefly.

b(3)

The length of the LB was 128 inches, including the 32-inch tail, and its diameter, with its ballistic envelope, was 28 inches; it weighed 8900 pounds, largely due to the very massive steel case.

b(3)

The Mark 8 Weapon

b(3)

This figure also indicates some of the more important dimensional characteristics of the warhead of the bomb.

b(3)

UNCLASSIFIED

Fig. 5.13

b(3)

b(3)

UNCLASSIFIED

b(3)

Fully loaded weapons can be safely stored side by side in any relative positions. In flight, safing is achieved by tapes on the arming mechanism, which interrupt the pyrotechnic chain; these are pulled out before the bomb is dropped.

The Abner Initiator

b(3)

The initiator designed for the Mark 8 weapon is called the Abner, shown in section in Fig. 5.14.

b(3)

The

b(3)

close contact between the polonium and beryllium results in the occurrence of the (α, n) reaction and the emission of neutrons.

UNCLASSIFIED

b(3)

After impact tests of the Mark 8, no significant change was observed in the neutron background of the Abner initiator.

Prior to assembling the parts of the Abner, the uniformity of the polonium coating is checked by means of autoradiography, using a pinhole camera. The alpha particles from the polonium produce a blackening of the film, after development. This is inspected visually for obvious flaws and by means of a microphotometer to determine the degree of uniformity of the polonium coating. The inspection tests after assembly are similar to those described for the Tom initiator, namely, gamma-ray intensity measurement, to determine the strength in curies, and a neutron background count. The Abner is also examined radiographically by means of X-rays, to make sure that it has been assembled correctly.

The Mark 9 Weapon

The Mark 9 weapon is an atomic artillery shell; it was designed to burst in the air at a prescribed time after launching from a 280-mm gun.

b(3)

The over-all length is

UNCLASSIFIED

54.8 inches, and the diameter is 11 inches at the base; the total weight is 805 pounds, and its maximum range is about 26,000 yards.

UNCLASSIFIED

b(3)

The Mark 9 is said to be safe from the nuclear standpoint when immersed in or filled with water and in any position relative to another similar weapon.

b(3)

The temperature limits for storage are set at 110° to -40°F and 110° to -20°F for operation.

The Squab Initiator

b(3)

The initiator employed is called the Squab and two are used in each weapon for safety.

b(3)

UNCLASSIFIED

UNCLASSIFIED

b(3)

Fig. 5.15

In addition to the counting and other inspection tests, the Squab units are radiographed, by means of X-rays. These tests are essentially the same as those applied to the Abner initiator, as described above.

The TX-11 Weapon

b(3)

In addition, it must be capable of external carriage by an aircraft at high speeds. These requirements are achieved by certain mechanical modifications which need not be considered here. The TX-11 bomb will also have an improved fuzing system.

b(3)

UNCLASSIFIED

Fabrication of Gun-Type Weapon Components

The fabrication procedures for the projectile, target, and initiator are much the same as those used for the components of implosion weapons. The oralloy is first cast in vacuum, and then machined to the proper size.

b(3)

5.7 Critical Assembly Measurements

Determination of Critical Mass

b(3)

UNCLASSIFIED

However, these estimates must always be checked by critical measurements of the various partial or complete assemblies.

The approach to criticality is studied by determining the neutron multiplication in a number of subcritical assemblies. Although, by definition, a self-sustaining chain reaction is not possible in a subcritical system, there is nevertheless some neutron multiplication, as may be shown in the following manner. It was seen in Section 1.2 that if S neutrons are introduced into a fissile system, kS neutrons will be present after the first generation, k^2S after the

second generation, and so on. For a subcritical system k is less than unity, but for a just critical system k is unity. The total number of neutrons produced will then be the sum of S, kS, k^2S, etc., for all the generations.

If the system contained no fissile material, and there were no absorption, the injected neutrons would be unaffected, and the number present would be S. The ratio of the number of neutrons formed in the assembly containing fissile material to that in a similar system with no fissile material is called the neutron multiplication, M, and is given by

$$M = \frac{S + kS + k^2S + \cdots}{S} = \frac{1}{1 - k} \qquad (5.1)$$

Provided k is less than or equal to unity, so that the series is not divergent, the expression for M reduces to $1/(1 - k)$. For a subcritical system, i.e., $k < 1$, the value of M is finite and, in general, greater than unity. In other words, although a self-sustaining chain reaction is not possible, there is finite neutron multiplication before the chain dies out. For a critical system, k is unity, and the neutron multiplication, as given by equation (5.1), is then infinite.

For the determination of critical masses, it is more convenient to consider the reciprocal multiplication, i.e., 1/M, which, by equation (5.1), is given by

$$\frac{1}{M} = 1 - k \ . \qquad (5.2)$$

As long as the system is subcritical, 1/M is finite, i.e., it is greater than zero but less than one; when the system becomes critical, 1/M is zero. The neutron multiplication is observed for several subcritical systems containing different masses of fissile material and the observed values of 1/M are plotted against the masses. The extrapolated mass corresponding to $1/M = 0$ is then the critical mass under the given conditions.

The neutron multiplication is determined by placing a neutron source inside an assembly of active material of prescribed shape and of known mass, and measuring the rate of arrival of neutrons at a counter. The measurements are then repeated with the same source and counter using a similar assembly of inactive material, e.g., tuballoy. The ratio of the neutron counts in the two cases is proportional to the multiplication, M. Determinations of M are made for a number of assemblies of increasing mass, and then 1/M is plotted against the mass, as in Fig. 5.18. The extrapolated mass, for $1/M = 0$, is the critical mass. The apparent multiplication, as obtained in the foregoing manner, depends upon the position of the detector, but the 1/M values should always extrapolate to the same point, as indicated in the figure.

This procedure can be used to determine critical masses for both tamped (reflected)

UNCLASSIFIED

and untamped assemblies.

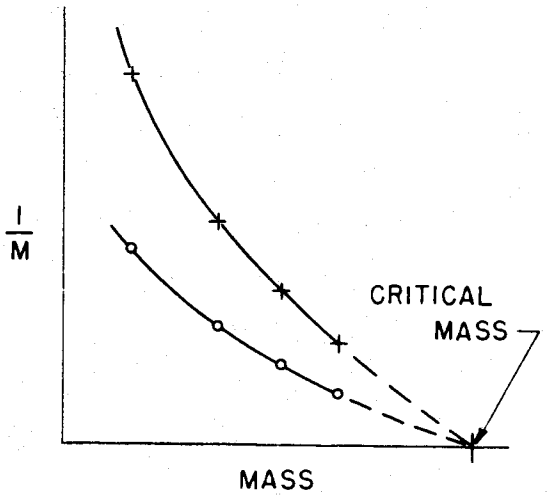

Fig. 5.18

[redacted] This number, required for efficiency estimates (Chapter 2), can be calculated from the available data.

Another aspect of critical experiments is to study safety measures to be used in the handling, fabrication, and storage of fissile materials. For example, the effect of water in causing criticality is investigated by means of paraffin, which has approximately the same neutron properties but is a solid. [redacted] Determinations are also made of the amounts of fissile material that can be safely melted, cast, or fabricated in various shapes.

The conditions for safe storage of weapons or weapon components are found by measuring what is called the cross multiplication. Suppose a number of cores (or weapons) are arranged at a certain distance apart, and the neutron multiplication in one of them, near the center of the array, is measured and found to be M_n. When all the other cores are removed, the multiplication in the same core is found to be M_1; then the cross multiplication, M_x, is defined by

$$M_x = \frac{M_n}{M_1} .$$

It is a measure of the effect on any one core of the surrounding cores. In order to be completely safe, the cores (or other components) should be separated by such a distance that the cross multiplication does not appreciably exceed unity. Then any one component is quite unaffected by the proximity of another one.

SECRET

UNCLASSIFIED

Determination of Alpha

As a measure of the neutron properties of a multiplying system, measurements are made of the multiplication rate, α, in various materials. However, instead of determining the rate of increase of neutron density with time, the rate of decrease, after fission, is observed. The initial rate is dependent on the same α as determines the increase of neutron density. Two methods for estimating α have been used. In the first, less convenient, procedure, which has hitherto been employed in only one experiment, a burst of neutrons is injected by means of a betatron (see Section 5.5) into an assembly that is between delayed and prompt critical. A large number of chains are thus initiated, and the prompt neutron decay rate is determined by means of neutron counters. From this decay rate the value of the (prompt) α for the given system can be calculated.

The alternative (Rossi) method makes use of a near (delayed) critical assembly, a single neutron being introduced at intervals, either by spontaneous fission or from a suitable source. Each (effective) neutron starts a chain, which soon dies out; then another chain is started and dies out, and so on for the duration of the experiment. Thus, instead of being subjected to the neutrons from a large number of chains almost simultaneously the counters are exposed over an appreciable period to neutrons from a large number of chains one at a time. The method is thus statistical in character.

The neutron counting is carried out by means of a 10-channel delay circuit. The first channel is activated by an initiating pulse corresponding to the entry of a neutron; then, after a pre-determined interval, the second channel is activated for a short time; then, after another interval, the third channel is activated, and so on for intervals ranging from 0.25 μsec to a total of a few milliseconds after initiation. From the accumulated counts for the various channels, the time rate of decay of the prompt neutrons after fission can be calculated and α determined.

The value of α obtained in this manner, with near delayed critical assemblies, differs from that which applies to the highly supercritical systems in a fission weapon. By finding experimentally how α varies with the mass of material, it is possible, in principle, to estimate the multiplication rate for supercritical masses. However, such data have not yet been applied in theoretical efficiency and yield calculations.

Chapter 6

Nuclear Weapons Tests

6.1 Purpose of Weapons Tests

Large-scale tests of assembled nuclear and thermonuclear devices are undertaken for many reasons. Some of these are: to proof-test a weapon or warhead before it enters the stockpile, as a check on the engineering, fabrication, and integration of the components into an effective whole; to test new designs of weapons and components before undertaking their fabrication; to test new principles and ideas which show promise for weapon developments; to provide information required to confirm or correct theoretical calculations and to enable further work to proceed, etc. The reasons may perhaps be summarized in the statement that the purpose of weapons tests is to check the efficacy of new designs of both components and assembled devices and to supply information that is essential for long-range improvements.

Although many basic data can be obtained in the laboratory and by calculation, there are numerous aspects of development work which require full-scale tests. [redacted]

[redacted] In addition, advances in the thermonuclear field are very largely dependent upon information that can be obtained in no way other than from an actual nuclear explosion. Such tests also provide opportunities for the development of new measurement techniques or for improving existing ones. Consequently, the testing of weapons and related devices is an important and continuing function, without which little progress could be made in weapons design and development.

Weapons test are sometimes performed for the purpose, direct or incidental, of studying the effects of atomic explosions on structures and materiel. Such information is required mainly for military planning and for civilian defense.

6.2 Atomic Proving Grounds

Introduction

The first test explosion of a nuclear weapon was made at Alamogordo, New Mexico (Trinity, 1945), and the next such operation (Crossroads, 1946), whose main purpose was to investigate the effect of atomic explosions on ships and their equipment, was carried out at Bikini in the Pacific Ocean. When it was decided, in the interest of safety, that no tests of nuclear weapons should be made within the continental limits of the United States, the Pacific Proving Grounds were established at Eniwetok Atoll. They were first used for Operation Sandstone in the Spring of 1948, and subsequently for Operations Greenhouse (Spring, 1951) and Ivy (Fall, 1952). The Castle tests (Spring, 1954) will also be conducted in the Pacific.

SECRET

UNCLASSIFIED

SECRET

UNCLASSIFIED

Because of the difficulties and delays associated with operations at a remote location, and because certain information was needed urgently for Operation Greenhouse, the decision not to test nuclear weapons within the continental United States was later rescinded, and the Nevada Proving Grounds were developed. The first tests (Operation Ranger) were made there during the early part of 1951. Since that time, tests involving devices of relatively low energy release have been performed, as far as possible, in Nevada, whereas devices for which large yields are expected are tested at the Pacific Proving Grounds. The operations carried out at Nevada, after Ranger, were Buster-Jangle (Fall, 1951), Tumbler-Snapper (Spring, 1952), and Upshot-Knothole (Spring, 1953).

Nevada Proving Grounds

The Nevada Proving Grounds are rectangular in shape, measuring 40 miles from north to south and 16 miles from east to west, located in southern Nevada. Within this area are two alluvial valleys or "flats," namely, Frenchman Flat and Yucca Flat (Fig. 6.1), with moderately level surfaces of loose dust and gravel. It is in these flats that the target areas are located; these areas can be used for tower shots, i.e., for devices which are detonated at the tops of towers, generally 300 ft. high, or for air bursts, i.e., weapons dropped from aircraft or shot from a gun. Areas F, in Frenchman Flat, and 9 and 10 have been used for weapons effects shots, as well as for development tests.

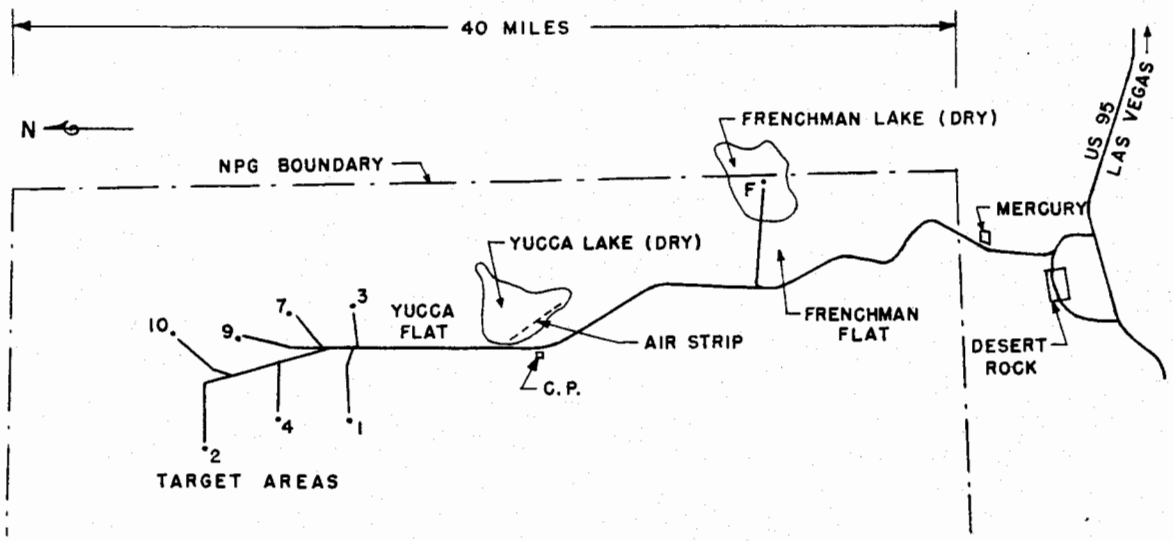

Fig. 6.1

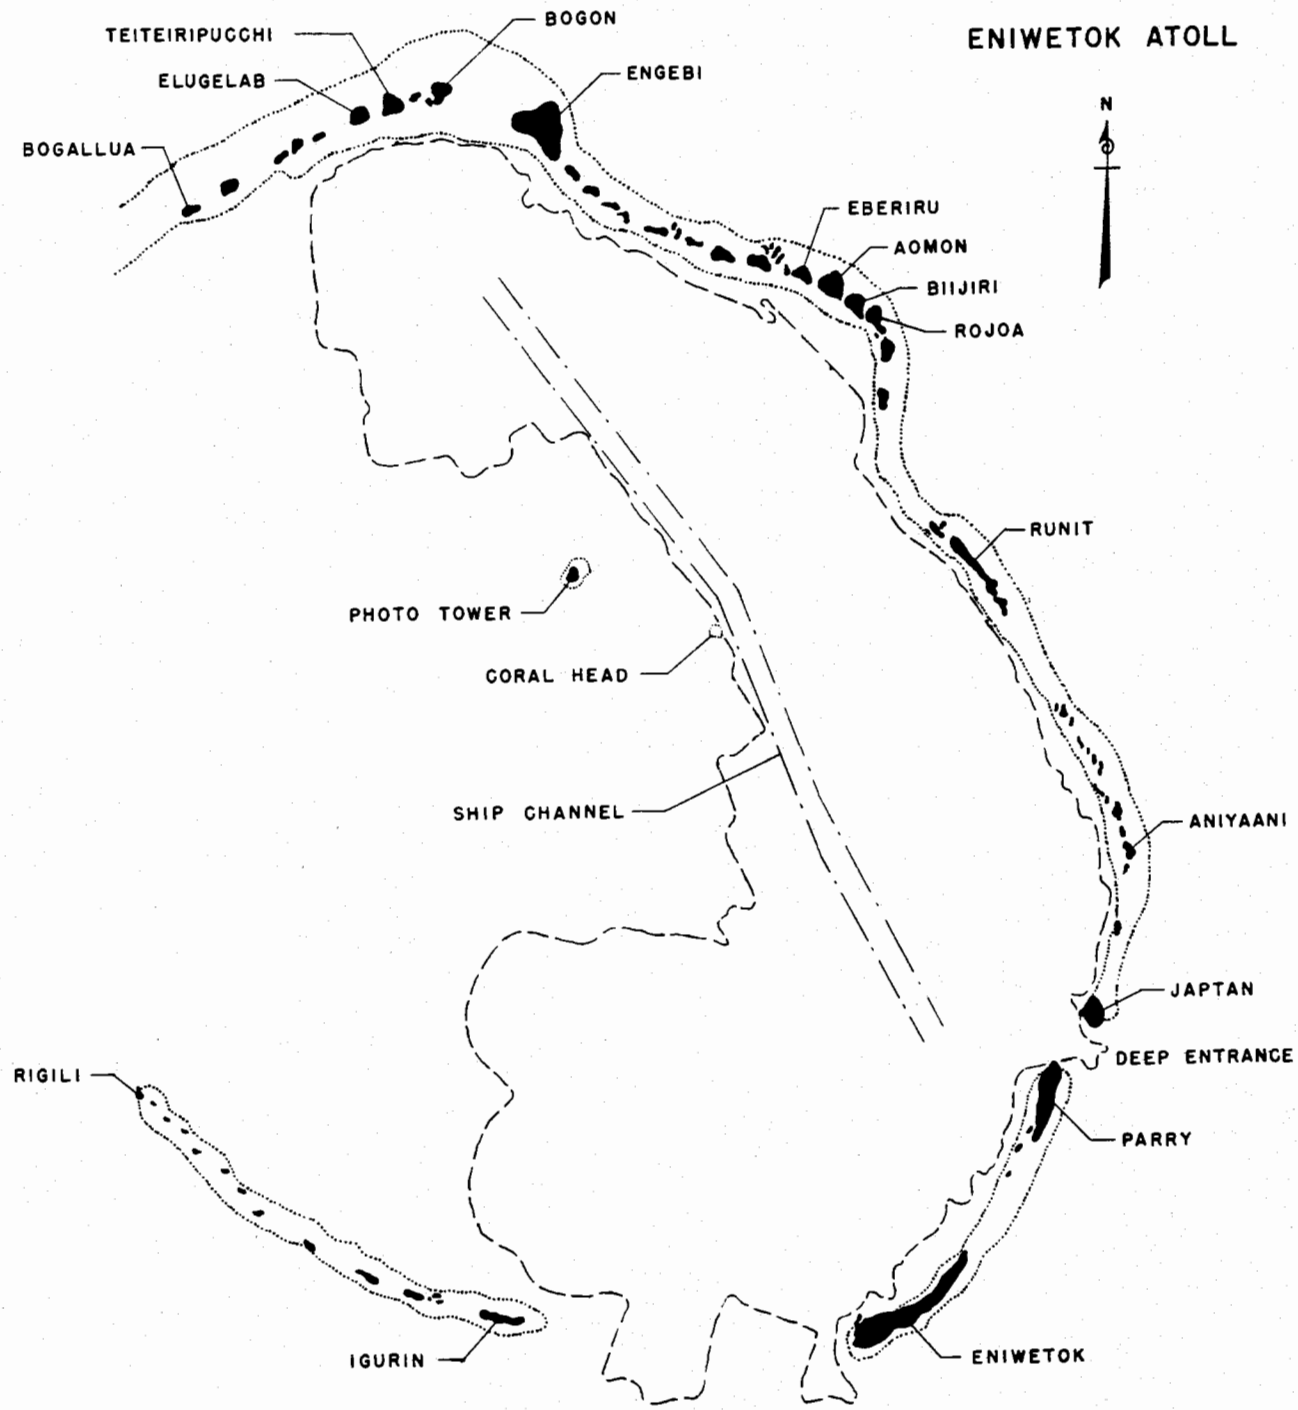
UNCLASSIFIED

SECRET

The Control Point (C.P.) area is located between Frenchman and Yucca Flats near the Yucca (dry) Lake. Here are a number of structures, including the control building where timing and firing signals originate. This building also houses the office of the test director and his staff, the weather service, and various scientific, electronic, and machine shop facilities. The Rad-Safe section, which is responsible for radiological safety operations, including personnel monitoring and decontamination, occupies another building in the C.P. area.

Associated with each of the target areas are a number of concrete shelters, usually underground and covered with protective mounds, for various instruments required to study the phenomena accompanying the nuclear explosions. These shelters are built to withstand shock and to protect the instruments from damage and film from radiation exposure; hence, they are of a relatively permanent character. The distance of the instrument shelter from the zero point is determined by the needs of the particular measurement to be made; it usually represents a compromise between the increased cost of long cables if the distance is large and of the heavier structure required if the distance is short. The instrument shelters are provided with power supply, cables to the target area zero point, timing signals, and various other facilities. Most of the equipment is activated by remote control, utilizing relays energized by signals from the central timing system.



The local headquarters for several organizations connected with NPG activities are at Mercury, Nevada, just outside the southern boundary of the Proving Grounds proper. Various administrative offices are located there, and offices and laboratory facilities are available for experimental groups in some thirty quonset huts. Living quarters are provided at Mercury for civilian and military personnel engaged in the test operations. Military personnel receiving tactical orientation are quartered at Camp Desert Rock, about three miles southwest of Mercury.

Pacific Proving Grounds

The Pacific Proving Grounds include the Eniwetok (Fig. 6.2) and Bikini Atolls (Fig. 6.3); although the latter has not been used since Operation Crossroads in 1946, new facilities are being installed for the Castle tests in 1954. The two atolls are about 180 miles apart, and communication between them is maintained by air, sea, telephone, and radio. These atolls, which are from 13 to 25 miles across, consist of more or less circular groups of small coral islands, covered to varying depths with coral sand. As a general rule, the individual islets are connected by a coral reef, although much of this may be submerged even at low tide. There are, however, gaps in the reef through which ships may enter the lagoon.

The test operations at the Pacific Proving Grounds are performed by a task force composed of scientific and military personnel whose headquarters are located on Parry Island or aboard ship. Living accommodation is provided on Eniwetok and Parry Islands, although during

an operation some personnel may spend most of their time in temporary camps on other islands where tests are being made.

Different islands are selected as target areas, according to circumstances. For example, Engebi, Aomon, and Runit were used for Sandstone; Engebi, Eberiru, and Runit for Greenhouse; and Elugelab and Runit for Ivy. In Castle it is planned to detonate some test devices over water in the lagoon. Instruments are located in shelters, similar to those at NPG; these may be on the target island itself or on an adjacent island. In addition, photo-towers for cameras are spread throughout the atoll. At Eniwetok the timing and firing signals originate from Parry Island, and at Bikini from Enyu Island. The signals are transmitted by cable or by radio according to circumstances, partly determined by distance and the importance of the experiments.

Because of the climatic and other conditions at the Pacific Proving Grounds, instrument shelters are primarily designed for use in a single test. Nevertheless, they may serve for several tests if they are in operative condition. In general, the facilities available are similar to those outlined above for the Nevada Proving Grounds.

6.3 Nuclear Explosion Phenomena

The Ball of Fire

In order to understand the significance of some of the measurements made in the course of weapons tests, it is desirable to review briefly certain phenomena associated with a nuclear explosion. After the initial stages of radiation flow and its cessation, when the temperatures are much higher, the bomb material will be at a more or less uniform temperature of about $1,000,000^{\circ}K$, i.e., 0.08 kev. In this condition there is a considerable emission of energy as electromagnetic radiations covering a wide range of wave lengths, from infrared (thermal) or longer, through the visible to the ultraviolet and beyond. Much of this radiation is absorbed by the air immediately surrounding the bomb, with the result that the air itself becomes heated to incandescence. In this condition, the detonated bomb begins to appear, after a few microseconds, as a luminous ball of fire.

As the ball of fire grows, and its temperature falls to about $300,000^{\circ}K$, at about 0.1 to 1 millisec after detonation, a shock wave develops. At first, the shock front coincides with the radiation front, but as the temperature falls, the (luminous) shock wave moves ahead of the radiation. The reasons why the shock front travels more rapidly than radiation under these conditions is somewhat as follows:

In a vacuum radiation photons travel with the speed of light, but as the high energy photons move forward into the air, they are likely to be captured by the molecules (or atoms) present. The resulting excited molecules (or atoms) retain their excess energy for a time and

then emit it as another photon of the same, or slightly different, energy. If the mean free path, i.e., the distance between successive captures, of a high-energy photon is taken to be 0.01 cm, and the life of the excited molecule is 10^{-8} sec, then the effective speed of the photon is about 10^6 cm per sec. But since the emitted photon moves off in a random direction, the rate of forward motion, i.e., in the direction the radiation is propagated, will be considerably less. In fact, it will be less than the velocity of the shock front at the high temperatures and pressures existing in the ball of fire.

Since the shock front is luminous, the diameter of the ball of fire, as seen by the (protected) eye or by a camera, is determined by the motion of the shock wave. The lagging radiation front is not seen because of the high luminosity of the surface of the ball of fire. As the shock wave expands, the ball of fire is observed to grow rapidly in size for about 20 to 100, or so, millisec, depending on the yield of the bomb. At the same time, the surface temperature continues to fall, and when it reaches about 2000°K, the shock front is no longer luminous.*

From roughly this point on, the apparent size of the ball of fire is determined by the radiation front which may now be visible, or by air heated by shock passage. The rate of increase of diameter with time is less than before, since the radiation front still advances more slowly than the shock front. Hence, the invisible shock front continues to travel ahead rapidly; after 1 sec it may be some 600 yards beyond the ball of fire and after 10 sec it may have advanced two miles or more.

The point at which the (invisible) shock front moves ahead of the (visible) ball of fire is call the "breakaway." As stated above, the surface temperature of the ball of fire is then about 2000°K. However, the temperature of the radiation front is considerably higher, and as this begins to replace the rapidly cooling and advancing shock front, the surface temperature of the ball of fire apparently increases once again. This effect may be enhanced by a decrease in the opacity of the air. The apparent surface temperature thus rises until the temperature of the hot core, i.e., about 7000°K, is attained, and it then falls steadily due to cooling of the gases by radiation and by expansion.

The variation of the surface temperature (T) of the ball of fire and its apparent radius (R) after the nuclear explosion, is indicated in Fig. 6.4, in which both scales are logarithmic. The breakaway point corresponds to the first minimum in the temperature curve, after which the surface temperature rises, as stated above. It is seen, from the marked change in direction of the R curve, that the ball of fire grows at a much less rapid rate after the breakaway point. The luminosity (or radiation flux per unit area) of the ball of fire depends on the

*Times and temperatures given in this and the succeeding paragraphs vary with the yield of the weapon. They are particularly applicable, however, to weapons with yields in the range from about 10 to 100 kt.

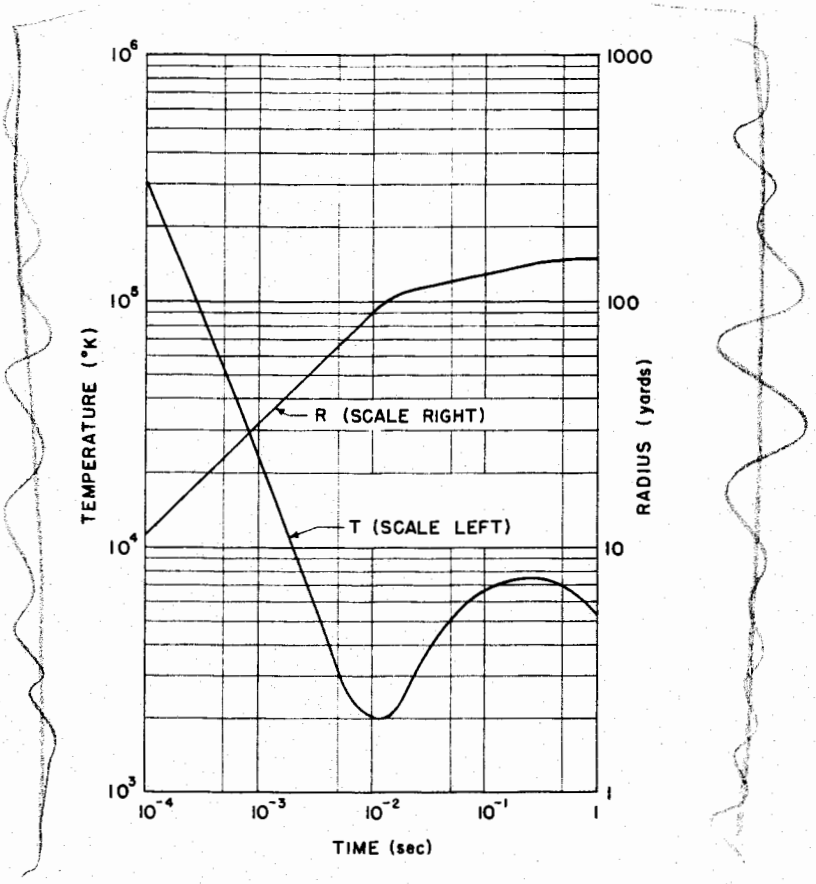

Fig. 6.4

surface temperature, being roughly proportional to T^4, at a given distance. It follows, therefore, that after the explosion the luminosity will first decrease to a minimum at the breakaway, increase to a maximum, and then gradually fall off to zero in the course of time.

It may be mentioned that various oxides of nitrogen are formed in the air surrounding the ball of fire and they have some influence on its luminosity. Above 5000°K these oxides are almost completely dissociated into atoms, but below this temperature some nitrogen dioxide, which is a brown gas, is formed. This undoubtedly contributes to the decrease in luminosity just before the breakaway. Molecules of gaseous nitrous acid have a similar effect.

At least for as long as the ball of fire is visible, it emits what is generally called prompt or effective thermal radiation, although it covers a considerable range of wave lengths. After traveling an appreciable distance in air, however, almost all radiations of wave lengths less about 3000 Å are absorbed. The proportion of the bomb energy liberated in the form of effective or prompt thermal radiation varies with the yield, as will be seen later.

Atomic Cloud and Fall-out

When the ball of fire has cooled appreciably, the vapors of fission products and other bomb residues condense to form a smoke made up of small solid particles having a range of sizes. This, together with any dirt or sand that may have been sucked up from the earth's surface, ultimately forms the atomic cloud. The rate of ascent of the cloud column depends upon the metorological conditions. At first it climbs rapidly, reaching an altitude of 10,000 ft in less than a minute, but later it slows down, so that the maximum height, of about 40,000 to 60,000 feet, may be attained in 10 minutes or so. The actual times and heights are determined by the energy release of the bomb as well as by the atmospheric conditions, but the values quoted may be taken as more or less typical.

Upon entering a region where the density of the atomic cloud is the same as that of the surrounding air, e.g., when the base of the stratosphere is reached, where the temperature of the atmosphere is almost constant and there is practically no motion due to convection, the cloud will spread out for a distance of several miles and form the characteristic mushroom shape. This is ultimately dispersed by winds into the surrounding atmosphere. If, in its ascent, the atomic cloud column should pass through a temperature inversion layer, it will tend to "mushroom" out horizontally to a small extent, but the main movement will still be upward, until the conditions are suitable for the extensive spreading just described.

When the cloud particles, which consist chiefly of highly radioactive oxides of fission products, uranium, etc., collide with particles of dirt they generally adhere. The resulting radioactive particles gradually fall back to earth, giving rise to the phenomenon known as "fall-out." The extent and nature of the fall-out depend on various circumstances associated with the height at which the nuclear device was detonated, the nature of the terrain, and the meteorological conditions. The importance of the fall-out lies in the fact that it may constitute a radiological hazard.

Gamma Radiation

Although gamma-ray emission accompanies the actual fission process, it is probable that this particular radiation is largely absorbed in the heavy bomb material, so that only a very small proportion escapes. However, within a very short time, usually a fraction of a microsecond, depending on the bomb model, gamma rays are produced by indirect or secondary processes. The two most important are due to the neutrons liberated in fission. First, there are the (n,γ) or radiative capture reactions, in which neutrons are captured by nuclei present in the bomb residues, followed by the emission of gamma rays. In addition, inelastic scattering of fast fission neutrons by heavy, e.g., uranium, nuclei also results in the production of high-energy gamma radiation. It is these secondary radiations which constitute at least the whole of what is called the "prompt" gamma rays associated with a nuclear explo-

The gamma rays liberated after the first few microseconds are referred to as "delayed" gamma rays. These radiations may be divided into two categories. Up to about 0.3 sec after the explosion, the delayed gamma rays are due mainly to (n,γ) captures by nitrogen of the air. The gamma rays produced in this manner have high energies, chiefly in the range from 5 to 8 Mev; at distances greater than 2,000 yards from the explosion they may make the major contribution to the gamma radiation received from a fission weapon.

The second category of delayed gamma rays is made up of radiations of lower energy (2 to 3 Mev) emitted in the radioactive decay of the fission products, especially those of short life, present in the ball of fire and in the atomic cloud. Although the delayed gamma radiation is actually formed, with decreasing intensity, over a long period of time, it is generally assumed, for practical purposes, that the emission lasts for a minute or so. In the first place, the fission products of very short life, which make the major contribution to the gamma radiation immediately after the explosion, will have decayed almost completely in this time. Further, by the end of a minute, or less, the radioactive cloud will have attained a height of some 2 miles, as indicated above, so that the delayed gamma radiation is attenuated to negligible proportions before it reaches the ground. The transmission of gamma radiation from the fission products is strongly affected by the hydrodynamics of the shock wave which removes a large proportion of the air between the bomb and detecting instruments on the ground.

Emission of Neutrons

The great majority of the neutrons liberated in a nuclear explosion are the prompt neutrons emitted simultaneously (or almost simultaneously) with the fission process itself. There are, in addition, the delayed neutrons, constituting less than 1 per cent of the total (Section 1.2), but these are of little significance in the present connection. However, even though the neutrons which succeed in leaving the detonated bomb originate as prompt neutrons, there is some delay in reaching the earth's surface.

It was seen above that some of the fission neutrons are captured in the bomb material and others undergo inelastic collisions and thereby have their energy decreased, i.e., they are slowed down. A few fast neutrons succeed in escaping, but the others are slowed down to some extent by elastic collisions with the light elements present in the HE system. The (relatively) slow neutrons are temporarily trapped here, but as the shock wave moves outward from the core, the material is dispersed and the neutrons escape into the surrounding air. The transport of the slow neutrons through space is thus strongly affected by the shock wave. In their diffusion through the atmosphere, some of the neutrons are slowed down still further and may then be captured by nitrogen nuclei.

Because of the various possible scattering processes which they may undergo, the neutrons

reaching a detecting instrument on the ground will cover a large range of energies. The distribution of the neutrons in this manner is referred to as the neutron spectrum. Those neutrons which have not been scattered have high energies, e.g., 3 Mev or more; others have energies in the intermediate range, while the great majority are slow neutrons. However, because of capture by nitrogen nuclei, very few have energies below about 0.2 ev.

b(3)

The proportion of neutrons produced in fission with energies as high as 14 Mev is very small, but if the D-T reaction is involved, a considerable number of neutrons of this energy will be detected.

6.4 Diagnostic Tests

Determination of Transit Time

A very great variety of measurements are usually made for each test shot, many of which depend upon the particular information required. However, for essentially all fission weapons the so-called standard diagnostic tests are made; these are the determination of the over-all transit time, the multiplication rate (α), and the energy yield of the device. Although yield measurements are always made, determinations of transit time and α are sometimes omitted. Apart from providing useful practical information, the results of the diagnostic tests serve to check theoretical estimates and to supply data upon which further calculations may be based.

For the measurement of the over-all transit time, i.e., from the instant of firing the detonators to the explosion time, two general methods have been used. In the case of a tower shot, a signal is sent over a coaxial cable to a distant cathode ray oscilloscope when the X-unit is fired. The first gamma rays to appear outside the bomb are picked up by a scintillation detector and a second signal is transmitted by cable to the oscilloscope. After making allowance for the difference in lengths of the cables and the time taken for the gamma rays to reach the detector, the transit time of the bomb can be determined from the separation of the two signals.

The procedure described above, which requires cable connections to the X-unit, cannot be used for an airdrop, and in this event the remote method is employed. A radio transmitter, operating at low power, e.g., about 20 watts, is attached to the bomb case. When the X-unit is fired, the output is instantaneously raised to several hundred watts, so that the signal can be detected at a distance and recorded on an oscilloscope. This continues until the intense ionization of the atmosphere, referred to as the "ion curtain," in the vicinity of the bomb, due to the gamma radiation, prevents further propagation of the radio signal. The level at which

this transmission is cut off is not known exactly, but it is believed to be at about the 30th generation, or so. Allowance for this delay is made in estimating the transit time from the duration of the radio signal. If the generation time is relatively long, e.g., for low values of α (Section 1.4), this correction may involve an appreciable error.

Determination of Alpha

Until recently, only one satisfactory method was available for determining the multiplication rate, α; it was based on a measurement of the time-dependence of the prompt gamma rays over a period of about 1 μsec. It can be seen from equation (1.16) that α can be determined if the neutron density, n, in the exploding bomb is known as a function of time. As seen above, the prompt gamma rays are produced, almost entirely, by the action of neutrons within the bomb. Hence, the prompt gamma-ray intensity, fairly close to the bomb, may be taken as being proportional to the neutron density. Consequently, α can be readily calculated from the variation of the prompt gamma rays with time.

Originally large (Rossi-type) ion-chambers, having a fast response, were used to detect the gamma rays, but these have now been replaced by scintillation detectors. The latter are located near the bomb, in the case of a tower shot, and long coaxial cables connect them to the horizontal plates of an oscilloscope. A constant, high-frequency sinusoidal signal applied to the vertical plate supplies a timing record. The oscilloscope trace is photographed and then analyzed to give the time dependence of the prompt gamma-ray intensity. By the use of additional cable, the gamma-ray signal is delayed, so that an intensifier pulse to the oscilloscope can build up and thus permit the trace to be photographed.

In order to cover the large range of intensity, several scintillation detectors may be placed at various distances from the bomb. A common timing system is sometimes used for all the oscilloscopes to which they are connected. The detectors nearest to the explosion record the lower intensities of gamma radiation, whereas those which are more remote indicate the higher intensities. Proper allowance is made, of course, for the attenuation with distance.

For an airdrop the scintillation detectors cannot be placed near the bomb. Consequently, they are located on the ground at known distances from the assumed detonation point. Because of the absorption of the radiation, the intensities at the detectors are relatively small and for high bursts amplifiers may have to be used.

b(3)

Another procedure for obtaining α, which avoids destruction of the detectors, etc., and can be used either for tower shots or airdrops, was first tried out at Operation Sandstone, but did not reach a satisfactory state of development until the Upshot-Knothole test in 1953. One

of its great advantages is that measurements can be made at a distance of 10 miles or so, where the instruments are under direct control, and no coaxial cables are necessary.

When the prompt gamma rays are degraded in energy and absorbed by the air around the bomb, they produce a luminosity, called the Teller light. The intensity of this light is proportional to that of the prompt gamma rays and, consequently, to the neutron density.

b(3)

[redacted] It is essential that the only light measured should be that coming directly from the bomb to the observer.

In one arrangement for recording the luminosity at very low levels, without the necessity of amplification of signals, the Teller light from the bomb is reflected by a mirror system (Fig. 6.5) and falls on the photomultiplier tube. This is placed as close as possible to the deflecting plates of a cathode-ray oscilloscope tube in a light-tight box. The timing and delay circuits are analogous to those used in the method already described. To provide a wide field of view, the mirrors are in duplicate; consequently, a moderate change in the expected position of the exploding bomb will not affect observation of the Teller light.

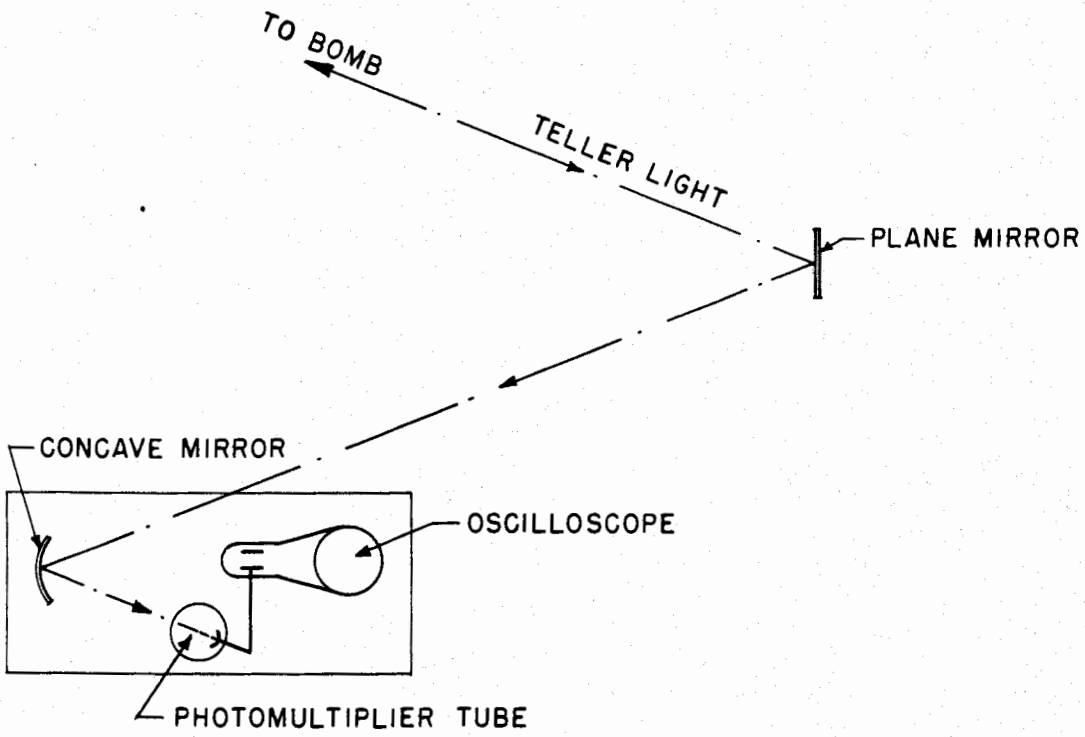

Fig. 6.5

6.5 Determination of Yield

Introduction

The efficiency, ϕ, of a fission device may be expressed as the ratio of the actual number of nuclei undergoing fission to the total number of fissile, i.e., uranium-235 or plutonium-239, nuclei present in the core (Section 2.1). If this is multiplied by the energy which would be obtained by the fission of all fissile nuclei, the result would give the total energy yield.

Something like ten or more different methods, of varying degrees of accuracy, can be used to determine the yield of a nuclear explosion. Two of these, namely, the radiochemical procedure and the ball of fire method, have been generally employed for diagnostic purposes, the others being mainly of secondary interest. Until 1953, the radiochemical method was the only one which gave an absolute value of the yield, and the ball of fire (and other) measurements had to be calibrated empirically with radiochemical data. An important recent advance has been the development of an absolute procedure for calculating yields from ball of fire measurements.

The Radiochemical Method

The efficiency of a nuclear explosion, as defined by equation (2.1), may be written in the equivalent form

$$\phi = \frac{\text{Total number of fissions}}{\text{Number of fissile nuclei in core}} = \frac{F}{U + P} \qquad (6.1)$$

where

F = Total number of fissions (or number of nuclei undergoing fission)

U = Number of U-235 nuclei originally present in core

P = Number of Pu-239 nuclei originally present in core.

It should be noted that whereas F, in the numerator of equation (6.1), includes fissions in all species that may be present or formed in the explosion, e.g., uranium-238, plutonium-240, etc., the quantities U and P in the denominator refer only to the fissile nuclei in the core; uranium-235 present in tuballoy (natural uranium) is not included, neither is any uranium-238 that may undergo fission. Thus, in principle, an efficiency greater than unity is possible, according to the definition given above. *

Suppose that after the explosion a representative ("post-shot") sample of the bomb residues is recovered. By analysis for certain fission products, as described below, it is possible to

*The quantity defined here is sometimes called the "bomb efficiency" to distinguish it from the "core efficiency," i.e., when F = number of fissions in U-235 and Pu-239 only.

determine the number of fissions that have occurred in the sample. Let

f = number of fissions corresponding to sample analyzed

θ = fraction of bomb in sample analyzed,

then

$$f = \theta F, \tag{6.2}$$

and, upon combining equations (6.1) and (6.2),

$$\phi = \frac{f}{\theta(U + P)} \cdot \tag{6.3}*$$

Since U + P may be regarded as known, the determination of the efficiency and yield of a nuclear explosion is reduced to the estimation of f and θ for a given post-shot sample (or samples).

The measurement of f involves the chemical separation of a particular fission product from the sample of bomb residues and the determination of the amount present by means of its radioactivity. The measured activity of the specified fission product is corrected for decay during the time which has elapsed since the nuclear explosion and for possible losses in the chemical separation; if A is the resulting corrected activity, expressed as the rate of particle emission, then it can be shown that

$$A = \epsilon\lambda y f, \tag{6.4}$$

where

ϵ = counter efficiency, i.e., fraction of particles emitted which are actually counted

λ = radioactive decay constant of the fission product

y = yield of the given product in fission.

Although λ and y are known, with moderate accuracy, and ϵ can be measured, it is more convenient to combine $\epsilon\lambda y$ into a single factor. This can be determined by subjecting a small quantity of uranium-235 or plutonium-239 to the action of neutrons, of known density, so that the number of fissions induced can be calculated. Thus, f for a given sample is known. The specified fission product is then separated chemically and counted, so that the activity, A, is measured. Then, from equation (6.4), the corresponding value of $\epsilon\lambda y$, for the particular counter, fission product, and fissile material, can be obtained.

*The symbols used throughout this section are those commonly found in J-Division reports, with two exceptions: the efficiency is represented here by ϕ, as is customary in other LASL reports, and θ is employed for the fraction of bomb in the sample. The J-Division symbols are E and ϕ, respectively.

UNCLASSIFIED

The fission products which have been used most extensively in efficiency measurements are molybdenum-99 (half life 67 hours) and zirconium-97 (half life 17 hours). These isotopes have convenient half lifes, and their fission yields, which are among the largest, are not greatly dependent upon the energy of the neutrons causing fission. The λy values for molybdenum-99 are almost identical for fission of uranium-235 and plutonium-239, so that no correction is necessary if the bomb core contains both of these fissile species. For this and other reasons, molybdenum is the preferred isotope. For zirconium, the λy's are slightly different and the value used to determine f depends upon the composition of the core.

The fraction θ of the bomb in the post-shot sample can be determined by analyzing for one of the major constituents, e.g., uranium-235, plutonium-239, or total uranium, and correcting for the amounts lost in nonfission reactions, such as (n,γ), (n, 2n), etc. Since the total amount of each of these species present in the original bomb is known, the fraction of the bomb in the sample can be calculated.

Another method for determining the fraction of the bomb in the post-shot sample makes use of a different principle. A radioactive tracer, in known amount, is included in the bomb before detonation. If the quantity present in the post-shot sample is then measured, the fraction of the bomb in the sample can be calculated. The supposition is here, of course, that the tracer is uniformly distributed throughout the whole of the bomb residues, and this may not be the case. Measurements of this kind have been made with polonium-210 as tracer, but with indifferent success. Nevertheless, it is proposed to make further determinations with this isotope and also with curium-242 as tracer.

Determination of Fraction of Fissions in U-235, Pu-239, and U-238

It is of interest to know what proportion of fissions has occurred in uranium-235, plutonium-239, and uranium-238, respectively. Radiochemical methods have been developed for this purpose, although they are not too accurate. The fraction of the total fissions involving uranium-235 is represented by a, the fraction in plutonium-239 by b, and that in uranium-238 by c, so that

$$a + b + c = 1. \qquad (6.5)$$

Hence, if any two of a, b, c are determined, the third is known.

The value of c can be obtained by utilizing the experimental fact that the ratio of the cross section for the U^{238} (n, 2n) U^{237} reaction to that for the fission of uranium-238 is roughly constant, independent of neutron attenuation in the uranium. Hence, if the amount of uranium-237 in the bomb residue sample is measured, by means of its radioactivity, the number of uranium-238 nuclei which have undergone fission, and hence, c, can be calculated.

UNCLASSIFIED

The determination of a and b is possible, in principle, if there are available two fission products which have very different yields (or activities) for the fission of uranium-235, plutonium-239, and uranium-238. Let

R_{25} = ratio of activities for U-235 fission

R_{49} = ratio of activities for Pu-239 fission

R_{28} = ratio of activities for U-238 fission,

so that the observed activity ratio, R, is given by

$$R = aR_{25} + bR_{49} + cR_{28}. \qquad (6.6)$$

Since $a + b + c = 1$, then, if the three activity ratios, R_{25}, R_{49}, and R_{28}, have been determined, any two of the fractions a, b, c, can be calculated provided the third is known. For weapons containing only uranium-235 or plutonium-239 as the fissile material, the problem is, of course, simplified.

Of the pairs of isotopes that may be used in the foregoing connection, one is always chosen to be molybdenum-99; the other may be silver-111, palladium-112, cadmium-115, or cerium-136. Although the method is sound, in principle, it has not yet given satisfactory results. This is believed to be due to a partial separation (or fractionation) of the elements present in the fission products. Consequently, the post-shot samples do not always have the same composition as the bomb residue as a whole. Such is not the case for molybdenum-99, and that is one reason why this isotope is much used in yield determinations.

Provided c is known, a and b can be calculated if the measured ratio of uranium-235 to plutonium-239 in the post-shot sample is compared with the known ratio in the original bomb. This method involves corrections for the amounts of these two isotopes lost in nonfission reactions, as well as for the formation of plutonium-239 as a result of neutron capture by uranium-238, followed by two stages of beta decay.

In a test shot the fraction a can be measured by incorporating into the oralloy an indicator, such as titanium, thorium, thallium, or tungsten. The titanium and thorium react with fast neutrons, i.e., $Ti^{47}(n,p)\ Sc^{47}$ and $Th^{232}(n,2n)\ Th^{231}$, respectively, whereas the thallium and tungsten capture slow neutrons, i.e., $Tl^{203}\ (n,\gamma)\ Tl^{204}$ and $W^{186}\ (n,\gamma)\ W^{187}$ followed by $W^{187}\ (n,\gamma)\ W^{188}$, to form characteristic, identifiable products. By assuming that the uranium-235 and the indicated isotope have been subjected to the same neutron flux, it is possible, from a determination of the product formed and the known cross section of the reaction, to calculate the number of uranium-235 nuclei which have undergone fission.

Somewhat analogous procedures can be used to determine b, except that, as in the method described above for c, the indicator or detector species is already present. In addition to undergoing fission, plutonium-239 is involved in the reaction Pu^{239} (n,γ) Pu^{240} Consequently, if the amount of plutonium-240 present in a post-shot sample is determined, and allowance made for the proportion in the original plutonium and the amount lost in various neutron reactions, the number of plutonium-239 fissions can be calculated. It is of interest to note that the plutonium-240 is determined with a mass spectrograph rather than by its radioactivity. The alpha particles from the 240-isotope are not easily distinguished from those emitted by plutonium-239 because of their similar energies.

Another reaction for determining b is Pu^{239} (n, 2n) Pu^{238} with fast neutrons. In this case, the amount of plutonium-238 in the bomb residue sample can be estimated from its alpha radioactivity since the particles can be resolved from those emitted by the other plutonium isotopes.

The plutonium used in weapons invariably contains some plutonium-241 as an impurity; this is a beta-particle emitter with a half life of 14 years, the decay product being americium-241, half life 470 years. It is seen, therefore, that the plutonium components of bomb cores which have been stored for some time will contain appreciable amounts of americium-241. In the exploding bomb, the latter will undergo the reaction Am^{241} (n,γ) Am^{242}, followed by beta decay of the americium-242 to form curium-242. The curium-americium ratio in the post-shot sample will thus be roughly proportional to the amount of fission which has occurred in the plutonium-239.

Sample Collection

The collection of representative samples for radiochemical analysis after a nuclear explosion has proved to be quite a difficult matter. For reasons not clearly understood, fractionation occurs in the highly complex system, so that a particular portion of the bomb residue may not have the same composition as the average of the whole. In addition to the requirement that the post-shot sample shall be representative, it must be of sufficient size to make accurate analysis possible; it must not be contaminated during collection, and it must be capable of relatively rapid recovery and delivery to the laboratory.

Various methods of sample collection have been tried out at one time or another; the most satisfactory results have been obtained either by the use of drone aircraft guided through the atomic cloud after an explosion or by means of manned aircraft flying into the cloud. The samples collected are of two types: "snap" samples in which a container is filled with essentially gaseous material, and particulate samples obtained by drawing the air and other gases through a filter. The mission of the manned aircraft is planned so as to give satisfactory samples with minimum radiation exposure of the crew.

Attempts have been made to collect post-shot samples in specially equipped rockets fired through the atomic cloud or in heavy bottles placed on the ground so that they are enveloped in the ball of fire. Neither of these, however, has proved as successful as the methods based on the use of drone or manned aircraft.

Efficiency of Thermonuclear Devices

In an explosion of a device involving both fission and thermonuclear reactions, the procedures described above will give only the fission yield. The thermonuclear yield may perhaps also be obtained by radiochemical methods, but the techniques are still in the early stages of development. The basic principle is to determine the density of the 14-Mev neutrons produced by the D-T reaction (Section 1.6) and the result can then be employed to calculate either the amount of burn-up of the hydrogen isotopes or the energy released in the thermonuclear reactions.

To achieve this end, a threshold neutron detector is included in the device. This is an element that reacts with neutrons with energies in excess of a certain threshold value, thereby forming a radioactive product whose amount can be determined by particle counting. Some of the reactions which have been proposed for this purpose and the neutron energy thresholds are quoted in Table 6.1. If essentially only the 14-Mev neutrons are to be detected, then the energy threshold of the detector should be as close to this value as possible.

Table 6.1 Internal Threshold Detectors

Element	Reaction	Threshold (Mev)
Nickel	Ni^{58} (n, 2n) Ni^{57}	11.7
Arsenic	As^{75} (n, 2n) As^{74}	10.4
Scandium	Sc^{45} (n, 2n) Sc^{44}	11.2
Germanium	Ge^{70} (n, 2n) Ge^{69}	11.5
Rhodium	Rh^{103} (n, 2n) Rh^{102}	~ 10
Sodium	Na^{23} (n, 2n) Na^{22}	~ 11
Thallium	Tl^{203} (n, 2n) Tl^{202}	~ 8

The choice of suitable detectors for 14-Mev neutrons has been somewhat restricted by the necessity for the products to be distinguishable from the normal fission products. However, studies are being made of certain elements falling in the fission product range but which form nuclei having a positron activity or a characteristic gamma radiation when they react with fast neutrons. There are apparently no positron emitters among the products of fission.

The Ball of Fire Method

It was seen in Section 6.3 that for an appreciable period of time the growth of the ball of fire is determined by the propagation of the shock front at its surface. Since the shock wave characteristics are dependent on the total energy released in the explosion, it is apparent that there will be a relationship between the size or growth rate of the ball of fire and the yield of the bomb.

Cameras of several different types have been used for this purpose, but two are now regarded as more or less standard. These are (a) the Eastman high-speed, motion-picture type camera, which takes photographs at the rate of about 2,000 frames per second, and (b) the Rapatronic (rapid action electronic) camera, which takes a single frame, with an extremely short exposure at a definite time after the explosion. Although the motion-picture type camera has the advantage of providing a number of successive exposures, the Rapatronic camera, which uses a magneto-optical system in place of a mechanical shutter, produces a clearer picture. In a test shot, several Rapatronic cameras are employed and they are set to give exposures at different times.

The cameras are mounted on towers at known distances from the point of the explosion. Then, from the measured dimensions of the developed image on the photographic film and the focal length of the lens system used, the actual size of the ball of fire, at any given time, can be calculated.

A number of different relative methods for determining yield have been used. They are essentially based on the scaling laws derived from a hydrodynamical treatment of the shock waves arising from "similar" explosions. For two such explosions indicated by the subscripts 1 and 2, the distance traveled by the shock wave, which is equivalent to the radius, R, of the ball of fire, is proportional to the cube root of the energy release or yield, Y, at such a time, t, that R/t is the same in both cases; hence

$$\frac{Y_2}{Y_1} = \left(\frac{R_2}{R_1}\right)^3_{R/t}, \qquad (6.7)$$

where the subscript R/t implies a constant value of this quantity. Thus, if the radius (or diameter) of the ball of fire has been measured at various times for a bomb of known yield, it is possible to determine the yield for any other bomb. As already stated, this ball of fire method is relative, and depends upon a knowledge of yields determined by the radiochemical procedure. Strictly speaking, equation (6.7) applies only when the ambient pressures are the

same in both cases, and appropriate corrections must be made for any differences.

According to the theory of strong shocks, the rate of propagation of the shock front and, hence, in the present case, the rate of increase in the radius or diameter, D, of the ball of fire, is given by

$$D = kt^n, \tag{6.8}$$

where k, for a particular bomb, is a constant related to the yield,* and the exponent n is dependent upon γ, the ratio of the specific heats of the material at the shock front. When γ is 1.4, the value of n is close to 0.4, and then equation (6.8) can be written as

$$D = kt^{0.4}. \tag{6.9}$$

It appears that k is roughly proportional to $Y^{1/5}$, so that a good approximation when n is 0.4, has been found to be

$$Y = C\rho_o k^5 = C\rho_o \frac{D^5}{t^2}, \tag{6.10}$$

where C is a constant determined from observations on the balls of fire produced by bombs of known yield; ρ_o is the density of the ambient air.

To use equation (6.10) for the determination of yields, the data for D at various times t, obtained from the Rapatronic camera films, are plotted and the point found at which n in equation (6.8) is 0.4. Upon substituting the corresponding values of D and t into equation (6.10), the yield can be calculated.

Recently a new, absolute (analytic) method for obtaining yields, independent of scaling principles or knowledge of yield of other bombs, has been developed. It permits the calculation of the total energy produced in the nuclear explosion at any time up to breakaway, using hydrodynamic and thermodynamic principles. According to this method, which takes into account such factors as the transport of radiation in the early stages of the development of the shock front, the large mass of the bomb, and time variations in the equation of state of air and in the ratio of the specific heats at the shock front, the yield may be represented by

$$Y = \frac{F}{32}\rho_o n^2 \frac{D^5}{t^2} \tag{6.11}$$

*The factor k is generally represented by ϕ, but this symbol is used here for the efficiency.

where F is a complex numerical factor which varies from one bomb to another, and even with time for a given bomb. It may be noted that equation (6.11) is somewhat similar to (6.10); however, the empirical constant C in the latter is now replaced by the quantity $Fn^2/32$ which must be determined for each explosion.

The important point of the analytic method is that it has provided a method for evaluating F in each case by the application of hydrodynamic theory to measurements and calculations involving the motion and shape of the shock front, i.e., the surface of the ball of fire, and other available data. The exponent n is obtained at any time, t, in accordance with equation (6.8), from a log-log plot of D as a function of time.

In order to verify the new absolute method, it has been applied to the data obtained in several test shots; it has proved to be a valuable addition to the methods for determining bomb yields. Unlike the radiochemical procedure, ball of fire calculations are applicable directly, without special correction, to devices in which thermonuclear, as well as fission, reactions occur.

Yield Determination: Other Methods

Although the radiochemical and ball of fire measurements have been accepted as the standard procedures for estimating yields, there are other methods, some of which have special advantages. One of these is an absolute method involving a determination of the time interval between the arrival of the shock wave and of the acoustical (sound) wave at a given point. This can be measured with sufficient accuracy with a stop watch; then, knowing the distance from the explosion, the absolute yield can be calculated. A result of fair accuracy can thus be obtained very soon after the explosion.

Another rapid, but relative, method makes use of an instrument called a Bhangmeter. It is a photoelectric device whereby the intensity of the light from the ball of fire is recorded as a trace on an oscilloscope with a retentive fluorescent screen. The trace is photographed with a Land (Polaroid) camera which permits immediate, in situ, development of the exposed film. The elapsed time between the explosion and the first luminosity minimum (see Fig. 6.4), i.e., the breakaway time, can thus be determined very quickly.

It is evident from the discussion in Section 6.3 that this time interval is essentially that during which the shock front coincides with the luminous surface of the ball of fire. Consequently, a relationship between the breakaway or luminosity minimum time and the yield of the explosion is to be expected. It has been found empirically, from measurements on various tests shots, that

$$Y \approx 0.038t^{2.3},$$

UNCLASSIFIED

where Y is the yield in kiloton units and t is the time in milliseconds to the luminosity minimum. Although the accuracy of the Bhangmeter method is probably ± 15 per cent, it has the advantage of giving a yield value within a few minutes of the explosion.

The other methods of yield determination do not appear to possess any special advantages in most instances, although they may be valuable in special cases. Their main interest lies in the fact that they relate the yield to other phenomena accompanying the explosion. Thus, the total gamma-ray dosage, the thermal radiation, and the slow neutron flux are dependent, in a more or less definite manner, on the energy yield. Some reference to these matters will be made below.

6.6 General Test Experiments

Gamma-Ray Measurements

The experiments already described for the determination of α give the time variation of the prompt gamma-ray intensity. When scintillation counters of known efficiency are used, it is possible to calculate the total number of prompt gamma rays escaping from the bomb, provided their mean free path (or absorption coefficient) in air is known. Although this number is approximately proportional to the bomb yield, it is influenced by the tamper thickness, the material surrounding the tamper, and other structural factors.

The change with time in the intensity of the delayed gamma rays, coming mainly from the fission products, has also been determined. Because of the very large range of the intensities, scintillation detectors with logarithmic attenuators have been used. Thus, a quantity related to the logarithm of the gamma-ray intensity, rather than to the intensity itself, is recorded.

Of particular interest from the radiological standpoint is the total gamma-radiation dosage as a function of distance from the explosion. This quantity, expressed in roentgens, is determined by exposing photographic films at various points; the blackening of the films, from which ordinary light is excluded, is a measure of the radiation dosage received. As a fair approximation, the results may be expressed by

$$\text{Total Dosage} \approx 1.9 \times 10^{9} \frac{Y}{D^2} e^{-\frac{D}{\lambda}} \text{ roentgens,} \qquad (6.12)$$

where

Y = bomb yield in kt

D = distance from explosion in meters

UNCLASSIFIED

SECRET

λ = mean free path of gamma radiation

$$= 370 \times \frac{1.12 \times 10^{-3}}{\rho}$$

ρ = density of air in g/cm^3.

UNCLASSIFIED

At a specified distance from the explosion, the radiation dosage is seen to be roughly proportional to the yield, for a given density of air.

Neutron Measurements

Neutron measurements have been made at test shots for a variety of purposes. Among these may be mentioned the following: energy spectrum of neutrons, neutron flux as function of time, and total number of neutrons arriving at different distances from the explosion. In addition, neutron measurements have been found particularly useful for the study of thermonuclear processes.

The neutron spectrum from a nuclear explosion is studied by means of a number of (external) threshold detectors (see Section 6.5) placed at a given location at a known distance from the bomb. The most important detector elements, the reactions they undergo, the half lives of the products, and the neutron energy thresholds are given in Table 6.2. Depending on its thickness and cross section, a definite fraction of all neutrons having energies above the threshold value are captured by a given detector, and from the radioactivity acquired, the total

Table 6.2 External Threshold Detectors

Element	Reaction	Half Life (days)	Threshold (Mev)
Gold	Au^{197} (n,γ) Au^{198}	2.69	Slow
Sulfur	S^{32} (n,p) P^{32}	14.3	3.0
Iodine	I^{127} $(n,2n)$ I^{126}	13.0	9.45
Zirconium	Zr^{90} $(n,2n)$ Zr^{89}	3.25	12.0

number of neutrons in various energy ranges can be determined. If the gold is covered with cadmium, only neutrons with energies of about 0.18 ev are detected. By exposing detectors at several distances, the neutron intensity is found as a function of distance.

The neutron spectrum can also be studied by the Phonex (photographic neutron experiment) method using nuclear track plates, i.e., plates coated with a special emulsion that records individual tracks of charged particles. A collimator channel, through a thick gamma-ray shield, produces an essentially unidirectional beam of neutrons which bombard a thin layer of polyethylene (Fig. 6.6). The recoil protons thus produced, at known scattering angles, are detected by the nuclear track plates. The corresponding neutron energies can be calculated from the lengths

SECRET

UNCLASSIFIED

SECRET
UNCLASSIFIED

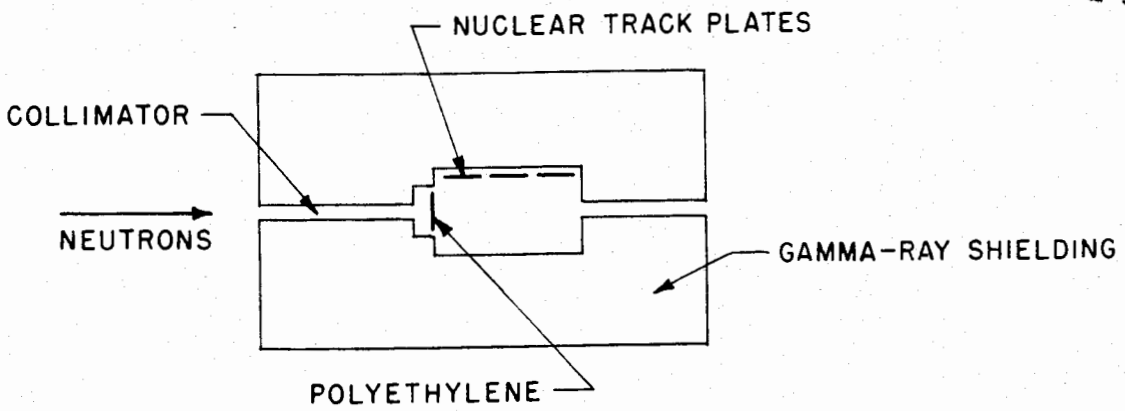

Fig. 6.6

of the proton tracks after development. The number of tracks of various lengths provides an indication of the distribution of the neutrons over a range of energies. The Phonex method can be adapted to study the 14-Mev neutrons liberated in the D-T reaction for the purpose of determining the burning temperature; the general principles are described in Section 6.10 (Tenex measurements).

The neutron dosage decreases with increasing distance from the explosion in an exponential manner, as is to be expected, but there is no simple relationship between the neutrons received at any point and the bomb yield. In view of the somewhat indefinite secondary character of the neutron emission, as indicated in Section 6.3, this is perhaps not too surprising.

The time dependence of neutron emission is determined by means of a "fission catcher." A strip of cellophane is drawn, at a known rate, past a thin uranium foil exposed to neutrons from the atomic explosion. As the neutrons are captured they cause fission in the uranium, and the radioactive products are collected on the cellophane. The variation of activity along the strip is then a direct measure of the variation of the neutron flux with time.

Determination of Compression

b(3)

The results were not too decisive, but the method is, nevertheless, of interest, since it is the only one developed so far whereby compressions in an actual test shot might be determined.

b(3)

If a

SECRET
UNCLASSIFIED

known number, n_o, of these neutrons enter a thickness x of material in which they are attenuated, either by absorption or scattering, the number, n_x, which emerges is given by

$$n_x = n_o e^{-N\sigma x}, \qquad (6.13)$$

b(3)

[redacted]

From the results, and the known cross section, it is possible to determine the thickness, x, of the material by equation (6.13). Hence, the compression at the time of an implosion can be calculated. It should be noted that the quantity N in equation (6.13) depends on the density of the material and, so, also on its compression.

6.7 Shock Wave Measurements

The Mach Effect

In order that nuclear weapons may be used most effectively, it is necessary to study various properties of the shock wave and related phenomena. The information obtained in this manner can also be utilized for the development of defensive procedures. For these and other reasons, various measurements of shock wave phenomena are undertaken in connection with nuclear weapons tests.

When the shock wave from an explosion strikes the ground, a reflected wave is produced which travels faster than the original shock. As a result, at a certain distance beyond the zero point, the reflected wave overtakes the direct one and the two shocks merge into a single shock. This phenomenon is called the Mach effect. The region near the ground where the direct and reflected shocks merge is called the Mach stem, and here the pressure is considerably greater than that of the individual shock waves. The point--in reality a circle--where the direct, reflected, and Mach shocks meet is referred to as the triple point. Its path, as it moves outward from the explosion point, is known as the triple point path (Fig. 6.7). The investigation of the Mach effect is an important aspect of shock wave studies.

SECRET
UNCLASSIFIED

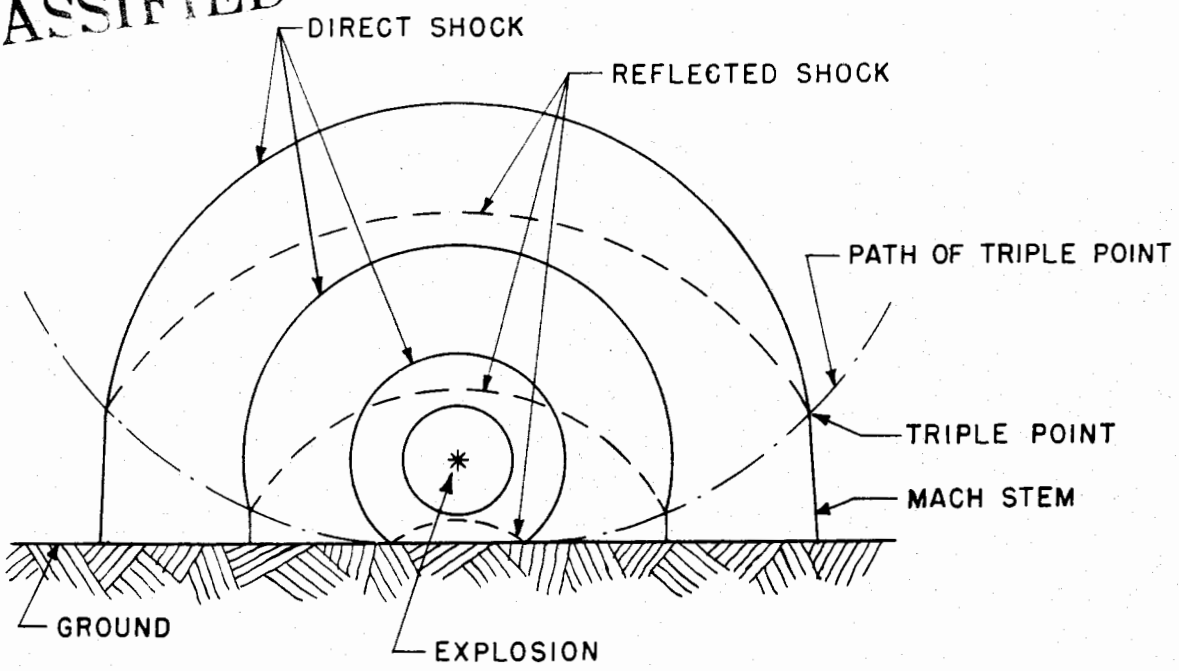

Fig. 6.7

Free-Air Peak Pressure

The shock pressures in the air above the triple point path, i.e., where the Mach effect is not apparent, are called the free-air pressures; these can be determined by observing the time of arrival of the shock front at a series of points at known distances from the explosion. From these times of arrival the shock velocity can be determined and the maximum or peak pressure at various distances can then be calculated from shock-wave theory.

One method used for observing shock arrival times was to attach blast switches to a number of cables held by balloons. Upon arrival of the shock, the switch closes and sends a signal to a distant receiving station, by cable or radio. This procedure has been found to be rather expensive and so it has been replaced by the method of rocket-trail photography.

In passing through a region occupied by a shock front, light is refracted, so that objects seen through the shock wave appear to be distorted; this fact permits times of shock arrival to be determined. Just prior to the explosion, a fan-like grid of vertical smoke trails is produced from a number of rockets launched from the ground at various distances from the zero point. These trails are photographed with a motion-picture camera, at about 100 frames/sec. The arrival of the shock front at a point between the camera and any trail is indicated by an

UNCLASSIFIED
SECRET

apparent shift in position of the trail due to refraction. The method can be used to determine shock pressures as high as 10,000 psi.

Material Velocity Measurements

Material velocity or mass-motion studies have been found to be a useful means of determining free-air peak pressures as a function of distance and also as a means for studying many hydrodynamic variables associated with shock waves. The general principle of the mass-motion method is to label a parcel of air with smoke and then to record photographically, with a motion-picture camera, the movement of the visible cloud when struck by the shock wave. From the displacement of the cloud and the camera speed, a displacement-time curve can be obtained. The maximum slope of this curve gives the material velocity associated with the peak shock pressure. Then from the shock-wave theory, this pressure can be calculated. The mass-motion procedure is probably most valuable at distances where the shock pressure is not too high.

Three methods have been found satisfactory for labeling a region of the air with smoke. These are, first, the use of a jet-assisted take-off (JATO) unit on the ground, with its nozzle pointing upward. Upon ignition this produces a vertical column of white smoke, extending for about 150 feet, which can readily be photographed. The second method utilizes aerial, fireworks bombs ("aerial salutes"); these are fired vertically from a mortar and produce a visible puff of smoke at 100 to 350 ft in the air. Finally, for considerable heights above the ground, smoke shells, fuzed to explode at the desired altitude, are shot from a 90-mm antiaircraft gun.

Mach-Region Peak Pressures

The rocket-trail method described above has been found to give information concerning the Mach triple point path and the shape of the Mach stem in its early stages, as well as of pressures in the Mach region. For studies at or near ground level, arrival times can be determined by means of blast switches or by various methods of direct pressure measurement. Such direct observations are usually restricted to shock pressures below about 100 psi. Several types of pressure gauge have been used for this purpose with more or less success. Mention may be made of foil, indenter, and Wiancko gauges.

The foil meter has a series of thin metal diaphragms of different diameters, so that different pressures are required to rupture them. The maximum diameter not ruptured indicates the maximum shock pressure at that point. In the indenter gauge, the pressure is determined from the indentation produced in a sheet of copper. However, at the present time it is believed that the Wiancko guage, which is a modification of the Bourdon pressure gauge, will prove most satisfactory.

Pressure-Time Measurements

Measurements of the shock pressure as a function of time are usually made on the ground; the indicators may be of the self-contained type or they may be connected, to recorders at a distance. For pressures less than about 50 psi the signals from Wiancko gauges may be transmitted by buried cable to be recorded on magnetic tape at a receiving station. The tape record then provides an indication of the variation of shock pressure with time. For somewhat higher shock pressures, e.g., up to about 120 psi, the inductance gauge has been used. In this device a change in pressure causes a diaphragm to move and this causes a variation in the inductance of an oscillator. The resulting frequency modulated signal, after amplification, is transmitted to a station and recorded on magnetic tape.

The self-contained instrument for determination of the time variation of shock pressure consists of a mechanical piston driven by the pressure against a spring restoring force. The piston, damped with oil of suitable viscosity, has a stylus attached, and this scratches a record directly on a rotating drum coated with graphite.

Another, somewhat more elaborate, method for studying the shock pressure near the ground as a function of time makes use of an interferometer gauge. The pressure-sensitive element is a circular quartz diaphragm which is part of an optical system producing a circular pattern of interference rings when illuminated with monochromatic light. When pressure is applied to the diaphragm, its motion, which is proportional to the pressure, causes a change in the number of lines in the interference pattern. From this change, the applied pressure can be determined. The interference pattern is recorded over a short period of time by means of a high-speed, moving-film camera.

Air Density in Shock Waves

An instrument, called a beta densitometer, has been developed for determining the variation with time of the density of air in the shock wave. The essential principle is that the number of beta particles from a given source which can penetrate, i.e., not be absorbed by, a layer of air of a certain thickness depends on the density of the air. Strontium-90, of 1 curie strength, is used as the beta-particle source, and a scintillation device with a photo-tube is the detector. From the observed intensity of the beta radiation, the density of the air between the source and the detector can be estimated.

The problem to be solved is how to eliminate the effect of the background radiation which will inevitably be considerable after an atomic explosion. Two methods have been used to achieve this end. In the first of these, two detectors are employed: one is exposed to the beta particles and the background radiation and the other to the background alone. The readings from the detectors are balanced against one another and the results give an indication of the

beta-particle intensity. In the other method only one detector is required, but in front of it is a rotating "chopper" which cuts off the beta radiation at definite intervals. The difference in the detector response with and without the chopper is a measure of the beta radiation.

Other Shock Measurements

In addition to the foregoing, various other measurements of shock and blast phenomena may be made in connection with a weapons test. Special gauges are used to determine the high pressures close to the exploding bomb, and the variation of the pressure with height above ground has been observed with gauges attached to pylons. Shock wind velocities are measured with double-ended Pitot tubes and ground shock with standard self-recording accelerometers or by means of seismic devices which record displacement. In the case of underground or underwater detonations, various studies of arrival times and shock pressures are made beneath the surface of the earth or water, respectively.

6.8 Spectroscopic and Radiation Measurements

Spectroscopic Studies

Spectroscopic studies of the radiations from a nuclear explosion are made for a variety of purposes. Among these are the following: determination of the temperature and energy distributions at the surface of the ball of fire as a function of time; investigation of the space distribution of various materials in the ball of fire; and identification and variation with time of the light-absorbing molecules and ions formed in front of the bomb, due largely to the action of gamma radiations and high temperatures on the gases present in the atmosphere.

The type of spectrograph and associated equipment employed depends on the main object of the particular observation. High-dispersion (concave grating) instruments are used, with stationary photographic plates, to provide detailed information concerning the total bomb light. On the other hand, for time variation studies, high-speed (quartz prism) spectrographs are required, but these have only moderate dispersion, so that less detail is available. The spectra at definite intervals are recorded by means of motion-picture type, framing cameras. To determine the space distribution of materials over the fireball, the image of the latter is focused on the center of the viewing slit of the spectrograph. Each point on a spectral line can be related to a definite location on the fireball surface, and so information concerning space distribution of the spectrum, and of the materials responsible, may be secured.

An analysis of the spectra obtained around the first luminosity minimum (Fig. 6.4) makes it possible to identify the various substances formed in front of the ball of fire. These include normal, excited, and ionized molecules of oxygen and nitrogen, ozone, atomic oxygen and

probably nitrogen), water molecules, hydroxyl radicals, nitric oxide, nitrogen dioxide, and nitrous acid (HNO_2) molecules.

In the later stages of development of the ball of fire, usually after the minimum, spectral lines due to elements present in the bomb begin to appear.

b(3)

The conditions are, in general, not favorable for the observation of lines due to uranium, plutonium, and fission products. This has been attributed to the strong iron spectrum, which masks the lines of many other elements, to absorption by the atmosphere, and to other factors.

The apparent (or black-body) temperature of the surface of the ball of fire is determined as a function of time by measuring the ratio of the spectral flux intensities in two wavelength regions, e.g., around 3700 Å and 6200 Å. From this ratio, the temperature of an equivalent black body, to which the ball of fire is a good approximation, can be derived by using the Planck radiation law. The flux measurements are made with photoelectric cells equipped with suitable filters that permit the passage of radiations within a narrow band. The signals from the photocells are amplified and recorded by means of oscilloscopes and attached moving-film cameras.

Transmission of Radiation

An important aspect of radiation measurements is the determination of the transmission of radiation as affected by absorption and scattering due to molecules and dust particles present in the air. The transmission is strongly dependent on the density, humidity, and clarity of the atmosphere, so that the existing conditions will affect both ball-of-fire photography and thermal radiation measurements. Since the former is of great significance in determining bomb yields, transmission measurements are often made prior to a test shot to make sure that good photographs of the ball of fire will be obtained.

A searchlight of known luminous intensity is set up close to zero point and a focused beam of light from it falls on a photocell several miles away. The beam is modulated at 60 cycles/sec by a mechanical chopper and the receiver system is designed so that it will detect and record light at this modulated frequency only. The system will consequently be independent of daylight. The transmission of the atmosphere is then evaluated from the intensity of the light received by the photocell.

Thermal Radiation Measurements

All the energy of a bomb ultimately appears as thermal radiation or heat, but the portion released within the first minute or two of the explosion, due to the high temperature of the

fireball surface, is of special interest. This has been referred to in Section 6.3 as the prompt or effective thermal radiation. The latter description is applied because it is this radiation which is responsible for skin burns, and possibly of fires out to considerable distances from a nuclear explosion. Prompt thermal radiation studies are thus of interest, not only because they provide information concerning the phenomena of a nuclear explosion, but also because of the importance of these thermal radiations from the weapons standpoint. Measurements are usually made of the total energy released as prompt thermal radiation and of the energy variation with time.

The total prompt thermal radiation is measured in two ways. One method makes use of a conventional ballistic thermocouple, the output of which is measured with a thermopile recorder connected to a photoelectronic galvanometer. In the other method a blackened container is filled with air which expands, due to the temperature increase, when radiation is absorbed. The amount of the latter is calculated from the movement of a diaphragm indicator. By using data for the transmission of radiation by the atmosphere just prior to the explosion, such as those described earlier, the total energy liberated by the bomb as prompt thermal radiation can be estimated.*

It was thought at one time that a definite fraction of the energy of the explosion appears as prompt thermal radiation. More recent measurements have shown, however, that this fraction varies with the bomb yield. The results can be expressed, to a fair degree of accuracy, by the relationship

$$Y_{th} = 0.42Y^{0.9 \pm 0.04} \qquad (6.14)$$

where the prompt thermal radiation yield, Y_{th}, and the total bomb yield, Y, are expressed in kilotons. It follows, therefore, that for a 20 kt bomb about 28 per cent of the energy is released as prompt thermal radiation, but in a 100 kt bomb the proportion is only 23 per cent.

The amount of radiation energy, Q, delivered per unit area at a distance D from the explosion is represented by

$$Q = \frac{Y_{th}}{4\pi D^2} e^{-kD} \qquad (6.15)$$

where k is the attenuation coefficient of the air for the thermal radiation emitted in the explosion. The value of k, which determines the transmission of radiation, depends on the state

*The transmission coefficient depends to a marked extent on the wavelength of the radiation and this must be taken into account in the calculation.

of the atmosphere between the bomb and the point of observation. It can be determined by direct observation of the value of Q at various distances and substituting in equation (6.15) or it can be calculated from transmission measurements.

The thermal radiation intensity is determined as a function of time either by a high-speed bolometer or by means of photoelectric cells. In the bolometer, which has a resolving time of about 25 μsec, a rapidly rotating "chopper wheel" is used to provide successive short exposures of a blackened platinum wire several thousand times per second. From the time change of resistance with temperature, the rate of variation of the radiation intensity can be found. The purpose of the "chopper" is to modulate DC voltage, so that the resulting AC output can be amplified and recorded on magnetic tape.

For very short times, e.g., 0.1 to 100 μsec, after the explosion the change in radiation intensity within a certain wavelength band can be measured by photocells, with suitable amplification, e.g., by means of a photomultiplier tube. The instantaneous current is a measure of the instantaneous radiation intensity in that particular wavelength range reaching the cell.

6.9 High-Speed Photography

High-Speed Framing Cameras

Observations of the ball of fire in the very earliest stages of development are of interest since they provide information concerning the transition from radiation to shock phase, on the effects of the yield-to-mass ratio, and on the perturbation of the fireball due to proximity of the earth's surface. These data are required to permit refinement of hydrodynamic theory as applied to growth of the ball of fire. Neither the Eastman motion-picture camera nor the Rapatronic camera used in ordinary fireball measurements (Section 6.5) is quite suited to this purpose. The former because of the relatively low frame rate and the latter because each camera gives only a single exposure.

The problem has been solved by means of high-speed, framing cameras. Three models are in general use, their nominal frame rates being 5×10^4, 9×10^4, and 3.5×10^6 frames/sec, respectively. By means of such cameras a considerable number of photographs of the ball of fire can be made during the first hundred microseconds after the explosion.

The high frame rates are achieved by using a rotating mirror to reflect images in turn on to a number (50 to 100) of lenses, each of which focuses an image upon a section of strip film. Although the mirror rotates continuously at high speed, the camera is so designed that the action is effectively, although not actually, stopped each time the mirror reflects light on to one of the lenses. From the known angular velocity of the rotating mirror and the distance between the lenses, the time for each frame can be calculated.

Because of the very short exposures, the attenuation of light between the ball of fire and the camera, several miles away, is very important. It is necessary, therefore, to monitor the light path prior to the test shot, by the method already described, if high-speed photography is to be used for ball-of-fire measurements.

Rotating Mirror (Streak) Cameras

The rotating mirror, streak cameras used in weapons tests are essentially the same as those described in Chapter 4 for testing detonators and HE lenses. A rotating mirror reflects light continuously from a number of sources on to a film strip; the distance between the points at which the traces from the different sources commence is a measure of the time interval between the initiation of the respective sources. The writing speed is such that 2 mm is equivalent to 1 μsec. The essential purpose of the streak cameras in weapons tests is thus to determine elapsed time between two or more events.

One such use is to measure the time interval between the fission and fusion reactions in separate parts of a two-stage thermonuclear device. Each type of process will induce Teller light (see Section 6.4) in the surrounding air, so that two streaks will appear on the camera film. The distance between the beginning of the two streaks gives the time between the two reactions.

Another application of the rotating mirror, streak camera is to determine shock velocity and pressure within a device by studying so-called "hot spots." These are points (or small areas) down the length of a case at which the arrival of the shock front from a fission bomb is indicated by strong light emission. By means of a pipe and mirror arrangement, the camera observes only certain selected points, the light from all other parts of the bomb being blocked out. From the positions of the streaks indicating the arrival of the shock front at successive points a known distance apart, the velocity and shock wave and, hence, the shock pressure can be calculated.

The propagation of the shock wave through a particular metal, which is part of the bomb case, can also be studied by the hot-spot procedure. This is done by making the shock wave traverse different thicknesses of the metal, by drilling the bomb case at some points and adding pads of the same material at others. The various spots will thus become luminous at different times and the intervals between them can be estimated from the camera streaks.

6.10 Thermonuclear Burning Studies

Tenex Measurements

The primary purpose of the Tenex (temperature neutron experiment) measurements is to make use of the 14-Mev neutrons produced in the D-T reaction to estimate the thermonuclear

SECRET

UNCLASSIFIED

burning temperature. Strictly speaking, these neutrons have an energy of 14 Mev only if the reacting deuterium and tritium nuclei are at rest. But if these nuclei are in motion, the neutron energy will be 14 Mev plus four fifths of the kinetic energy of the reacting particles in the center-of-mass (C-of-M) system. Actually the center of mass is in motion relative to the observer, so that there is a Doppler energy shift superimposed on the energy in the C-of-M system. Consequently, neutrons released in the D-T reaction will have energies covering a band in the vicinity of 14 Mev. The higher the velocity of the particles, i.e., the higher the nuclear temperature, the broader the band. The velocity distribution is roughly Gaussian, with the half width depending on the temperature.

A scintillation detector is placed at a considerable distance from the explosion, so that neutrons of different energies belonging to the 14-Mev group arrive at different times. These are recorded on a synchroscope, and the velocity distribution can then be determined from the observed "times of flight." From this distribution, the temperature of the thermonuclear reaction system can be estimated. *

When studying thermonuclear devices of high energy yield, the recording instruments must be located a considerable distance away. If the detectors can be placed near the explosion point, long cables are necessary to transmit signals to the recorders. Such lines must be protected from extraneous gamma radiations by extensive earth fills which are costly. On the other hand, if the detectors are close to the recording instruments, the radiations from the bomb, e.g., neutrons and gamma rays, suffer considerable attenuation due to absorption, so that weak signals are received.

In the Ivy tests the problem was solved by transmitting the radiations through a helium channel since this gas is a poor absorber for both neutrons and gamma rays. The channel consisted of a plywood box, 8 ft by 8 ft in cross section and nearly 9,000 ft long, filled with a number of thin-walled polyethylene balloons containing helium gas at slightly above atmospheric pressure. Lead baffles inserted in the box served to provide a number of well-collimated paths, which were used for Tenex and other measurements related to thermonuclear burning.

In order to reduce attenuation still further, an evacuated metal pipe, 6 inches internal diameter and about 7,500 feet in length, is to be used as the radiation path in the Castle tests. A pressure of 0.1 atm is believed to be adequate for the purpose, although it is expected that a much higher vacuum will be maintained.

*The energy distribution can also be determined, and the temperature estimated, by the Phonex measurements described in Section 6.6.

UNCLASSIFIED

SECRET

Dinex Measurements

The progress of the thermonuclear D-T reaction as a function of time can be studied by following the rate of emission of the 14-Mev neutrons. This may be done by the Dinex (diagnostic neutron experiment) method.

b(3)

Because of the very short time scale, allowance must be made for the time of flight of the neutrons over the distance from their origin to the detector. This requires a knowledge of the neutron energy and makes it necessary to keep out scattered neutrons since the distance they have traveled is uncertain.

The neutrons enter through a collimator, which serves to define their direction and to eliminate scattered neutrons, and then bombard a hydrogenous material, e.g., polyethylene, as in Fig. 6.6, The recoil protons pass through a magnetic analyzer which accepts only those protons produced by 14-Mev neutrons. These protons fall upon a collector, which is essentially a Faraday cage giving a current of the order of 10^{-19} amp per proton per second. Every proton collector is made to drive a bank of cathode-ray oscillographs, each unit being attached to a recorder of different sensitivity. This procedure is necessitated by the very large range of signal levels, from initiation to the peak of the thermonuclear burning. With the arrangement described, each instrument records over a different range of proton and, hence, 14-Mev neutron, intensities. From the oscillographic records, the rate of emission of the 14-Mev neutrons can be determined.

Ganex Measurements

The Dinex method requires a large amount of shielding to prevent gamma radiation from reaching the proton detector. This problem has been overcome in the Ganex (gamma-ray neutron experiment) method for measuring the time variation of the 14-Mev neutrons as an indication of the rate of the D-T reaction. The 14-Mev neutrons, after passing through a moderately good collimator, fall upon a "converter" of iron. As a result, these neutrons are inelastically scattered by the iron nuclei and inelastic scattering gamma rays are thereby produced. Some gamma radiation also arises from (n,γ) capture in the iron. A scintillation detector is placed behind a collimator which points at the converter and the gamma-ray output is observed, as a function of time, by means of an oscilloscope.

One advantage of the Ganex method is that the converter can be placed near the neutron source and the gamma radiation is then transmitted through the air to the detector some distance away, without the necessity of using long cables. However, the lack of good energy discrimination makes the procedure unsatisfactory at low gamma-ray levels because of interference by radiations from extraneous sources. This difficulty is partially overcome by the use of a helium or vacuum path for the gamma radiations, as described in connections with the Tenex measurements.

Gamma-Ray Experiment

A method for studying the time characteristics of D-T burning makes use of the gamma radiation accompanying the reaction. In this experiment it is essential that the gamma-ray beam should be well collimated and that the collimator should point at the region of the bomb where the thermonuclear processes are occurring. The gamma rays are observed by means of a scintillation detector connected to an oscilloscope; the time variation of the observed signal is then directly related to the progress of the thermonuclear burning.

For the George experiment (Operation Greenhouse) the detector was placed near the device and the signal was carried by buried cables to the oscilloscope which was not too far away. In the Mike (Ivy) shot, however, for the reasons given above, the gamma radiation was transmitted through a collimated channel in the long helium-filled box described earlier. For the Castle tests, the vacuum pipe referred to above will be used.

X-Ray Experiment

Nuclear reaction temperatures can be determined by utilizing the fact that at these temperatures the "thermal" radiation emitted is in the soft X-ray region, with energies in the range from 1 to 10 kev. From the energy or wavelength of this radiation, it is possible to estimate the temperature of the emitter. The method is usually not applicable to fission bombs because of the considerable absorption of the X-rays by the bomb materials. But for certain thermonuclear devices, where the absorption is not so great, the X-ray method can be used to derive reaction temperatures.

There are several difficulties associated with the measurements, among which may be mentioned the following: the 1 to 10 kev region has been little studied; a very high time resolution is required because of the rapidity of the thermonuclear burning; and the detecting devices must cover a wide range of intensities. The method used with some success at the Greenhouse tests was to permit the "thermal" X-radiation from the experimental device to travel down an evacuated pipe and to fall on a detector, called a fluorescer. This is a foil coated with a compound of either potassium, manganese, or copper; these elements are sensitive to X-rays in the regions just above 3.6, 6.5, and 9.0 kev, respectively.

If X-rays of the appropriate energy strike the fluorescer, one of the K-electrons of the element present will be ejected; when its place is taken by another electron, the characteristic K-radiation of either potassium, manganese, or copper will be emitted. This is allowed to fall upon an aluminum surface shielded from the direct X-ray beam, and as a result photoelectrons are produced. The electrons are accelerated by a high voltage and the resulting signal can be recorded on an oscilloscope. By observing which of the fluorescers produces its characteristic X-radiation, an estimate may be made of the energy of the primary (thermal) X-rays and hence of the temperature of the material emitting them.

Chapter 7

Laboratory Organization and Activities

7.1 History and Responsibilities

The Los Alamos Scientific Laboratory was established in April 1943, at Los Alamos, N. M., on the site of the 25-year-old Los Alamos School for Boys. Operated from the first by the University of California, its purpose has been to carry out experimental and theoretical work in connection with the military applications of nuclear energy. The Laboratory was originally planned as a temporary installation to make atomic weapons for World War II. However, even before 1947, when the University of California's contract to operate the Laboratory was transferred from the Manhattan Engineer District to the Atomic Energy Commission, it was apparent that the Laboratory would have to be continued for an indefinite period in the interests of national security. It has now become a permanent plant with outstanding equipment and facilities for research and development in both fundamental and applied aspects of nuclear energy.

The operations of the Laboratory embrace, of necessity, much more than direct weapons work. The improvement of current weapons design and the development of weapons of new types requires much basic research in a host of scientific and technical fields. But, because the main concern of the Laboratory is with nuclear weapons, such research is invariably of a character which will provide a better understanding of the complex processes associated with fission and thermonuclear reactions.

The general responsibility of the Laboratory is for the design and development of systems for effecting supercritical assemblies of fissile material, and for the design of high-explosive, nuclear, and related components for atomic weapons. Components outside of those which produce the supercritical system are the responsibility of other installations, such as the Sandia Corporation at Albuquerque, N. M., which is concerned primarily with ordnance engineering details. However, since the nuclear, ordnance, and other aspects of a weapon cannot be completely separated, close liaison is maintained by the Laboratory with other agencies.

Since the Laboratory is not intended to be a production unit, fabrication of components is restricted to a few prototype specimens which are used either for experimental and test purposes or as samples. Large-scale production of items designed in the Laboratory is carried out by other AEC contractor establishments, although such work is done to specifications laid down by the Laboratory. The Laboratory also establishes procedures for the surveillance and testing of components which it has designed. This again requires cooperation by the Laboratory with outside AEC contractors.

SECRET

UNCLASSIFIED

7.2 Laboratory Organization and Personnel

The organization of the Laboratory is made up of the Director's Staff, eight Technical Divisions, each divided into several more or less separate Groups, and a number of Administrative and Service Departments and Groups. From time to time special (DIR) projects of an exploratory nature are established; these remain under the supervision of members of the Director's Staff until they have reached the stage where they may be transferred to one of the Technical Divisions.

Certain aspects of the work of the Laboratory are guided by technical committees. Some of these are permanent but most are of a temporary character, being set up to deal with a specific project (or projects) involving the activities of several Divisions. These committees may consist solely of members of the Laboratory or they may include representatives of other agencies, such as the Sandia Corporation, the Armed Forces Special Weapons Project, the Air Force Special Weapons Command, Bureau of Ordnance (Department of the Army), etc.

An outline of the activities of each of the Technical Divisions of the Laboratory is given below, as well as brief statements of the main functions of the Administrative and Service Departments and Groups. It is perhaps redundant to state that the Laboratory is made up of individuals, and that the progress of the Laboratory is determined entirely by the ideas and activities of the men and women it employs. Since it is impossible to mention in this Report all who have contributed materially to the Laboratory's progress, the names are given only of those holding senior positions on the Director's Staff, in the Technical Divisions and their constituent Groups, and the Administrative and Service Departments and Groups. Unfortunately, this compromise fails to give recognition to many who merit it, but it is the best that can be done in the circumstances.

At the present time, at the beginning of 1954, the Laboratory has about 2800 full-time employees, of which nearly 900 are members of the professional (medical and scientific) staff, the remainder performing administrative, secretarial, and technical services. The professional staff is divided into two categories, namely, staff members and research assistants; their academic standing is indicated by the numbers in the following table.

	M.D.	Ph.D.	M.S.	B.S.	Total
Staff Members	8	313	116	283	781
Research Assistants	-	-	25	77	107

DIR Projects

DIRP. Under direction of Darol K. Froman

Group Leader DIRP-1: L. D. P. King

Group Leader DIRP-2: R. Philip Hammond

The objective of the DIRP project is to design, build, and operate an experimental high-temperature (430°C) and high-pressure (5000 psi) homogeneous reactor of a novel type. Such a system is of fundamental interest from the standpoint of the behavior of aqueous uranium solutions at or near the critical point. It is also of practical interest as a possible replacement for the existing Water Boiler as a neutron source and for the exploration of homogeneous systems for their possibilities with respect to the production of useful power from nuclear fission.

DIRX. Under direction of Marshall G. Holloway

This project was responsible for the coordination and over-all development and production of thermonuclear weapon warheads, including those for the Castle tests (Spring 1954). As of about January 1, 1954, the development activities of DIRX are being transferred to technical committees, while the design of the outer cases of thermonuclear devices and the integration of the components into a complete warhead design is being taken over by the new Group W-6. Production of the warheads will be under the supervision of the Assistant Director for Production. As an element of Task Force Seven, DIRX will remain responsible for the field assembly of the thermonuclear test devices at Castle.

7.4 Technical Division Activities

CMR Division

Division Leader: Eric R. Jette

Alternate Division Leader: Robert D. Fowler

Assistant Division Leader: Robert L. Shehan

CMR Division performs chemical and metallurgical research on fissile materials and other special bomb constituents, such as deuterium and tritium and their compounds. Development and service support are provided in these fields to other divisions of the Laboratory. Nuclear components for prototype weapons and test devices are fabricated in conjunction with the Shop Department, and production methods for fissile and other materials are developed. Production and fabrication procedures originated by CMR Division are available as a starting point when new components are assigned to other AEC contractors for production. Frequently, the first few stockpile units are actually fabricated while a suitable outside facility is being tooled up.

Group CMR-1. Group Leader: Charles F. Metz
Associate Group Leader: Robert T. Phelps
Alternate Group Leader: Herman Ashley

Group CMR-1 provides a general analytical service for the entire Laboratory, although most of its work is performed for other groups in the Division working with fissile materials. A wide variety of techniques are used including alpha- and beta-particle counting, spectroscopy, polarography, coulometry, and petrography. The spectrographic installation is exceptional in many respects. Special microchemical and spectrographic methods have been developed for the analysis of uranium and plutonium, and for traces of a large number of other elements of interest in the weapon field. Because of the expanding activities of the Laboratory, an active research and development section is concerned with the solution of analytical problems arising from the use of new materials.

Group CMR-2. Group Leader: Joe F. Lemons
Alternate Group Leader: Charles E. Holley

The main work of Group CMR-2 is research on the physical and chemical properties of plutonium compounds; in addition, however, it performs inorganic research which is not related to plutonium chemistry. The activities include preparation of compounds and investigation of their structures by magnetic susceptibility, paramagnetic and nuclear magnetic resonance absorption, and Raman spectra. Experiments are made on the physical chemistry of solutions, combustion and solution calorimetry, reaction kinetics, and radiation chemistry.

Group CMR-3. Group Leader: Dwayne T. Vier
Co-Group Leader: Melvin G. Bowman

Prior to the Spring of 1953, the principal task of Group CMR-3 was to fabricate experimental initiators for testing purposes and to provide a token production of new designs of initiators for the stockpile before fabrication could be taken over by an appropriate AEC supplier. This service required a continuous development program and supporting research in polonium

chemistry. As a consequence of this activity the Laboratory can be supplied with a wide variety of neutron sources, using polonium, having strengths up to 10^8 neutrons/sec, and alpha-particle sources up to several curies in strength.

Group CMR-4. Group Leader: Eugene S. Robinson
Alternate Group Leaders: Wesley M. Jones
Robert A. Penneman

Although Group CMR-4 is primarily concerned with research on isotope chemistry, it also performs a substantial amount of service work. The research work includes the preparation and chemical and physical study of compounds of the transuranium elements, neptunium, americium, and curium. Some of the information and techniques are being utilized by J Division in studying bomb residues for radiochemical yield determinations. Research is also being carried out on the chemistry of tritium. As part of its service function, the group purifies tritium, and supplies it to other groups and laboratories as required. Lithium tritide is also prepared by reaction of metallic lithium with tritium. Another section of CMR-4 makes foils of uranium, plutonium, and americium isotopes as well as those containing deuterium and tritium for various Laboratory activities. In addition, it performs many special services usually involving separated or enriched isotopes, e.g., boron-10 for neutron counters containing boron trifluoride.

Group CMR-5. Group Leader: Arthur S. Coffinberry
Alternate Group Leader: Fred W. Schonfeld

The activities of Group CMR-5 are concerned with the metallurgy of plutonium and its alloys. Studies are made of the structure, phase relations, physical and mechanical properties, resistance to corrosion, and ease of fabrication. Because of the health hazard, virtually all equipment is enclosed in dry boxes. Apart from direct application of alloys, e.g., plutonium-gallium, to weapon design, the program is of interest to AEC installations, who call upon CMR-5 for information and service work, particularly in relation to the use of plutonium alloys in breeder reactors.

Group CMR-6. Group Leader: James M. Taub
Alternate Group Leader: Denton T. Doll

CMR-6 is the metal-fabrication group, working in cooperation with the Shop Department; it furnishes fabricated shapes, materials, and services to the Laboratory and to other AEC

projects. The unusual shapes, sizes, and types of materials handled frequently require ingenuity and a novel approach, so that much development work is performed in support of the service activities. The functions of the group are divided into eight sections. The ceramics section forms and fires special refractories and applies enamel and ceramic coatings to metals.

It also operates a plating shop for GMX-7. The fabrication section carries out such operations as sheet rolling, wire drawing, swaging of rods, forging, welding, or deep drawing of various metals, including uranium. The facilities of this section are being increased by the installation of a 5000-ton hydraulic press early in 1954. The general foundry section operates furnaces for the vacuum casting of tuballoy and its alloys, in sizes ranging from about 1 pound to 2 tons. Other nonferrous metals and their alloys are also vacuum cast. The task of the physical metallurgy section is to provide mechanical testing services, e.g., tensile strength, compression, shear, hardness, and impact tests, and metallographic information for the Laboratory. It also acts in a consulting and advisory capacity on general metallurgical problems. Many common plastic materials and techniques are used by the plastics section in filling job orders. Metals, oxides, and other compounds are incorporated into plastics for special purposes and several unusual materials have been coated with plastics. The powder metallurgy section has fabricated into various shapes numerous elements and alloys, especially those which cannot be fabricated by standard methods. With but few exceptions, all oralloy parts used by the Laboratory are made by the oralloy section. These include components for devices tested at the Proving Grounds as well as those used for critical mass and other studies. In addition to vacuum casting of oralloy, foils, sheet, wire, and special shapes are made for experimental purposes. Machining is done in the oralloy machine shop which is part of the oralloy section but is staffed by the Shop Department.

Group CMR-7. Group Leader: James R. Lilienthal

Alternate Group Leader: Charles M. George

The principal functions of Group CMR-7 are to maintain instruments used in CMR Division, especially for radiation monitoring and plant control, to aid members of the Division in instrumentation problems, and to develop new instruments and apparatus for CMR and other Divisions of the Laboratory. These include radiation detection instruments for various purposes, automatic temperature controls, tritium process lines, Raman scanning mechanism, etc.

Group CMR-8. Group Leader: Richard D. Baker

Alternate Group Leader: Ralph W. Kewish

The work of Group CMR-8 is concerned with the chemistry of uranium and falls into two

broad classes, namely, (a) research and development, and (b) production. In addition to performing fundamental research in uranium chemistry, attention is given to the development and engineering of new methods and to the improvement of existing methods for the purification and recovery of uranium from a wide variety of residues. The production program involves the recovery and purification of oralloy residues originating in the Laboratory, the recovery and purification of uranium-233, and the preparation of normal and enriched uranium alloys.

Group CMR-9. Group Leader: Edward F. Hammel, Jr.
Associate Group Leader: Adam F. Schuch

Group CMR-9 is a research group whose primary interest is in cryogenics, i.e., the properties of matter at very low temperatures; for this purpose excellent equipment is available for work in the range from 20°K to below 1°K. Studies are made of the properties of liquid and solid hydrogen isotopes and of liquid helium isotopes. In addition, one section of the group is making equation-of-state measurements with gases at high pressures, e.g., tritium up to 2000 atm. The section provides a consulting service to the Laboratory on high-pressure problems.

Group CMR-10. Group Leader: R. Philip Hammond
Alternate Group Leader: John W. Schulte

The main activity of Group CMR-10 is the preparation of kilocurie sources of radiolanthanum for use in the RaLa experiment by Group GMX-5 and sources of lower strength, from 10 millicuries to 100 curies, for other purposes. A remote-control facility for separating the lanthanum-140 from its parent, barium-140, is operated by the group, and a research and development program is carried out to improve separation methods and to anticipate a variety of demands. The facilities are frequently used to repack or combine strong gamma-ray sources for other Laboratory groups. The responsibility for maintaining the uranyl nitrate solution in the Water Boiler, operated by Group P-2, at an acceptable pH and uranium concentration has been assigned to CMR-10. This has led to an active interest in radiation chemistry, aerosol removal, and isotope-exchange reactions.

Group CMR-11. Group Leader: Richard D. Baker
Alternate Group Leader: Wayne C. Hazen

This group was originally established as a production facility for plutonium weapon components, starting with Hanford nitrate solution and ending with the nickel-coated, finished plutonium hemispheres. However, since the establishment of other AEC production facilities, this aspect of the work of Group CMR-11 has been reduced essentially to stand-by status. Consequently, the group now devotes itself to research and development in connection with fabrication of plutonium and its alloys into various shapes and with the recovery and purification of

plutonium from residues and wastes. Such work is in progress on plutonium casting, with emphasis on precision die-casting for possible use in the production of thin sections of the metal. Special problems have required the preparation of plutonium metal of high purity and of particular compounds. A remote-control plant for the production of metal from plutonium nitrate solution has been built and operated, and research has been carried out on the chemical reactions involved in the many steps of this process. The group is also concerned with a detailed study of nickel carbonyl and the decomposition reaction used for coating various bomb components with nickel.

Group CMR-13. Group Leader: Robert B. Gibney

Group CMR-13 was organized in January 1953 to do metallurgical research in metals, other than plutonium, of interest to the Laboratory. Its activities include a study of the effect of heat treatment on the low-temperature properties of uranium-molybdenum alloys, and the development of a "stainless" uranium alloy. The latter will be prepared and its mechanical properties studied by the group, but the corrosion characteristics will be evaluated by CMR-5. In cooperation with GMX Division, the high-speed loading of metals will be investigated to determine whether phase transitions occur during implosion.

D Division

Division Leader: Ralph Carlisle Smith

Alternate Division Leader: Philip F. Belcher

The Documentary (D) Division handles substantially all written matter of a scientific nature other than stockpile information on weapons and SF (source and fissionable) materials. It is a control point for such matter, in addition to being the source of many technical writings. While D Division is divided into groups, the scientific personnel, in particular, serve in several capacities which cut across group lines. The primary functions of the Division include patents and inventions, classification, declassification, security liaison, editorial and technical information, and summary reports and publications.

Patents and Inventions: All technical reports and publications of the Laboratory are reviewed by scientific and engineering members of the Division for possible inventions to be protected by the Government. The Division reports such inventions directly to the AEC, Washington, D. C., and when requested prepares, secures execution of, and prosecutes patent applications on them.

Classification: All technical and much other outgoing mail from the Laboratory is reviewed by D Division to make certain that the scientific information contained therein is correctly classified. This centralized review enables the Laboratory to maintain a uniform

classification policy. The Division provides the Executive Secretary for the Santa Fe Operations Classification Board and the Los Alamos Field Office Classification Board, which render classification decisions on all aspects of the weapons development and weapons test programs of the AEC. The leader of D Division usually serves as the AEC classification representative in Joint Task Force and continental test organizations in order to maintain this uniformity of classification policy.

Declassification: Within the Division there is a small group which handles declassification of various technical developments and the associated papers originating in the Laboratory. Although responsible reviewers are available throughout the Laboratory and at Sandia, much of the declassification and review is performed by scientific members of D Division.

Security: Security liaison with the AEC and the FBI is maintained through D Division.

Editorial Services and Technical Information: All activities relating to scientific and technical reports within the Laboratory and to the AEC's weapons test organization are administered. Reports received in draft form are given technical editing and prepared for reproduction. The Division also prepares the weekly LASL Bulletin. Requests for information directed to the Laboratory from outside the AEC and contractor organizations are forwarded to the Division for handling directly or for transfer to the SFO Information Office or other appropriate organization.

Libraries: The Division operates the Report Library, where classified reports from the AEC and its contractors and from other sources, especially the Department of Defense, are controlled and disseminated, with the detailed inventory procedure prescribed by AEC regulations. In addition, the Division operates and controls the technical library of the Laboratory and the library at the Health Research Laboratory, that also serves the Los Alamos Medical Center.

Summary Reports and Publications: The Coordinating Organization Director for Military Utilization Projects of the AEC is the Director of the Laboratory, and his executive representative is the leader of D Division. The responsibility for summary and survey technical reports resides in the Director, but in many cases the responsibility for preparing such reports is transferred to the Division. Various books, written by present and former members of the Laboratory personnel, have been prepared under the direction of the Division. Such books and reports have appeared in the National Nuclear Energy Series, have been published by the GPO, or have been issued by the Laboratory.

The Technical Illustration section of D Division prepares drawings and sketches for reports and also the more complex multicolor illustrations and exploded views necessary for briefings of the Joint Chiefs of Staff, and members of the AEC, Joint Task Force, and continental test organizations. A museum, in which the history and development of atomic weapons

will be illustrated, is being established in the old ice house of the former Los Alamos School.

Group Functions: As indicated previously, the scientific personnel in D Division serve in several different capacities, so that there is no precise group organization. However, four groups are at present in existence and their functions are indicated briefly below.

Group D-1. Group Leader: Ralph Carlisle Smith

Alternate Group Leader: William R. Spensley

Group D-1 is concerned with the review of inventions and the preparation of patent applications of such as may warrant protection.

Group D-2. Group Leader: Helen F. Redman

Alternate Group Leader: Elbert E. Steele

The library activities of the Division, including the Report Library, the Technical Library, and the Health Research Laboratory Library are under the control of Group D-2.

Group D-6. Group Leader: Leslie M. Redman

This group is concerned with matter related both to classification and declassification of mail, technical developments, and reports.

Group D-7. Group Leader: David M. Stearns

Group D-7 is responsible for editorial services and technical information, and for the preparation of the weekly Laboratory Bulletin. The Technical Illustration section and the Museum are also part of Group D-7.

GMX Division

Division Leader: Duncan P. MacDougall

Alternate Division Leader: Eugene Eyster

GMX Division has two principal and related missions. These are, first, to carry out research, development, and engineering for production on the firing and HE systems of implosion devices; and, second, to study experimentally the behavior of implosion systems, without fissile material, during and subsequent to the detonation of the high explosive. The work includes the design and testing of X-units, detonators, implosion lenses, and HE inner charges, and studies of the symmetry and other properties of the shock waves accompanying an implosion.

Group GMX-1. Group Leader: Gerold H. Tenney

Alternate Group Leader: James W. Dutli

All nondestructive testing and inspection, which is largely radiographic in character, is performed for the Laboratory by Group GMX-1. For this purpose use is made of X-ray machines with peak voltages up to 1000 kv, a 22-Mev betatron, and various gamma-ray sources,

including radium and cobalt-60. Several commercially available inspection tools, such as Magnaflux and Reflectoscope, and others that have been specially developed, are used in non-destructive tests not involving radiations. This group is part of GMX Division primarily for historical reasons; the first radiographic inspections made at Los Alamos were carried out on HE charges.

Group GMX-2. Group Leader: Louis C. Smith

Group GMX-2 carries out research, testing, and early development on high-explosive materials. In addition to a laboratory, in which small-scale chemical work can be performed, the group has a number of processing buildings and an environmental test chamber in which a wide variety of climatic conditions and changes can be simulated. Explosive materials of interest, which cannot be purchased commercially, are synthesized by an organic chemistry section. The group has a special interest in the development of plastic bonded explosives for various purposes.

Group GMX-3. Group Leader: Melvin L. Brooks

This is the largest group in GMX Division and it is concerned essentially with the HE systems for implosion bombs. Group GMX-3 designs, develops, and engineers for production the HE lenses and inner charges for these weapons and also the HE systems required for special experiments. Research and development is carried out on the techniques of fabrication of lenses and inner charges, and all HE charges and systems used in the Laboratory are made by GMX-3. In addition, the group writes product specifications for all HE systems fabricated in AEC plants, assists these plants to get into production on new designs, and provides support to the AEC on day-to-day acceptance of finished items. Facilities are available for casting, machining, inspecting (radiographic and dimensional), and assembling HE systems. The group also operates a large magazine area.

Group GMX-4. Group Leader: Eric L. Peterson

Alternate Group Leader: Frederick Tesche

The primary activity of Group GMX-4 is to study the behavior of imploding systems by the pin technique. For this purpose, a number of firing points are operated; with each point is an instrument (or recording) chamber containing a large number of oscilloscopes and similar devices. Measurements of tamper velocity and symmetry, and of shock velocity and symmetry in the pusher, tamper, and ball, made by the pin method, constitute an important stage in the development of new implosion systems. In addition to these implosion studies, research is carried out on shock waves and equations of state, using the same basic technique and equipment.

Group GMX-5. Group Leader: Donald Mueller

Alternate Group Leader: George H. Best

The functions of Group GMX-5 are mainly concerned with a study of motions and, especially, compressions occurring in the metal components of an implosion system by the RaLa method. The scintillation detectors for gamma rays and the fast amplifiers now available give an over-all response time of about 0.01 μsec.

b(3)

Because the equipment and techniques are particularly applicable, GMX-5 has been devoting a large portion of its effort to studies of the behavior of thermonuclear initiators.

Group GMX-6. Group Leader: Frank J. Willig

Alternate Group Leader: Frank A. Lucy

Group GMX-6 utilizes high-speed photographic equipment, including both motion-picture type and streak cameras, to observe the behavior of imploding systems and of mock-ups of various features of such systems. The group also makes use of photographic technique for fundamental studies of shock waves and equations of state. While GMX-6 has some electronic timing and control equipment, the bulk of its observations are made by the cameras referred to above.

Group GMX-7. Group Leader: R. L. Spaulding

Alternate Group Leader: A. D. Van Vessem

This group does research and development on firing systems for implosion weapons, including both X-units and detonators. For detonators, GMX-7 carries the project all the way from early design studies, through development and engineering for production. It usually does some early production for stockpile in addition. Most of the detonators are now made elsewhere, but the group still supplies specifications, procedures, and gives any assistance that may be required.

At present all detonators for the AEC are accepted by Group GMX-7, but it is expected that the responsibility for routine acceptance will soon be taken over by AEC staff, with the group providing support in the form of advice and occasional spot checking. Although GMX-7 does research and development on X-units, the engineering, production, and surveillance are not done by the Laboratory. However, final X-unit designs are in all cases certified by the group with respect to their ability to fire detonators properly.

Group GMX-8. Group Leader: Arthur W. Campbell

Alternate Group Leader: Charles W. Mautz

The test firing of lenses and of other HE charges is performed by Group GMX-8. For

UNCLASSIFIED
SECRET

this purpose a number of individual firing points are operated. Each point has a protected shelter, which houses the rotating mirror (streak) camera and electronic equipment, and a firing mound upon which charges up to a thousand pounds of HE can be safely fired. Some of the work of GMX-8 is done as part of the development program on new lens systems, and the remainder of its service function consists of firing, on a sampling basis, of lenses which are in routine production by GMX-3. The two primary quantities measured are the transit time and the trace spread. The transit time, i.e., the time required for the detonation wave to pass through the lens, is measured by timing the interval between the closing of two electrical circuits. The trace spread, which is a measure of the failure of the detonation wave to emerge simultaneously at all points across the lens face, is determined by a streak camera. GMX-8 also uses the same equipment to perform fundamental studies on various properties of detonating HE material, such as detonation velocity, detonation zone structure, etc.

Group GMX-9. Group Leader: Berlyn Brixner

The work of GMX-9 is to develop new and improved types of cameras for the entire Laboratory; it also operates a stock room of optical and photographic equipment and accessories of unconventional design. High-speed streak cameras and ultra-high-speed frame cameras, having frame rates from 5×10^4 to 3.5×10^6 frames/sec, have been developed. The group is also concerned with cameras for oscilloscopes and similar instruments. The design and fabrication of turbine drives for the high-speed cameras is performed by GMX-9, and prescriptions are developed for entirely new lens systems where no available lens will satisfy the special requirements.

H Division

Division Leader: Thomas L. Shipman, M. D.

Alternate Division Leader: Harry O. Whipple, M. D.

The essential purpose of the Health (H) Division is to protect and maintain the health of all Laboratory employees. In addition to providing the usual industrial medical and safety services, the Division is responsible for the supervision of radiological safety activities, including radiation monitoring. Because of the unusual nature of the problems arising from operations involving plutonium, polonium, and other radioactive materials, the Division carries out appropriate biomedical research. The organization of the health services for the Laboratory differs somewhat from that in most AEC installations and industrial groups in the respect that all such services are grouped into a single organization with Division status.

The work of H Division may be divided broadly into two categories. Groups H-1, H-2, H-3, and H-5 are essentially health and safety service groups having both preventive and

SECRET
UNCLASSIFIED

remedial functions. Since the members of these groups frequently encounter special problems which they are not prepared to solve alone, there are two additional Groups, H-4 and H-6, for research and development. Although much of the work of these two groups is concerned with problems of immediate interest to the Laboratory, a considerable amount of fundamental research, bearing on the over-all weapons program, is carried out in the fields of biophysics, biology, and medicine. In spite of the group structure of H Division, it is seldom that any problem arises that can be handled entirely by members of any one group. There is thus considerable co-operation among the groups, and on occasion the facilities of all six groups may be devoted to a single problem.

Group H-1. Group Leader: Dean D. Meyer

Alternate Group Leader: Leo G. Chelius

Group H-1, which is the largest group in the Division, is responsible for radiation monitoring. Although in certain parts of the Laboratory monitoring may be done on a more or less routine basis, it is still necessary to have a group of experienced monitors who are ready for all eventualities. The members of the group are thus prepared to do alpha-particle monitoring, beta-gamma monitoring, neutron hazard evaluation, and personnel decontamination. One section of Group H-1 supervises all equipment decontamination, while another is in charge of film badges and photodosimetry for the entire Laboratory.

Group H-2. Group Leader: Robert S. Grier, M. D.

This is the occupational health group, frequently referred to as the industrial medicine group. It is staffed by three physicians and seven nurses, who, with various assistants, provide the services offered by the medical department in any large industry. Group H-2 performs pre-employment and termination physical examinations and any other examinations that may be necessitated by routine or occupational requirements. The group renders the customary first-aid for minor injuries and illnesses, and institutes investigations where working conditions may be questioned. In view of the unusual nature of the Laboratory activities, special studies, frequently requiring a certain amount of clinical research, are underway most of the time. Problems of this kind frequently involve co-operation among this group and the monitoring (H-1), safety (H-3), and industrial hygiene (H-5) groups. The physicians on the staff of H-2 are available at all times to any employee who may desire medical advice.

Group H-3. Group Leader: Roy Reider

Group H-3 is small, consisting of the group leader and three assistant safety engineers who fulfill the functions commonly performed by safety engineering groups in industry. In the Laboratory, however, a wide variety of problems of an unusual character are encountered. Members of the group must be familiar with the transportation, storing, and handling of

explosives, and they must also be well grounded in matters relating to both temperatures and pressures that may be extremely high or extremely low. They must also be well informed in connection with traffic safety and fire prevention.

Group H-4. Group Leader: Wright H. Langham

Biomedical research is the primary function of Group H-4, which is divided into four sections, dealing with biochemistry, radiobiology, radiopathology, and organic chemistry, respectively. Most of the work of this group is composed of relatively short-term studies on problems of direct or indirect interest to the Laboratory. In addition, there are a number of long-range research programs of a more or less basic nature.

Group H-5. Group Leader: Harry F. Schulte

Alternate Group Leader: Edwin C. Hyatt

The work of Group H-5 is concerned with industrial hygiene; its general function is similar to that of Group H-1, although it deals primarily with toxic rather than radiation hazards. The field section of this group carries on a continuous program of air sampling and other studies, wherever called for in and around various shops and laboratories. The air samples may be examined for relatively common industrial poisons, such as lead, mercury, carbon tetrachloride, benzene, etc., but in addition techniques must frequently be devised for the large number of potential poisons which are often unique to the Laboratory operations. Among their other responsibilities, the engineers of H-5 must be prepared to approve or disapprove the adequacy of ventilation hoods and similar laboratory installations. Members of the group are able to advise other Laboratory workers on the best methods for performing unusual tasks which may involve an element of danger. The laboratory section of Group H-5 is responsible for the assay of urine specimens for plutonium; this technique has been found to provide a very reliable index of exposure to the element or its compounds. The members of this section also carry out a wide variety of other analytical procedures, their range of work being considerably more extensive than that required of most State industrial hygiene laboratories. Finally, H-5 has a test operation section which is the outgrowth of the group's very extensive interest in problems connected with the fall-out following test shots at the Nevada Proving Grounds.

Group H-6. Group Leader: Thomas N. White

Meteorological Service: George J. Newgarden, Major, USAF

The radiological physics group, H-6, is composed of three sections, which are responsible for special problems, field test activities, and meteorology, respectively. The special problems section performs research and development primarily designed to support the monitoring work of Group H-1. In addition, members of this section may concern themselves with

UNCLASSIFIED

SECRET

problems of special interest to other groups. The field test section was established to maintain continuity of information concerning safety matters at weapon tests, both in the Nevada and Pacific Proving Grounds. The meteorology section, staffed by members of the Air Weather Service, USAF, not only provides daily weather forecasts for the immediate Los Alamos area, but also supplies technical assistance to any member of the Laboratory with a problem involving meteorology. A considerable amount of time of this section is devoted to matters of primary interest to J Division.

J Division

Division Leader: Alvin C. Graves

Alternate Division Leader: William E. Ogle

Associate Division Leaders: John C. Clark
Roderick W. Spence

The work of J Division is concerned with the general weapons-testing activities of the Laboratory. The Division is responsible for organizing field tests at the Nevada and Pacific Proving Grounds. In addition to the actual detonation of weapons being tested, this work calls for the provision of suitable personnel and equipment to plan and make the wide variety of diagnostic and other measurements associated with weapons tests. The development of special techniques as required by novel circumstances is an important aspect of this work. Finally, the Division acts as a liaison between the Laboratory, the AEC, and military Task Forces that may be involved in the conduct of the tests.

Group J-1. Group Leader: Armand W. Kelly

The functions of Group J-1, which is concerned with personnel and administration, include procurement of military personnel for the Division activities, processing personnel for travel to the Proving Grounds, and general administration for Laboratory personnel taking part in the weapons tests. The group also determines the working space and living quarters required for those participating in the tests and makes the necessary arrangements to meet these requirements.

Group J-3. Group Leader: Duncan Curry, Jr.

Associate Group Leaders: B. Carl Lyon
Philip L. Hooper

Plans and operations are the responsibility of Group J-3, which determines the operational requirements for the scientific programs in full-scale test activities and makes arrangements for facilities, equipment, and other necessary support. Detailed operation plans and orders are prepared, and provision is made for adequate communications and transportation facilities for the test groups at field locations.

UNCLASSIFIED

SECRET

Group J-6. Group Leader: Robert H. Campbell

Alternate Group Leader: Robert W. Newman

This group handles the construction and engineering aspects of field test operations. Its work includes liaison between the test group and the AEC and its contractors, and involves following the progress of the construction through to completion to be sure that the facilities are adequate for the purposes of the test groups. Group J-6 is also responsible for arranging a system of machine-shop facilities at the Proving Grounds for the repair, maintenance, and minor fabrication of equipment for scientific observations.

Group J-7. Group Leader: Theodore J. Blechar

Alternate Group Leader: James H. Hill

Group J-7 provides such engineering services and advice to the experimental groups as may be requested. It establishes design specifications for experimental equipment and makes drawings for shop fabrication, records, reports, etc. Equipment to be fabricated is routed through the machine shops, and items made by the shops or purchased from commercial vendors are checked, tested, and installed before delivery to the experimental groups.

Group J-10. Group Leader: Herman Hoerlin

Alternate Group Leader: Daniel F. Seacord, Jr.

The work of this group, in the field of blast hydrodynamics, is theoretical and analytical and is concerned with hydrodynamic yield, operational effects, and diagnostic experiments. In the determination of absolute yield, Group J-10 utilizes observations of the ball of fire. The calculations involve studies of theoretical wave forms, equations of state, radiative transport, and surface interactions. The responsibility for operational effects is primarily the prediction of blast and thermal effects for test planning. In this connection studies are made of previous test results on blast, damage criteria, water-waves, and propagation of shock waves in an inhomogeneous atmosphere. The purpose of the diagnostic work is to furnish information on the hydrodynamic aspects of experiments done by other groups in the Division.

Group J-10 also studies thermal radiation from the diagnostic, operational, and tactical standpoints. Most of the experimental work is conducted by the Optics Division of the Naval Research Laboratory, with which close liaison is maintained. Measurements are made of the prompt thermal radiation (thermal yield) and of the thermal power as a function of time. This includes studies of the spectral characteristics of the bomb energy in the infrared, visible, and ultraviolet regions. Spectroscopy is applied to determine the time dependent temperature and energy distributions of the radiant surfaces and of the space distribution of bomb components in the fireball. The propagation of radiation through air at normal and high temperatures is investigated, and optically-absorbing reaction products of air constituents formed by nuclear

and thermal radiations are identified. Recently, the study of selected optical problems, such as films for high-speed photography, have been added to the responsibilities of this group.

Group J-11. Group Leader: Roderick W. Spence

Alternate Group Leader: Jere D. Knight

Group J-11 employs the methods of radiochemistry to study yield, efficiency, neutron economy, and other behavior parameters of nuclear tests. Yield and efficiency are obtained from measurements of fission products and fissile elements remaining in airborne and surface debris collected after the explosion. By determining the radioactivity of other elements, such as those present in structural materials, in the environment, or deliberately introduced as "detectors" in or near the test device, information is obtained concerning local and over-all neutron economy and the performance of individual components. In support of this work, research is carried out on the properties of radioactive nuclei, on nuclear reactions, and on the chemistry of radioactive materials. Particular attention is paid to the study of isotopes and reactions obtainable only in the high neutron fluxes and temperatures of the interior of an exploding nuclear device.

Group J-12. Acting Group Leader: Leon J. Brown

Alternate Group Leader: Donald D. Phillips

Neutron flux measurements are made by Group J-12 on both fission and thermonuclear devices. The external neutron flux data contribute information concerning the total neutron economy and, in boosted and thermonuclear systems, make possible calculation of the total thermonuclear burning. b(3) [redacted] Measurements of high-energy (10 Mev or above) gamma-ray intensities associated with nuclear explosions add to the knowledge of neutron economy. Appropriate laboratory research is performed in support of this program, which involves the use of threshold detectors for (n,γ), (n,p), $(n,2n)$, and (γ,n) reactions, of nuclear emulsion plates, and of photocell-phosphor combinations for time studies.

Group J-13. Group Leader: Newell H. Smith

Alternate Group Leader: John S. Malik

This group studies fission-reaction history by determination of the neutron-multiplication rate (α) during the early stages of the explosion; this involves measurement of the intensity of prompt gamma rays which increases at the same rate as the neutron population. More efficient and more economical methods for determining the multiplication rate are being developed.

Group J-15. Group Leader: Gaelen L. Felt

Diagnostic and other tests by optical methods represent the prime function of Group J-15.

Diagnostic experiments for full-scale tests, utilizing optical, e.g., high-speed photographic, techniques, apart from spectroscopic, are designed to provide information concerning radiative and hydrodynamic behavior of nuclear devices in the stages immediately following the detonation. Non-diagnostic experiments, using exploding devices as sources, are also planned for research chiefly into various aspects of radiation hydrodynamics. The group designs and tests assemblies and instrumentation systems for carrying out these experiments. The field phase of the work is planned and executed and the data obtained are analyzed, reduced, and reported in suitable form. Liaison is maintained with outside contractors doing photographic work for the Laboratory in connection with weapons tests, and this work is subjected to general supervision.

Group J-16. Group Leader: Bob E. Watt

The primary responsibility of Group J-16 is the study of the reaction history in thermonuclear experiments. In general, the observations are made on the emission of neutrons and gamma rays, often in collimated systems, in order to determine the locality and efficiency of the thermonuclear burning. Gamma-ray intensity measurements as a function of time are made up to a period of seconds; these measurements may be applied to independent determinations of thermonuclear and fission yields. Other phenomena are being investigated, e.g., electromagnetic signals, for the purpose of developing new techniques which are either simpler than those now in use or which are adapted to special cases, such as operational or air drops. Basic cross section and diffusion calculations required for the interpretation of neutron and gamma-ray signals from thermonuclear devices are an important aspect of the work done. Radiation detection instruments which satisfy the special requirements of field work, namely, high time-resolution combined with improved sensitivity as compared with those available commercially, are being developed.

P Division

Division Leader: J. M. B. Kellogg

Alternate Division Leader: Richard F. Taschek

The activities of P (Physics) Division fall into two more or less distinct parts. One part, involving somewhat less than half of the total personnel, is devoted to the design and construction of a wide variety of electronic equipment for use in many Laboratory activities. The second part is concerned with problems of basic experimental physics and includes measurement of neutron cross sections for various processes, charged-particle reactions, fission physics, beta-ray spectroscopy, particle-counter development, and the investigation of controlled thermonuclear reactions. In general, many of the activities of P Division are dictated by the over-all interests of the Laboratory.

Group P-1. Group Leader: John K. Lamb

Alternate Group Leader: Richard J. Watts

Group P-1 designs and constructs electronic equipment, mainly at the request of other Laboratory groups but sometimes to anticipate a possible future demand. Maintenance and repair service is provided for various electronic instruments including those used for health monitoring. The group procures or makes much standard Laboratory equipment, including power supplies, pressure and vacuum controls, amplifiers, scalers, pulsers, and pulse-height analyzers. An electrical standards laboratory is maintained where checks can be made against standardized units of inductance, capacitance, resistance, and emf. There is also a clock, accurate to one part in 10^8, and facilities for determining frequencies.

Group P-2. Group Leader: Carroll W. Zabel

The enriched, homogeneous nuclear reactor, known as the Water Boiler, is operated by this group; the usual operating power is 25 kw. The maximum thermal neutron flux, in a reentrant tube 1 inch in diameter through the center of the reactor sphere, called the "glory hole," is 10^{12} neutrons/cm^2-sec. In addition, there is an appreciable flux of fast neutrons. The fast-neutron reactor, known as Clementine, has been dismantled and a new thermal reactor, with a power of 1000 to 2000 kw, is being planned. With the aid of the Water Boiler, experimental work is done on the fission process, e.g., angular correlation of fission fragments, velocity distribution of slowed fission fragments, and energy of fission fragments. Some studies are being made of radioactive nuclei, mainly, but not exclusively, of fission products. A uranium-235 "converter," used with the Water Boiler, provides a fission spectrum of neutrons, and with these a number of total neutron cross sections have been measured as a function of energy in the range from 7 to 12 Mev. Determinations are also made of the average fission cross section of uranium-238 for fission spectrum neutrons, and inelastic scattering cross sections for many elements, including fissile species. Group P-2 provides neutron irradiation services to the Laboratory and, to a limited extent, to other AEC contractors.

Group P-3. Group Leader: Richard F. Taschek

Alternate Group Leader: Arthur Hemmendinger

This group operates two electrostatic (Van de Graaff) accelerators, both providing a maximum potential difference of 2.5 Mv. These are used for the investigation of light-particle reactions; yields and cross sections for these reactions, and angular distributions and energies of the particles produced are measured. The interaction of neutrons with light elements (thermonuclear) and heavy elements (fission) and with other elements are studied. With the latter, the (n,2n) reactions are of special interest for radiochemical studies in weapons tests. Group P-3 makes precision measurements of fission cross section and of the number of neutrons released in fission as functions of neutron energy for high-energy neutrons.

Groups P-4 and P-6. Group Leaders: James H. Coon
Elizabeth R. Graves

These groups work mostly with 14-Mev neutrons produced by the bombardment of tritium, in a zirconium target, with deuterons accelerated by a 250-kv Cockcroft-Walton apparatus. The interactions of these neutrons with various thermonuclear fuels, possible tamper materials, and fissile materials are of special interest. Among the investigations being made with 14-Mev neutrons are the following: study of gamma rays produced by bombardment of various substances; inelastic and elastic scattering; total cross sections of elements; number of neutrons produced in fission; neutron multiplication; cross sections for (n,2n) reactions; and cross sections for the production of unwanted particles in their interaction with lithium nuclei. Group P-4 also calibrates neutron sources, using a standard graphite "pile." A Cockcroft-Walton accelerator, with a potential difference of 600 kv, is under construction.

Group P-7. Group Leader: James L. Tuck

By means of a 250-kv Cockcroft-Walton accelerator, Group P-7 is studying charged-particle reactions at relatively low energies, equivalent to those of interest for thermonuclear processes. Precision measurements of the cross sections for the D-D and D-T reactions at low energies have been made in this manner. The group is also devoting attention to the "Perhapsatron," which is a device whereby a controlled thermonuclear reaction may perhaps be initiated by using the "pinch effect," i.e., by the magnetic self-constriction of a high current discharge.

Group P-8. Group Leader: Clyde L. Cowan, Jr.

The main objective of Group P-8 is the construction and operation of very large liquid or plastic scintillation counters. The present specific application of such counters is to the hope of detecting the free neutrino as a result of its interaction with a proton to produce a neutron and a positron. Because of the extremely low cross section for this reaction, it could be observed only by means of a large counting device. One form of the device, already in operation, has been used to measure the total radioactivity of the human body.

Group P-9. Group Leader: Joseph L. McKibben

Group P-9 is occupied with the construction, operation, and use of a large electrostatic (Van de Graaff) accelerator having a potential difference of 10 Mv. This is necessary to provide monoenergetic neutrons in the energy range from 6 to 14 Mev which is acquiring special significance in connection with thermonuclear devices. Hitherto, the accelerator has been operated up to a potential of 5 Mv. High-energy neutrons are used mainly for the measurement of fast-neutron cross sections of thermonuclear and fissile materials.

Group P-10. Group Leader: Louis Rosen

This group, which has no facilities other than nuclear-plate cameras and plate-reading

facilities, uses the nuclear photo-plate technique to study the interaction of neutrons with various materials. Observations are made in this way of the neutron spectrum from a multiplying assembly bombarded by high-energy neutrons; of charged particles resulting from the reaction of 14-Mev neutrons with the isotopes of lithium; of cross sections for deuteron disintegration in the D-T and D-He^3 interactions. Group P-10 reads the fast-neutron health (film) badges for the Laboratory. It has also done some work on Taylor instability.

Group P-12. Acting Group Leader: Keith Boyer

Group P-12 operates and uses the cyclotron which gives deuterons of about 11-Mev energy. This accelerator is to be rebuilt, so that it can go to higher energies and also be capable of accelerating a number of other ions. The main work at present is concerned with (n,2n) cross sections of uranium-238 and the fission cross section of uranium-239. The latter problem is related to the yield of thermonuclear devices as affected by the fission of uranium-239 formed by neutron capture in uranium-238. A long series of experiments of (d,p) and (t,p) processes with fissile materials is involved.

T Division

Division Leader: J. Carson Mark

Associate Division Leaders: Frank C. Hoyt
Robert D. Richtmyer

In general, the Theoretical (T) Division is engaged in applying the methods of theoretical and mathematical physics and mathematics to various problems of the Laboratory and in developing methods to deal with new problems as they arise in the weapon design field. Thus, a major part of the attention of the Division is directed at attempts to understand the effects of various factors in weapon behavior, to predict the behavior of weapon systems, and to propose new systems of interest. As a rule, a basically new scheme for a nuclear weapon is first called to attention within T Division and receives its preliminary consideration there. In addition to this primary function, and in a large measure as a basis for it, the Division engages in a wide range of theoretical studies, including analysis of experiments, nuclear cross section theory, nuclear reactor theory, equation-of-state theory, neutron diffusion theory, hydrodynamics, and techniques of numerical computation.

Because of the special nature and variety of T Division activities, it is not possible to describe its functions completely according to its group organization. The major part of the work of the Division is accomplished by individuals applying their own particular training and experience, in one or more of the fields of study mentioned above, to problems related to fission weapons, thermonuclear weapons, the needs of other Divisions of the Laboratory, or necessary basic research. There are, however, two functions which have required the efforts

SECRET UNCLASSIFIED

of groups of persons to handle them and to provide the necessary continuity of effort. These are, first, the very extensive numerical computations that have been made in connection with the problems of nuclear weapon design and behavior which are handled by Groups T-1 and T-7; and, second, the theoretical aspects of weapon design, which are the responsibility of Groups T-4 and T-5.

Group T-1. Group Leader: Bengt Carlson
Alternate Group Leader: Max Goldstein

Group T-1 provides a general computing service to the Division and other parts of the Laboratory. Use is made of a variety of computing equipment, ranging from desk calculators, through the standard IBM multipliers, tabulators, etc., to the IBM 701 calculator, which is one of the most recent, fast, electronic computing machines.

Group T-2. Group Leader: Frederick Reines

Group T-3. Group Leader: Rolf Landshoff
Alternate Group Leader: G. Foster Evans

Group T-4. Group Leader: Conrad L. Longmire

This group has given special attention to problems arising in the field of neutron diffusion theory, particularly as applied to calculations of efficiency and yield of actual or possible weapon designs. It is also engaged in a wide variety of other activities in the field of nuclear weapons.

Group T-5. Group Leader: George N. White, Jr.
Associate Group Leader: Harwood G. Kolsky

In addition to a number of activities in the field of applied mathematics, Group T-5 has given special attention to the implosion problem. Several hundred implosion calculations have been performed, making use of the equipment of T-1 for this purpose.

Group T-6. Group Leader: Harris Mayer

Group T-7. Group Leader: Nicholas Metropolis

Group T-7 has designed and built at the Laboratory a fully automatic electronic calculator, known as the MANIAC, which has been in operation since the Spring of 1952. At that time, it was one of the most advanced pieces of equipment of this kind in operation anywhere in the United States. The group provides a general computing service for the Laboratory on the MANIAC. It also investigates computing techniques and moves to take advantage of new developments and improvements in electronic computer design.

Group T-8. Group Leader: Stanislaw Ulam

Group T-9. Group Leader: Bergen Suydam

Group T-10. Group Leader: Louis Goldstein

UNCLASSIFIED SECRET

W Division

Division Leader: Raemer E. Schreiber

Alternate Division Leader: David B. Hall

Assistant Division Leader: Benjamin L. Moore

The work of W (Weapons) Division is devoted mainly to weapon development. The Division participates in the exploration of the nuclear aspects of new weapon designs and has the basic responsibility for carrying the engineering of these designs through the development, testing, and production stages. Although this function of W Division applies essentially to the atomic warhead, some of its programs include joint responsibility with other organizations for over-all design of new weapons. The Division is also responsible for the acceptance and assembly procedures for nuclear components and for the development of field and laboratory equipment for stockpiling and inspecting active material. In connection with this activity, appropriate instructional and training manuals are provided for the Armed Forces.

Group W-1. Group Leader: George B. Sabine

Alternate Group Leader: W. W. Carter

b(3)

[redacted] The engineering functions include the design of experimental components, mechanical and environmental testing, preparation of special components for nuclear tests, and the development of detailed designs and specifications for the production of nuclear components which are stockpiled. The preparation and loading of nuclear materials for tests at the Nevada and Pacific Proving Grounds are the responsibility of the group.

Among the development activities are the origination and specification of handling, storage, and inspection procedures for nuclear components, e.g., design and prototype procurement of handling tools and inspection gauges. The manuals and military liaison section prepares and issues instructions for the handling of stockpile nuclear material. Research and development is carried out in allied fields, such as isotopic analysis of heavy elements, neutron-counting techniques, and methods for determining the enrichment of oralloy.

Group W-2. Group Leader: Hugh Paxton

Alternate Group Leader: John D. Orndoff

The main activity of Group W-2 is concerned with experiments on chain-reacting systems. It operates the remote-control laboratory for studies of critical and near-critical assemblies. Research is performed on the detailed behavior of chain-reacting systems, including the effect of small amounts of "poisons" on a critical assembly and the interpretation of the results in

terms of neutron cross sections. Critical mass determinations are made with a wide variety of systems, both for the purpose of studying their fundamental behavior and to provide information concerning the nuclear safety of weapon configurations or of manufacturing processes involving fissile materials. Members of the group act as consultants on nuclear safety to the Laboratory and to associated AEC contractors.

Group W-3. Group Leader: Donald MacMillan

Alternate Group Leader: Harlow Russ

The responsibilities of Group W-3 fall into two somewhat distinct categories. In the first place, it is responsible for essentially all gun-type weapon development work carried out by the Laboratory. b(3)

[redacted] A detailed treatment of some aspects of the work of this group is given near the end of Chapter 5.

Group W-4. Group Leader: Arthur Sayer

Alternate Group Leader: Robert K. Osborne

Group W-4 acts as a liaison between the theoretical and experimental work on fission weapons. Estimates are made of the influence on the expected yield of changes in the various parameters at the disposal of the warhead designer; among these are diameter of the HE system; diameter and mass of the tamper; and mass, composition, and geometrical arrangement of the fissile material. By means of calculation and empirical procedures, proposals are made for the optimum (or near-optimum) design for a specific weapon application. The group is also concerned with practical problems of weapon fabrication in evaluating the effect on yield of departures from ideal geometry of actual weapon designs.

Group W-5. Group Leader: Vernal Josephson

Alternate Group Leader: John R. Wieneke

Group W-5 has two unrelated functions. In the field of external initiation, it has developed the betatron (PRM) and pulsed D-T (ENS) initiators, and has conducted tests at the Nevada Proving Grounds which utilized the former device. In connection with thermonuclear weapon development, the group has the responsibility for the flight and drop testing, and for the organization and early conduct of the weapon assembly operations required under the Emergency Capability concept.

Group W-6. Group Leader: George M. Grover

Alternate Group Leader: Jacob J. Wechsler

Certain aspects of the work in the two-stage, thermonuclear weapon field, formerly conducted by the DIRX staff, is being taken over by Group W-6 as of January 1, 1954. The group will be responsible for the design of the outer case of the devices and for the integration of component designs into that of a complete warhead.

7.5 Administrative and Service Departments and Groups

Accounting Department. Head: A. Dwight Richardson

Keeps financial records and accounts of Laboratory operations.

ADP-SF Group. Group Leader: Glenn R. Champion

Maintains SF (Source and Fissionable) material accountability for the Laboratory.

Budget Office. Head: Leslie G. Hawkins

Prepares the budget for the Laboratory.

Business Office. Manager: Albert E. Dyhre

Maintains liaison on contracts with AEC and subcontractors; makes arrangements for travel and workmen's compensation.

Engineering Department. Head: John Bolton

Provides construction and maintenance engineering services for the entire Laboratory.

Graphic Arts Group. Group Leader: Loris Gardner

Functions include photography at the Laboratory and in connection with weapons tests; photostat, Ozalid, and litho reproduction; assembly and binding.

Mail and Records Group. Group Leader: Pat McAndrew

Alternate Group Leader: Blanche Gilman

Collects and distributes mail and other correspondence and keeps records with special attention to classified matter.

Personnel Department. Head: John V. Young

Performs customary personnel functions.

Shop Department. Head: Gus H. Schultz

Operates all professionally staffed machine shops for the Laboratory.

Supply and Property Department. Head: Harry S. Allen

Procures, stores, issues, and keeps account of all supplies and property; responsible for shipping and receiving.

Wage and Salary Department. Head: John A. Woodward

Performs customary wage and salary functions.

8.1 Introduction

DOE b(3)

Thermonuclear Burning

As seen in the preceding chapters, thermonuclear (D-D and D-T) reactions are used for the initiation and the boosting of nuclear fission chains.

The problem to be considered in this chapter is the development of methods whereby large amounts of energy may be produced from thermonuclear reactions.

The continuous release of energy in a thermonuclear system involves the propagation of a chain reaction; but this resembles a thermal chain, such as occurs in flame propagation, rather than a fission chain. In the latter, particles, i.e., neutrons, produced in one step of the reaction are the means for causing further (fission) reaction to occur. In a thermonuclear system, as in a flame, the energy liberated in the reaction raises a volume element to a high temperature. This heats an adjacent volume element sufficiently to permit the reaction to occur rapidly. The resulting increase of temperature then heats a further volume element, and so on, until the reaction (or flame) has spread throughout the whole system. It is this similarity between thermonuclear reactions and flame propagation that gives rise to the use of the term "burning" in the former case (see Section 1.6), as in the latter.

It should be noted that whether burning, i.e., propagation of the reactions, will occur or not, depends on a competition between the rate at which heat is produced by the reactions and that at which it is lost, from a given volume element, in various ways. The former must, of course, predominate if burning is to occur, and the temperature attained must be high enough for the reactions to be rapid.

Material and Radiation Energies

At temperatures of the order of a few thousand degrees, the energy of a system is almost entirely material energy, i.e., essentially thermal kinetic energy with perhaps a small amount of potential energy. This material energy, E_m, is proportional, approximately, to the mass, M, of the system and to its absolute temperature, T; thus,

DOE b(3)

$$E_m = aMT \,, \qquad (8.1)$$

UNCLASSIFIED

where a may, for the present purpose, be regarded as constant for the given system.

UNCLASSIFIED

DOE b(3)

8.2 Thermonuclear Reaction Rates

Barrier Penetration

In order for two nuclei to react, they must approach sufficiently near to one another to permit the short-range nuclear (attractive) forces to become effective. This approach will be prevented by the electrostatic (coulomb) repulsion between the positively charged nuclei. In other words, there is a potential barrier which must be overcome before the nuclei are close enough to interact. If r is the distance between the nuclei, then the height of the barrier at this point is equal to the coulombic energy, $ZZ'e^2/r$; Z and Z' are the respective nuclear

*For the basis of expressing absolute temperatures in energy (kev) units, see below.

UNCLASSIFIED

SECRET SECRET UNCLASSIFIED

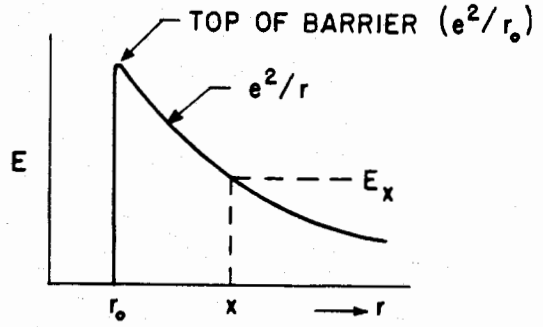

Fig. 8.1

charges and e is the unit (electronic) charge. Since Z and Z' are both unity for reactions between the isotopes of hydrogen, it is evident that these reactions involve lower potential barriers, and should occur more readily, than other nuclear reactions.

The potential barrier opposing the approach of two hydrogen nuclei is indicated in Fig. 8.1, in which the potential energy, E, equal to e^2/r, is plotted against the distance of approach of the nuclei. The potential energy is seen to drop sharply when the internuclear distance is r_o, for at this point the short-range attractive forces between the nuclei become effective. According to classical theory, therefore, the energy required to make nuclear reaction possible is equal to e^2/r_o, the potential energy at the top of the barrier.

As stated in Section 1.6, the energy e^2/r_o is of the order of 0.1 Mev; yet reactions between nuclei of hydrogen isotopes occur at appreciable rates at much lower energies. This fact has been explained by means of wave mechanics. According to classical theory, if the (kinetic) energy of a pair of nuclei is E_x (Fig. 8.1), they can approach no closer than a distance x. That is to say, they should be unable to come close enough to interact.

In terms of the wave mechanical concept, however, it can be shown that even though the energy is less than e^2/r_o, there is always a certain probability that the barrier will be penetrated and the nuclei will react. This probability is less the lower the nuclear energy, but it is, nevertheless, always finite, even though it may be very small. Consequently, nuclear reactions can occur at energies considerably less than that of the top of the potential barrier.

It may be noted that the probability of penetrating the potential barrier is greater for nuclei of low charge. This is another reason why reactions among isotopic hydrogen nuclei take place at lower energies than do those between nuclei of higher charge.

Of the reactions between pairs of nuclei of the three hydrogen isotopes, i.e., hydrogen ($_1H^1$), deuterium ($_1D^2$), and tritium ($_1T^3$), those involving H nuclei (or protons) are not important, mainly because the effective rates (or cross sections) of these reactions are relatively small.

DOE b(3)

UNCLASSIFIED

SECRET SECRET

UNCLASSIFIED

$$D^2 + D^2 \rightleftharpoons \begin{cases} He^3 + n^1 + 3.27 \text{ Mev} \\ T^3 + H^1 + 4.04 \text{ Mev} \end{cases}$$

$$D^2 + T^3 \longrightarrow He^4 + n^1 + 17.6 \text{ Mev}.$$

It is seen that there are two alternative D-D reactions; they take place roughly at the same rates, so that each may be regarded as occurring in half the D-D interactions.

D-D and D-T Cross Sections

The rate of a nuclear process is usually expressed in terms of the effective area per nucleus, i.e., the cross section. These cross sections can be determined experimentally by accelerating deuterons or tritons to known energies and determining the extent of interaction with other (stationary) nuclei. The results obtained for the second of the D-D reactions given above, represented by DD_p, and for the D-T reaction are shown in Fig. 8.2. The values for the other D-D reaction are very similar. The cross sections, $\sigma(E)$, are expressed in barns, i.e., in units of 10^{-24} cm^2, as a function of the deuteron energy in kev.

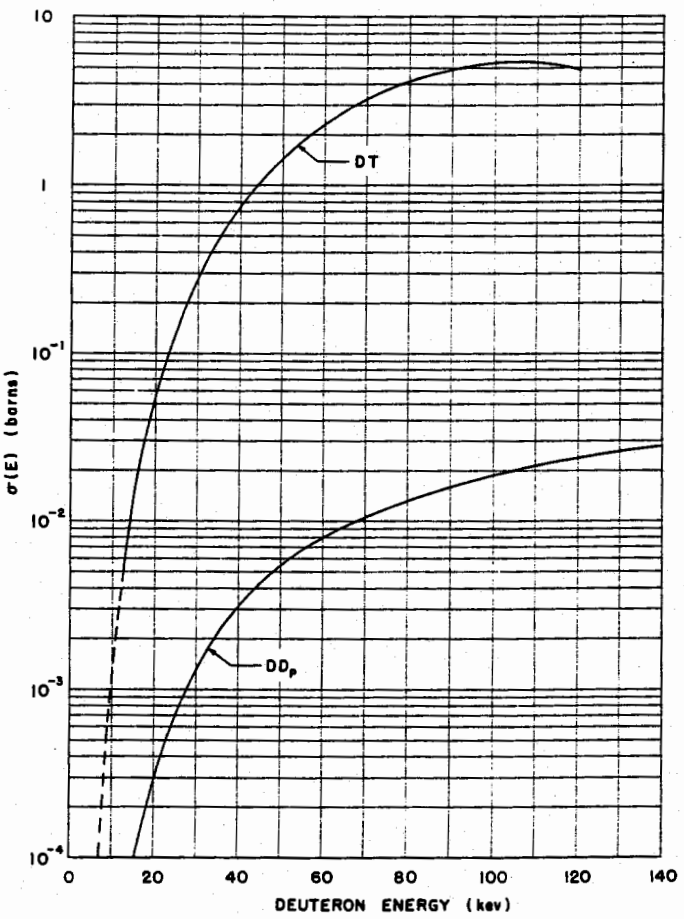

Fig. 8.2

The cross section, or reaction rate, is seen to increase with the energy, due to the increased probability of penetration of the potential barrier. It may be mentioned that the cross-section curve for the D-T reaction is not only somewhat higher than expected, but it also exhibits a maximum at energies around 100 kev (see Fig. 8.2). This is attributed to the phenomenon of resonance.

UNCLASSIFIED

Calculation of Reaction Rates

Consider a quantity of deuterium, and let the cross section, σ, represent the effective area of a nucleus of a given energy for the D-D reaction. If v is the velocity of the deuterium nucleus, then it will sweep out an effective volume σv in unit time, e.g., per sec. If there are N deuterons per cm^3, then the total effective volume swept out is σvN per cm^3 per sec. Since there are N deuterons present per cm^3, the number of effective D-D collisions, i.e., the rate of the D-D reaction, is equal to $\sigma vN^2/2$ per cm^3 per sec. The factor of one half is introduced here, for otherwise each D-D collision is counted twice. In the case of the D-T reaction, the corresponding rate would be σvN_dN_t per cm^3 per sec, where N_d and N_t are the numbers of deuterons and tritons, respectively, per unit volume.

It is seen from the foregoing argument that, apart from the density of the material, i.e., the number of nuclei per cm^3, the rate of a nuclear reaction is determined by the product σv. In a system at a given temperature, T, not all the nuclei will have the same energy and, hence, velocity.* The energies will, in fact, be distributed over a large range from very small to very large, as indicated qualitatively, in Fig. 8.3; $n(E)/n$ is the fraction of nuclei having energy E, per unit energy interval. If the energy distribution follows the Maxwell law, then the energy corresponding to the most probable velocity, per unit velocity interval, is equal to kT, where k is Boltzmann's constant; this is generally referred to as the energy corresponding to the temperature T.

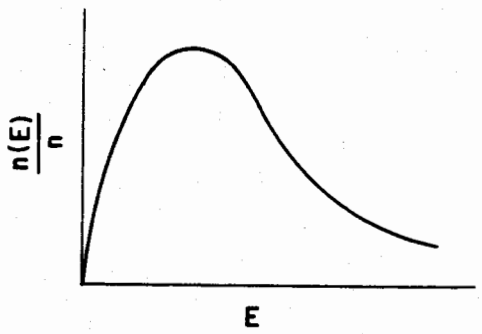

Fig. 8.3

As implied earlier, it has become the practice in the thermonuclear field to state the temperature as the energy kT, usually expressed in kev. Since k is 8.62×10^{-8} kev per degree, it follows that

$$\text{Temperature in kev} = 8.62 \times 10^{-8}\ T\ ,$$

where T is the absolute (Kelvin) temperature. Thus, a so-called temperature of 1 kev would correspond to a Kelvin temperature of 1.16×10^7 degrees.

*Since the energy E is kinetic, it is equal to $1/2\ mv^2$, where m is the mass of the nucleus; hence, v is determined by E, for a given species.

In order to determine the rate of a nuclear reaction at a given temperature, it is necessary to obtain a proper weighted average of σv, i.e., $\overline{\sigma v}$, over the whole energy range, since both σ and v vary with the nuclear energy. This can best be done by taking the experimental values of σ as a function of E (or of v), from Fig. 8.2, multiplying by the corresponding velocity, v, and then weighting each product according to the Maxwellian probability of that velocity. This operation may be expressed analytically by

$$\overline{\sigma v} = \frac{\int [\sigma(v)v] \; v^2 e^{-\frac{mv^2}{2kT}} \, dv}{\int v^2 e^{-\frac{mv^2}{2kT}} \, dv} , \qquad (8.5)$$

where the integrand in the denominator is the Maxwell factor. The values of $\overline{\sigma v}$ for one of the D-D reactions and for the D-T reaction, obtained somewhat in this manner, are plotted in Fig. 8.4 as a function of the temperature in kev. It is seen that, under equivalent density conditions, the D-T reaction is of the order of 50 to 100 times as fast as each of the D-D reactions at the same temperatures, at least in the range from 1 to 100 kev.

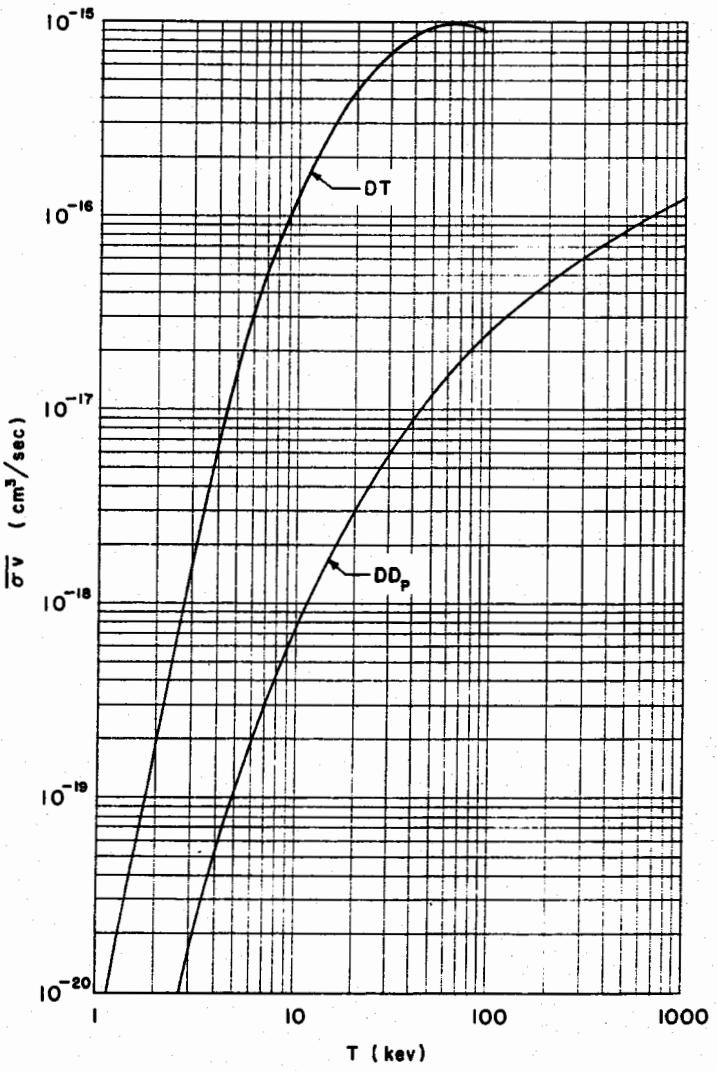

Fig. 8.4

The Reproduction Time

To illustrate the use of the data in Fig. 8.4, the energy reproduction time, i.e., the time required for the energy to double itself, in deuterium will be calculated. In every effective D-D collision, two deuterons are consumed, but in (roughly) half of these reactions a tritium nucleus is produced, which rapidly undergoes the D-T interaction with another deuterium nucleus. Thus, on the average, 2.5 deuterons are used up in every

effective collision.* From the arguments presented above, the number of effective D-D collisions is $\overline{\sigma v} N^2/2$ per cm^3 per sec, and so deuterons are consumed at the rate of $2.5\ \overline{\sigma v} N^2/2$ per cm^3 per sec. Since N is the number of deuterons present per cm^3, the fraction, F_t, of the deuterium reacting in time t sec is given by

$$F_t = \frac{2.5}{N}\ \overline{\sigma v}\ \frac{N^2}{2}\ t = 1.25\ \overline{\sigma v} N t\ , \qquad (8.6)$$

where t is assumed to be so short that N does not decrease appreciably.

If the two D-D reactions take place to, approximately, the same extent and every tritium nucleus formed rapidly undergoes the D-T reaction with another deuteron, the total energy liberated will be 4.04 + 3.27 + 17.6 = 24.9 Mev or, roughly, 25 Mev, for the consumption of five deuterons, i.e., 5 Mev or 5000 kev per deuteron. The energy ΔE produced in time t, per deuteron present in the system, is equal to F_t x 5000 kev, and so

$$\Delta E = 6250\ \overline{\sigma v} N t \text{ kev per deuteron.}$$

If E_{tot} is the total energy per deuteron present in the system, then the reproduction time, t_{rep}, i.e., the time required for the energy to double itself, due to the D-D and D-T reactions, is given by

$$t_{rep} = \frac{E_{tot}}{6250\ \overline{\sigma v} N}\ . \qquad (8.7)$$

DOE b(3)

UNCLASSIFIED

DOE 5(3)

Production of Lithium-6

The enrichment of lithium-6, from its normal isotopic proportion of 7.3 per cent to the 95 per cent or so desirable for thermonuclear devices, is carried out by a chemical, isotopic exchange process. Lithium amalgam, consisting of a solution of metallic lithium in mercury, is allowed to interact with an aqueous solution of lithium hydroxide in water. As a result of the exchange between the lithium isotopes in the mercury and those present as ions in the water, the ratio of lithium-6 to lithium-7, at equilibrium, is larger in the amalgam than in the aqueous solution. The separation coefficient is not much greater than unity, and appreciable enrichment is achieved by a continuous counter-current process. The lithium amalgam, flowing in one direction, becomes steadily richer in the Li^6 isotope, whereas the proportion of lithium-7 increases in the hydroxide solution. Because of the separation difficulties, highly enriched lithium-6 is still rare and costly.

EXPERIMENTAL STUDIES OF TAYLOR INSTABILITY

Work done by:
John C. Allred
George H. Blount
John H. Miller, III

Report written by:
John C. Allred
George H. Blount

PHYSICS

ACKNOWLEDGMENT

The work described in this report was undertaken at the behest, primarily, of Conrad Longmire and J. L. Tuck, to whom we are indebted for their continued interest and helpful discussions.

On account of the many specialized techniques which were required, we had need for consultation with various members of the Laboratory. A complete list would be long indeed, but we feel obliged to list the following as having been of great assistance in various phases of the work: Garrett Birkhoff, W. L. Briscoe, Berlyn Brixner, W. E. Buck, P. W. Byington, D. S. Carter, and R. E. Duff.

We wish also to note our appreciation of the very helpful cooperation of the Graphic Arts Group, under Loris Gardner and J. D. Elliott, and to Catherine Lacey and Opal Milligan of the Nuclear Microscopy Group for their assistance in analyzing the data.

Chapter 1

THE THEORY OF TAYLOR INSTABILITY

1.1 Potential Theory as Applied to Hydrodynamics

The equation of motion of a perfect fluid is[1]

$$\rho \frac{\partial v}{\partial t} + \rho v \cdot \nabla v = \rho F - \nabla p + 1/3\ \mu \nabla \nabla \cdot v + \mu \nabla \cdot \nabla v \tag{1.1}$$

where ρ is the density, v the velocity, F the body force (per unit mass), and μ the coefficient of viscosity. The equation of continuity is

$$\frac{d\rho}{dt} + \rho \nabla \cdot v = 0 \tag{1.2}$$

It can also be shown that the vorticity, ω, is given by

$$\omega = \frac{1}{2} \nabla x v \tag{1.3}$$

A very powerful method in hydrodynamics is that of potential theory, which enters when the motion is assumed to be irrotational and incompressible. For then

$$\frac{d\rho}{dt} = 0 \text{ and} \tag{1.4}$$

$$\nabla \cdot v = 0 \tag{1.5}$$

Further, since $\nabla x v = 0$, v is derivable from a scalar potential ϕ, owing to the vector identity $\nabla x \nabla \phi = 0$.

Hence

$$v = -\nabla \phi \tag{1.6}$$

where the negative sign is conventional and ϕ is called the velocity potential. ϕ satisfies Laplace's equation

$$\nabla^2 \phi = 0 \tag{1.7}$$

Under the conditions of incompressible, irrotational flow the equation of motion (1.1) becomes

$$\rho \frac{\partial v}{\partial t} + \rho v \cdot \nabla v = \rho F - \nabla p + \mu \nabla \cdot \nabla v \tag{1.8}$$

If we neglect viscosity and assume F to be derivable from a potential Ω (usually the gravitational potential), we can integrate the equation of motion to obtain Bernoulli's equation

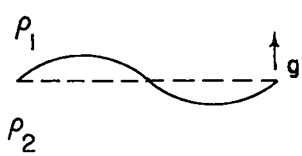
$$\frac{p}{\rho} = \frac{\partial \phi}{\partial t} - \Omega - 1/2\ v^2 + f(t) \qquad (1.9)$$

We note that if the motion is steady, f(t) is a constant.

Hence the solution for the velocity potential in irrotational, incompressible flow is that solution of Laplace's equation which satisfies (1.9) together with the physical boundary conditions.

Sir Geoffrey Taylor[2] has used the potential theory to discuss the motion of the interface between two incompressible fluids in a gravitational field, neglecting surface tension and viscosity. His result is that an infinitesimal sinusoidal displacement of initial amplitude η_0 grows as

$$\eta = \eta_0 \cosh \alpha t$$



where $\alpha = \left[kg \frac{\rho_2 - \rho_1}{\rho_2 + \rho_1} \right]^{1/2}$, provided $\rho_2 > \rho_1$ and the gravitational field is directed from ρ_2 toward ρ_1.*

Taylor's solution neglects the term $\frac{\rho v^2}{2}$ in Bernoulli's equation in order to linearize the theory. This term has likewise been neglected by subsequent workers, although its effect is perhaps important in the development of asymmetries in the interface, as we shall presently suggest.

1.2 Derivation of Instability Criteria

Rigorous mathematical discussions of the Taylor instability are to be found in the literature and will not be repeated here. It is possible, however, to give approximate derivations which lead to the same results and possibly give more physical insight into the effects of various quantities than do the more elegant presentations.

To this end, let us consider the equation of motion of an interface in an acceleration field of magnitude g, as indicated in the sketch. If η is the displacement of the interface, the restoring force will be of the order of

$$f = -\eta \lambda g(\rho_2 - \rho_1)$$

and the mass which must be moved is, approximately, $(\rho_2 + \rho_1)\lambda^2$, since the circulation in a wave is of depth of order λ.

*We may here observe that the effect of a gravitational field is completely equivalent to the acceleration of a system in a direction opposite to that of the gravitational force. Hence we may say that the interface is unstable if the acceleration is directed from the lighter to the denser medium or, equivalently, when the gravitational field is directed from the denser to the lighter medium.

For the purpose of determining the physical existence of a density gradient at a water-isoamyl alcohol interface, we observed by the schlieren technique a cell containing water and isoamyl alcohol. This cell was one of the halves of the acceleration tube used in our Lewis apparatus. The schlieren photographs which resulted are shown as Figs. 4.8, 4.9, and 4.10; these show the progressive thickening in time of the region of optical density gradient. Similar observations on interfaces of water-n-heptane showed only a line at the interface, due to the curvature of the meniscus. An effect similar to that observed with water-isoamyl alcohol was seen to occur at a water-n-octyl alcohol interface. However, the effect was much less pronounced.

According to the theory of the Taylor instability one expects that initially the amplitude of a disturbance grows as cosh αt, where α is a reproduction factor and t is the time. Cosh αt is approximately represented by $e^{\alpha t}/2$, an approximation which becomes increasingly more valid as αt increases. In the later stages of the growth the theory predicts that the lighter fluid will penetrate the heavy fluid at constant velocity, in analogy with the constant rate of rise of bubbles, while the heavier fluid will be in free fall under an acceleration which is constant, but may be diluted by an Atwood factor.[12] Hence one would expect the amplitude to increase according to a form such as $a = a_o + vt + 1/2\ at^2$. In very late stages the term t^2 should predominate and one would expect that the amplitude would be simply proportional to t^2 To check these predictions, we have measured the amplitude of disturbances of various wavelengths as a function of the time. These measurements were made primarily from the 16-mm negatives by means of Leitz Ortholux microscopes at low magnifications. At the same time the estimated mean position of the interface was measured so that the acceleration could be determined. The results of a typical set of such measurements are shown in Figs. 4.11, 4.12, and 4.13. In Fig. 4.11 we have plotted the square root of the observed mean displacement of the interface against the time. The result is a straight line, the slope of which measures the acceleration. The intercept on the time axis indicates the time at which the acceleration began on the arbitrary time scale. Taking the time zero thus obtained as the true zero in time, we have plotted in Fig. 4.12 lnA vs true time. We observe that, while the scatter of the points is considerable, a straight line can be drawn reasonably well through the first portion of the curve. The slope of this line is a measure of the α which is observed experimentally.

In Fig. 4.13 $A^{1/2}$ vs t is plotted for a typical observation. It is seen that in the latter stages of the growth a linear relation applies between these two variables. The slope of the line in this region is a measure of the acceleration of the heavier fluid into the light. Table 4.2b gives a comparison of the observed values of α with those predicted by the linear theory of Taylor and that of Pennington, which has taken into account the effects of surface tension

ABSTRACT

The initial growth of irregularities on an interface between two compressible fluids is studied for impulsive (i.e., shock) acceleration. It was found that the ultimate rate of growth is roughly the same as that given by the incompressible theory, if the initial compression of the irregularities and of the fluids is taken into account.

APPROVED FOR PUBLIC RELEASE

APPROVED FOR PUBLIC RELEASE

Chapter I -- INTRODUCTION

G. I. Taylor developed a theory of the growth of irregularities on the interface between two fluids of different densities when they are in accelerated motion. The fluids are assumed incompressible and the interface to have sinusoidal corrugations, so that the position of the interface in a suitably-oriented cartesian coordinate system is given by

$$z = a \cos kx \tag{1}$$

at some instant, where a and k are constants and where

$$k\,a \ll 1. \tag{2}$$

Then if there is an acceleration of the system as a whole and if g(t) represents the z-component of acceleration, the growth or decay of the amplitude a = a(t) of the corrugations satisfies the equation,

$$\frac{d^2}{dt^2}\,a(t) = k\,g(t)\,a(t)\,\frac{\rho_{(+)} - \rho_{(-)}}{\rho_{(+)} + \rho_{(-)}}, \tag{3}$$

where $\rho_{(+)}$ and $\rho_{(-)}$ are the densities of the fluids, on the +z and -z sides of the interface, respectively.

If viscosity, surface tension, compressibility are absent, (3) is rigorous so long as (2) continues to hold. If the irregularity consists of a superposition of sinusoidal corrugations, each satisfying (2), then

APPROVED FOR PUBLIC RELEASE

APPROVED FOR PUBLIC RELEASE

[redacted]
SECRET
UNCLASSIFIED

each of them satisfies also (3) with its appropriate value of k. For constant acceleration directed toward the denser fluid, (3) gives an exponential growth of a(t). It is also known that after ka has reached about 1, from there on the increase of a is more leisurely, at about a constant rate (the shape is no longer sinusoidal). It is therefore generally assumed that (3) describes fairly well the growth of long-wave-length irregularities of small amplitude ($ka \ll 1$), even though irregularities of very short wavelength have gone out of the linear range near the beginning of the acceleration, since the fuzziness of the interface caused by the short-wave-length irregularities may extend only over distances small compared to the amplitudes of the longer-wave-length irregularities. (3) has been used for calculating the growth of irregularities for practical purposes.

In some practical cases, part or all of the acceleration is impulsive; i.e., g(t) is very large during a very short time interval and zero or small outside that interval. Let v be the increment of velocity imparted by this acceleration, $= \int g(t)\,dt$; then if the situation before the acceleration is

$$a = a_o, \qquad \frac{da}{dt} = 0, \qquad \text{(before)}, \tag{4}$$

the situation immediately after is:

$$a = a_o, \quad \frac{da}{dt} = k\,v\,a_o\,\frac{\rho_{(+)} - \rho_{(-)}}{\rho_{(+)} + \rho_{(-)}} \quad \text{(immediately after)} \tag{5}$$

as can be seen by integrating (3).

UNCLASSIFIED

The limiting case of impulsive acceleration is acceleration by a shock. In this case the compressibility of the fluids certainly cannot be neglected, so that (3) cannot be used. The object of study reported here is to compute the growth of irregularities when a shock sweeps across a corrugated interface from a less dense to a more dense fluid.

In Fig. 1 are schematic before-and-after pictures, showing the incident shock, which is assumed plane, and the transmitted and reflected shocks, which are corrugated. Before the arrival of the shock, the materials are at rest, in accordance with the initial conditions (4). Pressure is assumed constant behind the incident shock.

It is clear that immediately after the passage of the shock, as depicted schematically in Fig. 1, the conditions will not be as given by (5), above. Instead, the amplitude a will be somewhat less than a_o, because of the overall compression of the fluids, and furthermore $\frac{da}{dt}$ will be zero, because the forward velocity imparted by the shock to the crest of the corrugation will be the same as that imparted to the trough, and $\frac{da}{dt}$ is simply one-half the difference of these. Until there has been time for communication, by sound signals, of effects over distances comparable with 1/k, there can be no difference in behavior between crest and trough. (In the incompressible theory, effects are transmitted instantaneously by fluid pressure, so that $\frac{da}{dt}$ can acquire a non-vanishing value immediately, as stated in (5) above.)

But as time goes on, the amplitude of the corrugation of the

[redacted]

APPROVED FOR PUBLIC RELEASE

APPROVED FOR PUBLIC RELEASE

[redacted]

UNCLASSIFIED

interface begins to grow, because near the crests, where the heavy fluid protrudes farthest into the light, the transmitted shock is slightly converging and the reflected shock slightly diverging; this produces a slight pressure excess in the heavy fluid and deficiency in the lighter, whereas at the troughs of the corrugations, the reverse situation holds; and these pressure perturbations are in such directions as to hold back the crests but accelerate the troughs into the heavy fluid. Our aim is to calculate these pressure perturbations and from them the motion of the interface.

One may surmise that by the time the shocks have moved to distances several times $1/k$ from the interface, the net result will be qualitatively as for the incompressible case; namely, the amplitude will have acquired a rate of change $\frac{da}{dt}$ of the same order of magnitude as that given by (5), and thereafter $a(t)$ will increase practically linearly with time. If the limiting value of $\frac{da}{dt}$ should be much greater or much less than for the incompressible case, this would perhaps be of practical importance in some problems, and would indicate the extent to which equation (3) is invalidated by effects of compressibility.

Chapter II - BASIC EQUATIONS.

Sec. 1. General. Referring to Fig. 1, we take a comoving coordinate system, after the primary shock has crossed the interface, in which the mean position of the interface is $z = 0$. Let w_1 and w_2

PHYSICS

(Distributed according to
TID-4500, 11th edition)

INTRODUCTION

The material below consists of a more elaborate analysis of various topics discussed in Report LA-1862, "Taylor Instability and Laminar Mixing". These topics are covered in a series of eight appendices, as follows:

		Page
Appendix A	Remarks on Similarity	5
Appendix B	Initial Acceleration	9
Appendix C	Stability of Heterogeneous Fluids	22
Appendix D	Steady State Bubble Rise	23
Appendix E	Remarks on Layzer's Model	49
Appendix F	Calculation of Interface Motion	52
	Note by E. Fermi: Taylor Instability of an Incompressible Fluid	67
Appendix G	Motion of Polygonal Interface (Fermi Model)	75
Appendix H	Globule Acceleration	85

TAYLOR INSTABILITY OF AN INCOMPRESSIBLE LIQUID

by

Enrico Fermi
September 4, 1951

This is an attempt to discuss in a very simplified form the problem of the growth of an initial ripple on the surface of an incompressible liquid in presence of an acceleration, g, directed from the outside into the liquid.

The model is that of a heavy liquid occupying at $t = 0$ the half space above the plane $z = 0$. It is well known that this is a state of unstable equilibrium. Any tiny ripple on the surface at the initial time grows in amplitude, first exponentially and later, when its amplitude has become comparable to the wavelength, by a more complicated law.

The case will be considered that there is initially a small amplitude sinusoidal ripple of wavelength λ. In a first phase this amplitude will increase exponentially like

$$\exp\left(\sqrt{\frac{2\pi g}{\lambda}}\, t\right) \tag{1}$$

This exponential law, however, will break down when the amplitude has become comparable to $\lambda\!\!\!^{-} = \lambda/2\pi$. We propose to discuss what happens in the subsequent phase.

This will be done by grossly schematizing the shape of the wave as indicated in Fig. 1.

Instead of a wave profile like the curve, a profile like ABCDEFGHIJ will be assumed.

It is clear from the symmetry of the problem that the points at the maximum and the minimum of the wave move in vertical directions. In Fig. 2 a half wave, from a maximum to the successive minimum is represented with the notations adopted. OO' is the initial level of the liquid. On account of the incompressibility, the amount of liquid below the plane OO', namely CO'DE must be equal to the amount of liquid ABCO missing from above. This condition leads immediately to the relationship

$$b = \frac{ax}{1-x} \tag{2}$$

Our schematic wave profile is then characterized by the two parameters a, x. The problem is to determine how they vary with time.

In principle the problem so simplified could be solved by expressing the kinetic energy T and the potential energy U of the liquid contained between the two boundaries OA, O'E as functions of a, x, $\dot{a}$, $\dot{x}$.

$$T = T(a, x, \dot{a}, \dot{x})$$

$$U = U(a, x)$$

One can then write the Lagrange equations

$$\frac{d}{dt}\frac{\partial T}{\partial \dot{x}} - \frac{\partial T}{\partial x} = -\frac{\partial U}{\partial x}; \quad \frac{d}{dt}\frac{\partial T}{\partial \dot{a}} - \frac{\partial T}{\partial a} = -\frac{\partial U}{\partial a} \tag{3}$$

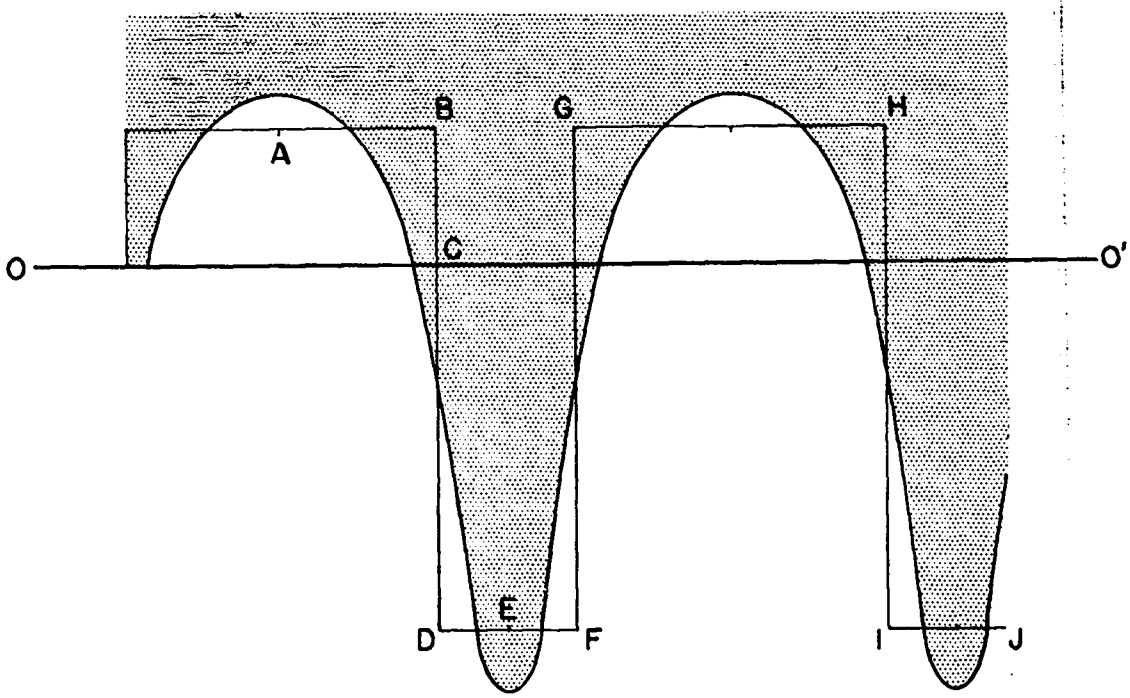

Fig. 1

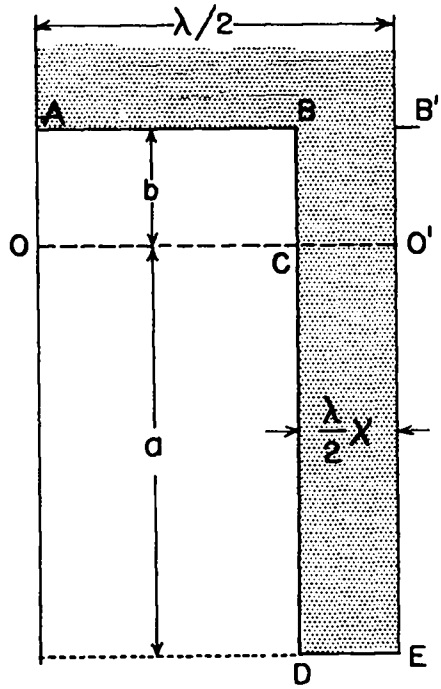

Fig. 2

which describe the law of variation of the two wave parameters $\underline{a}$, $\underline{x}$.

The potential energy U can be written down immediately. It is due to having moved the liquid originally contained in ABOC (weight per unit length perpendicular to the plane of the drawing = $\rho g \frac{\lambda}{2} b(1 - x)$, height of the center of gravity = $b/2$) to the lower position CDEO' with the center of gravity at a height $-a/2$.

In what follows the following unit will be used: unit of length, $\frac{\lambda}{2}$; unit of acceleration, g; unit of density, ρ.

One finds, then, the potential energy

$$U = -\frac{1}{2}\frac{a^2 x}{1-x} \tag{4}$$

The calculation of the kinetic energy is more difficult. In principle it could be carried out for a prescribed motion of the profile of the liquid by solving a Dirichlet problem. Instead of doing this, a much cruder method was followed in keeping with the crude approximation chosen for the profile of the wave.

When the amplitude of the wave is very large, it is evident that the kinetic energy is due primarily to the vertical component of the liquid velocity inside the domain BDEB'. The corresponding kinetic energy can be computed easily on the assumption that the vertical component of the velocity is constant on each horizontal section of BDEB'. One finds that this part of the kinetic energy is given by

$$T_1 = \frac{a^3 x^2}{6x(1-x)} \tag{5}$$

For small and moderate amplitudes of the wave, additional terms in the kinetic energy become important. One of them is the kinetic energy due to the horizontal component of the motion of the liquid BDEB'. This term of the kinetic energy is given approximately by

$$T_2 = \frac{a x \dot{x}^2}{6(1-x)} \tag{6}$$

Finally, the kinetic energy due to the motion of the liquid above the line AB' should be estimated. An approximate expression for this term of the kinetic energy yields

$$T_3 = \frac{\pi}{4} \frac{a^2 \dot{x}^2}{(1-x)^2} + \frac{\pi}{2} \frac{a x \dot{a} \dot{x}}{1-x} + \frac{\pi}{4} x^2 \dot{a}^2 \tag{7}$$

The kinetic energy is the sum of the three terms (5), (6), (7)

$$T = T_1 + T_2 + T_3 \tag{8}$$

As pointed out, the leading term at high amplitude is the first. For low amplitude all the three terms need to be considered.

Using the expressions (4) and (8) for potential and kinetic energy, one can write the Lagrange equations (3). That enables one to express the second time derivatives x and a in terms of x, a, $\dot{x}$, $\dot{a}$. One finds

$$\ddot{x} = \frac{ED-FB}{AB-BC}, \quad \ddot{a} = \frac{AF-EC}{AD-BC} \tag{9}$$

where

$$A = \frac{a^2}{3y} + \frac{y}{3} + \frac{\pi}{2} a, \quad D = a + \frac{\pi}{2} y$$

$$B = \frac{a}{2} + \frac{\pi}{2} y, \qquad C = \frac{a^2}{2y} + \frac{\pi}{2} a \tag{10}$$

$$E = \frac{a}{2} - \frac{\dot{a}^2}{2} - \frac{1}{6}\,\frac{(4x-1)a^2\dot{x}^2}{y^2} - \frac{a\dot{a}\dot{x}}{y} - \frac{\dot{x}^2}{6} - \frac{y\dot{x}\dot{a}}{3a} - \frac{\pi}{2}\,\frac{xy\dot{a}^2}{a} - \frac{\pi}{2}\,\frac{ax\dot{x}^2}{y} - \pi\dot{x}\dot{a}$$

$$F = a - \frac{\dot{a}^2}{2} + \frac{(1-2x)a^2\dot{x}^2}{2y^2} - \frac{a\dot{x}\dot{a}}{y} + \frac{\dot{x}^2}{6} - \pi\frac{y\dot{x}\dot{a}}{x} \qquad (11)$$

and

$$y = x(1-x) \qquad (12)$$

These equations have been integrated numerically by Miriam Caldwell. Initial conditions corresponding to a wave of very low amplitude were chosen as follows: $a = .01$, $\dot{a} = .0177$, $x = .5$, $\dot{x} = 0$. The results of the numerical integration are given in Table I.

t	a	b	x
0	.0100	.0100	.500
.5	.0243	.0228	.484
1.0	.0628	.0468	.427
1.5	.192	.083	.303
2.0	.584	.115	.165
2.5	1.218	.144	.106
3.0	2.195	.170	.072

Table I

The four columns of the table give, respectively: the time in units $\sqrt{\frac{\lambda}{2g}}$; the two amplitudes of the wave, a and b, below and above the original surface of the liquid expressed in units $\lambda/2$; and the quantity x that measures the asymmetry of the wave ($x = .5$ corresponding to a symmetrical wave). $x < .5$ corresponds to a wave in which the half wave below the original liquid surface is narrower than the half wave above. From an inspection of the table one will recognize that up to about

$t = 1$, the two amplitudes, $\underline{a}$ and $\underline{b}$, have rather close values and they grow approximately exponentially with a period not far from the one computed from the correct hydrodynamical theory of small amplitude waves

$$T = \sqrt{\frac{\lambda}{2\pi g}} = \frac{1}{\sqrt{\pi}} = .56 \quad \text{(in our units)} \tag{13}$$

Already, at $t = 1$, an appreciable asymmetry of the wave has developed. This becomes more and more noticeable for later times. At $t = 3$, for example, b is less than 1/10th of a.

The asymptotic behavior of $\underline{a}$, $\underline{b}$, and $\underline{x}$ for large values of the time is obtained from a discussion of equations (9). One finds that $\underline{a}$ increases proportionally to the square of the time, b increases proportionally to the square root of the time, and x is inversely proportional to the $3/2$ power of the time. More precisely, one finds the following limiting expressions

$$a \longrightarrow \frac{4}{7}(t - 1.04)^2 \tag{14}$$

$$b \longrightarrow .12\,(t - 1.04)^{1/2} \tag{15}$$

$$x \longrightarrow .21\,(t - 1.04)^{-3/2} \tag{16}$$

In other words, the lower tip of the wave falls with uniformly accelerated motion and with acceleration equal to $8g/7$. The upper half wave grows much slowly and its velocity decreases with time.

It is interesting to compare the results of this crude approximation with the experimental results obtained by D. J. Lewis,[1] as well as

---

[1] PRS 202A 81, 1950

with the results of G. I. Taylor[2] and of Taylor and Davies.[3] The present theory seems to represent correctly one feature of experimental results, namely the fact that the half wave of the heavy liquid into the vacuum becomes rapidly narrower, whereas the half wave pushing into the heavy liquid becomes more and more blunt. On the other hand, the present theory fails to account for the experimental results according to which the front of the wave pushing into the heavy liquid moves with constant velocity. According to the present theory the displacement is expected instead to be proportional to the square root of the time.

Major General P. W. Clarkson
Commander, Joint Task Force 132
Washington, D. C.

Dear General Clarkson:

One of the missions assigned the Commander Task Group 132.1 for Operation IVY is that of conducting technical measurements programs for the Atomic Energy Commission and the Department of Defense. The Turquoise Book attempts to "tell the story" behind these programs - the why as well as the where, when and how. Our Scientific Deputy, Dr. William E. Ogle, and his staff, have reviewed the material contained herein, in order that its readers may be assured that the why is correct and that the how is up to date as we go to press. In addition, Dr. Alvin C. Graves has indicated his agreement with the underlying philosophy of the individual presentations.

The basic purpose of such a publication is to present, in a form acceptable to prospective readers representing varied professions, the object of each experiment and the general manner in which it is to be conducted. It is true that we have included miscellaneous allied information as to project ownership and approximate personnel involved; however, as a word of caution, the Turquoise Book cannot be considered as a document for accurate personnel and fiscal accountability, nor does it present a definitive account of Atomic Energy Commission and Military support. There are established sources for these types of supporting information.

In the intervening period, prior to boarding the USS ESTES during the early morning hours of MIKE Day, changes in the detailed methods of conducting individual projects will undoubtedly be made. As you well appreciate, this is the way of scientific experimentation. All we can say now is that this is how we see the fifty-eight experimental projects on Thursday, 15 May 1952, M-169. Subsequent changes will be reflected in the official reports and history of the operation.

S. W. BURRISS
Commander, T.G. 132.1

Object of the Experiment:

Regardless of whether the desired thermonuclear reaction takes place, it is important that we have information as to how the fission phase operated. To obtain such information, it is natural to fall back on the classical diagnostic measurements for fission weapons, such as the measurement of alpha and yield. Fission yield measurements will, of course, be without significance in the presence of a large scale thermonuclear reaction. Hence one must rely upon the measurement of alpha as a primary indication of the proper functioning of the fission aspect of the reaction.

Method and Procedure:

A. The number of neutrons present at a given time in any array of fissionable material can be shown to be approximated by:

$$N = N_o e^{\alpha (t - t_o)}$$

in which N_o represents the number of neutrons present at time t_o. The number is a measure of the neutron multiplication rate in the array - and a positive alpha is indicative of a supercritical array. The alpha of an implosion weapon is not truly constant, but varies with the degree of criticality produced by the implosion and subsequent explosion. In fact, there is no true alpha immediately after initiation - the magnitude of the neutron population being governed by the statistical behavior of individual neutrons. Very soon, however, the total number of neutrons present becomes sufficiently large that the statistical behavior of individual particles represents a small percentage of the overall effect. Then equation (1) becomes valid, and alpha increases until the assembly is most critical - remains relatively constant throughout the so-called "incubation" period - and decreases to negative values as the weapon disassembles and becomes sub-critical. Documentation of alpha versus time, and particularly the value of alpha during the incubation period, is an extremely valuable tool for use in post-shot deduction of how a fission weapon behaved.

The classical method of measuring alpha is an indirect one, involving the measurement of gamma-ray fluxes. This is feasible since the number of gamma rays given off is proportional to the neutron population, which is in turn proportional to the number of fissions - and nuclear theory supplies us with these proportionality factors.

COPIED/DOE
LANL RC 30

The gamma-ray flux during this period of interest is determined by placing a phosphor-photocell detector near the case of the device. The phosphor is a quantity of material that fluoresces with high efficiency under gamma ray bombardment. The fluorescing process, of course, creates a light source which is observed by the photocell. The light output of the phosphor, and hence the signal produced by the photocell used to measure this light, is proportional to the instantaneous value of the gamma-ray flux. This signal is piped through coaxial cables to a relatively distant oscilloscope and applied to the horizontal plates. A constant high frequency sinusoidal signal is applied to the vertical plates of the scope to supply a time record, and the combination of these signals supplies a scope trace from which alpha can be measured. The combination of phosphor and photocell which generates the alpha signal is known as a scintillation detector.

B. Two scintillation detectors will be placed outside the case. The signals from these detectors will be fed to a recording station 3000 yards distant, on the Island of Bogon. A permanent record will be obtained by photographing the face of the recording oscilloscope.

Remarks:

The Radiation Division of the Naval Research Laboratory is responsible for four distinct projects (2.1, 2.2, 2.3, and 2.4) of the program entitled "Progress Of The Nuclear Reaction". The work loads imposed by these projects, however, are not separable. As a result, the NRL personnel under Dr. Krause's supervision will devote their efforts to all projects equally. In lieu of listing personnel requirements for the individual projects, the following table is presented; to represent the total proposed forward area requirements for the above mentioned four projects:

Object of the Experiment:

As was mentioned in the discussion of Project 2.1a, the measurement of alpha is a classical diagnostic experiment for fission weapons. Since the KING shot device is designed to exhibit heretofore unobtainable efficiency, a reliable and relatively complete alpha-versus-time measurement is particularly important to theoretical people in the field of weapon design.

Method and Procedure:

A. The method used herein is identical in principle to that outlined for Project 2.1a. An air drop, however, precludes the use of detectors placed near the bomb case. For KING shot, we are also interested in obtaining more of the alpha-versus-time curve than is required for MIKE shot. In particular, we are interested in the gamma intensity-versus-time curve from four or five generations before the break to the peak. The break point is that point at which the slope of the intensity curve starts to decrease. This implies measuring the constant alpha (of the incubation period) for four or five generations - then following the decrease of alpha from that value to zero.

Since a given scintillation detector and recording mechanism has a limited useful range of response to gamma intensity, and since the above mentioned portion of the intensity curve spans a wide range of intensities, a number of detectors must be used. Each detector and recorder combination is arranged to cover a small portion of the desired range - the arrangement being a matter of obtaining desired attenuations, either with lead shielding or physical location. We thus have a method for documenting the entire gamma-ray intensity-versus-time curve, as follows:

(a) For the early-time low-intensity portion of the curve, we place our detectors very near the bomb case. The low intensities of the early portion of the curve (many generations before the break) will still be high compared to the minimum detectable signal on the recorder - having been attenuated very little.

(b) For later-time high-intensity portions of the curve, we place our detectors at varying distances from the weapon, the distances being chosen in terms of the intensity range desired and the known air attenuation of gamma rays. The recorder may indicate a signal of the same strength as before, but correcting the signal for both air and distance

COPIED/DOE
LANL RC

attenuations will indicate that such a recorder deflection was caused by a signal of considerably greater intensity. If it is desired to cover two intensity ranges at one distance, one of the detectors can either be surrounded with a lead shield to achieve more known attenuation or be recorded with a lessened sensitivity.

A difficulty is inherent in the method we have outlined, however. Our arrangement of detectors to "see" various intensity ranges has involved only attenuations - that is, we started near the bomb and moved away. What do we do when our nearest available detector position is already far from the bomb - as in the case of a high air drop? The answer there is clear; either we amplify the attenuated signal somehow, or lose the early-time low-intensity portion of the record. Such amplification techniques are being developed, and a feasibility test was conducted quite recently at the Nevada Test Site - they are not sufficiently reliable as yet, however, to warrant depending upon them to furnish the very important KING shot alpha record. We now see why KING shot is being fired at such a low altitude (1500 - 2000 feet), when effects measurements would be greatly facilitated (especially from the viewpoint of tactical use) by its being a much higher (5000 - 6000 feet) burst.

B. The bomb will be fired at some 5700 feet north of station 250 on Runit, at the altitude prescribed above. Two detectors will be placed on the north end of Runit, and their signals will be piped through three inch coaxial cable to recorders in station 250. Hence the nearest detectors will be some 2000 feet from the bomb, and will start their measurement at approximately five generations before the break. Five or six more detectors will be placed near station 250, in order that the remainder of the intensity curve can be documented. The recorders for the latter will also be in station 250, and various recording sensitivities will be used to prevent gaps in the curve.

Object of the Experiment:

Consistent with the idea of obtaining as much diagnostic information about the thermonuclear reaction as possible, this experiment is designed to determine the timing of the fission phase. Knowledge of this time is important as it tells us whether or not the process took place in the predicted fashion.

Method and Procedure:

DELETED

At this writing, the feasibility of detecting primary neutron signals (rather than the secondary neutron-induced gamma ray signals) is being studied. If such a technique is feasible it may be adopted for IVY.

B. The above mentioned signals will be observed directly with scintillation detectors (see discussion of Project 2.1a) at the 3000 yard recording station on Bogon, and indirectly by means of light detectors at Bogon which observe phosphors located on Elugelab. In either case the photocell signal is applied to the vertical deflection plates of a cathode-ray tube in a sweep oscilloscope. The signal which must be applied to the horizontal deflection plate circuit of the tube, the sweep signal, may be obtained from the alpha signal of Project 2.1a (either directly or after having been passed through a fixed-time-delay circuit). The combination of these signals will supply the face of the tube with a trace which can be photographed to obtain a permanent record. In order that these measurements may be time tied to the alpha measurement of Project 2.1a - to obtain the desired elapsed time as our final result - the signal will also be passed through a fixed-time-delay line to a pulse generator, which in turn supplies a "pip" to the vertical

COPIED/DOE
LANL RC

plates of the tube.* In addition, it is expected that the direct observation detector on Bogon will also see the start of the fission reaction - if so, one record will contain the desired elapsed time without a time-tying requirement.

* Another time-tying technique involves the use of a precision delay (from the alpha signal) circuit. Either or both of these techniques may be used.

Object of the Experiment:

This experiment is a continuation of the diagnostic program for the MIKE device. It is designed to document the rise of the fusion reaction, in order that the theory upon which predictions of such phenomena are based may be substantiated.

Method and Procedure:

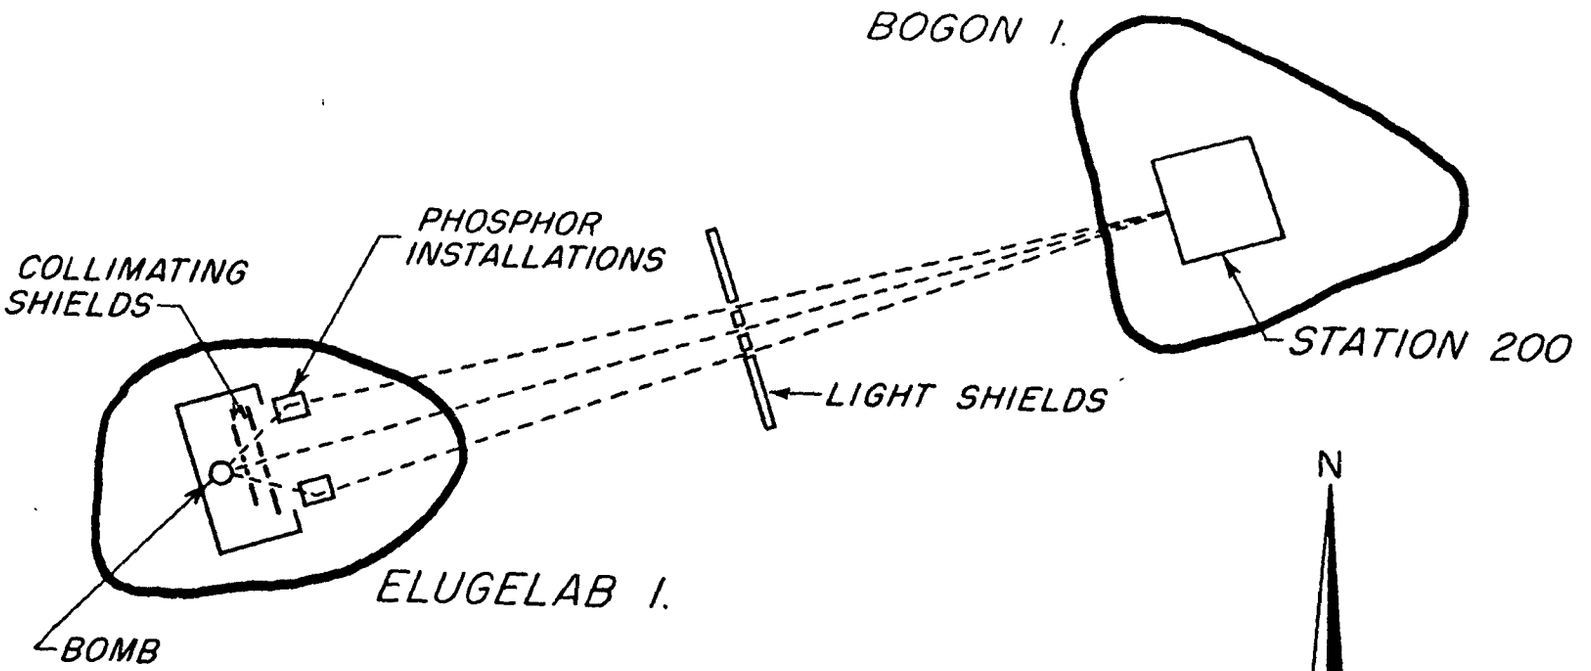
A. The activation of a chain fusion reaction will imply a flood of high energy neutrons. Many of these neutrons will be captured, and such capture will result in large numbers of high-energy gamma rays being produced. Documentation of these gamma rays will provide data which can be theoretically associated with the progress of the fusion reaction as a function of time. Observation of discrete non-intersecting areas of the case will also furnish information as to the space-wise development of the reaction.

B. A collimating shield will be placed close to the bomb to facilitate observation of small areas of the case. Present thinking conceives the collimator as consisting of two walls; the inner wall being six feet thick, fifteen feet wide, and thirty five feet high, of ordinary concrete, and with its inside face being separated from the case by two feet of air.

The collimated signals will be observed directly by means of scintillation detectors (see discussion of Project 2.1a) at the 3000 yard distant recording station on Bogon, and indirectly by means of light detectors at Bogon which observe phosphors located on Elugelab. As an indication of the electronic complexity of this experiment, let us consider the problems associated with obtaining permanent records of the above mentioned signals. When the fusion reaction takes place, a given signal will have an extremely high maximum value, and be existent for such a short period of time that excellent recording-time resolution is necessary to see it at all. The problem of recording the extreme maximum value of a signal, while retaining sufficient resolution for the detailed study of low magnitude results, is solved by using many scopes - each being adjusted to see only a portion of the total intensity range of the signal.

The signal is impressed on the vertical plate circuit of an oscilloscope, thereby causing a vertical deflection of the electron beam proportional to the impressed signal intensity. A voltage source (of sufficient strength that its "triggering" will cause the electron

beam to traverse the scope face in 2 to 5 microseconds) is available to the horizontal plate circuit. If this horizontal motion occurs at the proper time (when the experiment signal is available at the vertical plates), a two-dimensional trace will be produced on the face of the scope. This trace is a plot of the experiment signal and can be photographed to obtain a permanent record. We thus have introduced the auxiliary problem of triggering the horizontal sweeps at the proper time. This is essential as the sweeps are "one shot" affairs (a periodic sweep would supply a record most difficult of interpretation). The method of doing this is to trigger the horizontal plate voltage source with the experiment signal itself - then pass the experiment signal through a fixed-time-delay loop before impressing it on the vertical plates. However, this method has a serious drawback under certain conditions as we shall see below.



A qualitative picture of the over-all gamma-ray-induced signal from the device must now be considered. The fission phase will cause it to rise to a first maximum, after which it will fall off until the fusion phase starts. The latter burning will cause it to rise to a second maximum (the magnitude of which is determined by the "success" of the fusion process), after which it will fall off to zero. Uncertainties in the theoretical predictions of the magnitude of this signal, in the trough between the maxima, are such that the triggering of the low level scopes by their own signals is not feasible. The scope might be triggered too soon by the high background which follows the first maximum, and the record would be lost. By a low level scope we mean one which has been adjusted to see only the lower portion of the rise to the second maximum for the experiment. High-level scopes present no such problem, and can be triggered by their own signals, since no signal except the correct one can reach the intensities for which these will be set.

The low level scopes will therefore be triggered by passing the initial pulse (rise to initial maximum) through a time-delay circuit. As additional insurance, these low-level scopes may be duplicated, each having a different time delay in the triggering circuit, to take care of uncertainties in theoretical predictions.

The above is of course only a qualitative outline, and only partially indicates the complexities involved. It is presently estimated that four detectors, ten amplifiers and thirty oscilloscopes will be required for this experiment.

Remarks:

As an aid in the interpretation of results, additional "monitoring" observations will be made. For example, one phosphor will be "looking" at the sky, and one photocell will be observing an empty phosphor mounting.

Personnel Requirements in the Forward Area:*

	Approximate Number	From	To
Officer			
Enlisted			
Civilian			

Support Required:

* See "Remarks" on page 2.1a.4

Object of the Experiment:

Consistent with the idea of obtaining a maximum amount of diagnostic information from MIKE shot, this experiment is designed to measure the propagation of the fusion reaction throughout the device.

Method and Procedure:

A. The chain of events which makes these measurement possible is precisely the same as that outlined for Project 2.3.

B. The experimental procedures and the complexities involved herein are essentially the same as those outlined for Project 2.3. In this case, however, the collimation is arranged to observe different portions of the case. At the present time, some four positions are proposed. It appears that the recording oscilloscopes for this measurement can be triggered from the scopes of Project 2.3, since there will be no propagation to observe if the thermonuclear reaction fails. Present estimates indicate that four detectors, sixteen amplifiers, and thirty oscilloscopes will be required.

To insure sufficient collimation (and the absence of "cross talk" between independent signals) on the long-air line between phosphors on Elugelab and their associated photocells on Bogon, some 15 to 25 wooden light shields will be required.

Remarks:

1. Monitoring observations will be made for this experiment in a fashion similar to that mentioned for Project 2.3.

2. It may be possible to detect neutrons directly with the phosphor-photocell combinations, rather than the neutron-induced gamma rays. Such a technique is desirable, since it involves observation of the primary signal. Feasibility studies along these lines are being conducted at present.

dura
valu
We t
grap

DELETED

Method and Procedure:

A. The initial time pulse for transit time measurement is obtained electrically from the detonator firing system. The second, or terminal, pulse is obtained by detection of the initial flood of gamma radiation from the bomb.

B. For air drops such as KING shot, 2 small radio transmitters are installed within the ballistic case of the weapon. The signals from these transmitters are monitored by 4 receivers, two located in each of two aircraft which accompany the dropping plane. The signals are keyed by the electrical impulse which fires the detonators - thus supplying the initial time to the receivers. The flood of gamma radiation, which accompanies the start of the nuclear reaction, ionizes the air around the bomb and hence makes the transmission of radio signals impossible. Hence a phenomenon (namely, the interruption of a signal) is observable at the receivers to indicate the end of the transit time period. Both of these signal perturbations (the pulse and the interruption) are supplied to the vertical deflection plates of an oscilloscope. A time index is supplied to the scope by a horizontal sweep similar to that used in television receivers, upon which is

52

superimposed, by pulsing the vertical deflection plate circuit, a series of equally spaced (microsecond intervals) timing pips. The duration of the sweep is such as to include all reasonable transit time values for the weapon, and the sweep is triggered by the initial pulse. We thus obtain an oscillograph of the phenomena, which can be photographed for permanent record, with a built-in time scale.

[redacted]

Object of the Experiment:

One of the basic requirements for any experimental program involving the detonation of an atomic weapon is the determination of whether or not the weapon behaved as predicted - and if not, why not. For fission weapons, the classical method of meeting this requirement has been to conduct a trio of so-called "diagnostic" experiments - the purpose of which was to determine the alpha (α), transit time (τ), and yield (W), of the weapon is question.

At this writing, the only available "absolute"* methods of determining yield are those which involve radiochemical analysis of bomb debris. The existence of hydrodynamical scaling laws, however, has made several "relative" methods of yield measurement available to us. One of these makes use of the fireball diameter at early times. By a relative method we mean one which gives as its result a number which is proportional to the yield. In this case the magnitude of the proportionality factor must be deduced from comparisons of fireball photography results with results of radiochemical analysis methods. Such comparisons have been made on previous experimental programs, with the result that the above mentioned proportionality factor is well established for yields up to 100 KT. [redacted] The IVY program will serve to supply more evidence in higher yield ranges.

The advantage of having complete and reliable information as to the size of this factor over as wide a range of yields as possible is clear. Operational use of atomic weapons will undoubtedly make immediate knowledge of weapon yield imperative, which precludes use of the time-consuming laboratory techniques of radiochemical analysis. Also, it may well be unfeasible to collect acceptable bomb debris samples in the face of enemy defenses. Fireball photography is a potentially feasible method for determining weapon yield quickly and under combat conditions. It is also conceivable that the nature of future experimental programs will be such as to preclude acceptance of the logistical problems associated with the collection of bomb debris samples. For such programs, fireball photography is a well established alternate method for determining yield.

* By an absolute method we mean one which gives, as its final result, the yield of the weapon directly - rather than a number proportional to the yield.

COPIED BY
LANL RC

[redacted]

Method and Procedure:

A. The primary data to be obtained from this experiment are photographic records of the early fireball growth. These data will enable film analysts to determine the fireball diameter at certain specified early times. Such information, when combined with existing data on the above mentioned proportionality factor, will give initial estimates of the weapon yield. Later, when the results of radiochemical analysis are available, additional information as to the proper size of the proportionality factor for such yields will be available.

B. For MIKE shot six Eastman (~2000 frames/sec) motion picture cameras will be operated in a fall-out-proofed shelter on Parry island. Because of the earth's curvature, these cameras will obtain yield only in the event of a large energy release. Three additional Eastmans will be operated from Engebi (in shielded boxes on concrete pillars), to enable a yield determination if the energy release is small (50-300KT). A rapatronic (single frame, with very fast exposure, at a definite delayed time after zero) camera will be operated from the photo tower on Parry.

In addition to the above "primary" cameras, the Mitchell (~100 frames/sec) cameras mentioned under Project 3.2 will give some fireball growth data with much less time resolution.

For KING shot, six Eastmans and one Rapatronic will be operated from the photo tower on Parry. Again, additional long-time resolution data will be obtained from the Mitchells of Project 3.2.

Electronic devices will be used to supply the timing marks to the motion picture camera films, and to operate the Rapatronic at the proper time after zero. Theoretically, one picture at a known time after zero is all that is needed. In the past, however, it has been wise to use motion picture cameras, thereby increasing the probability of obtaining a good picture and increasing the accuracy of the final result by allowing an average to be taken over a multitude of results. The Rapatronic is included in the program to allow a yield estimate to be made from one picture, and to test the accuracy of such a "one picture" result.

It is hoped that sufficient reliability can be built into the Rapatronic technique, and that sufficient confidence can be developed for the scaling of its result, to enable the Eastmans to be eventually discarded in favor of the Rapatronic for this measurement. An obvious decrease in the cost and complexity of the experiment would result, and evidence already exists to support the opinion that no accuracy would be sacrificed. In fact, accuracy may be improved be-

[redacted]

cause of:

(a) The simple R-C network used to supply the necessary time delay to the Rapatronic is highly reliable and capable of excellent laboratory calibration, whereas the time at which a given Eastman picture is taken is not easily determined with the same precision.

(b) The short exposure of the Rapatronic "stops" the fireball growth better than the Eastmans, with the result that a given Rapatronic picture is "better" (a clearer record, capable of more accurate measurement) than any one frame of an Eastman film.

We thus see that the inclusion of the Rapatronics in this project constitutes both duplicate coverage and a feasibility test. If the inherent advantages of the Rapatronic technique can be shown to offset the increased statistics offered by the Eastmans, the ultimate experimental goal, (that is, to obtain a maximum of measurement accuracy and reliability with a minimum of effort and complexity) will be closer.

Remarks:

1. It is interesting to note, in the case of MIKE shot, that fireball photography may be forced to assume the role of a primary measurement for the first time. This possibility exists because of the relatively great uncertainties associated with determination of the fusion yield by means of radiochemical analysis. If it does turn out that a fusion yield is unobtainable with radiochemistry, that yield will be obtained by subtracting the radiochemical fission yield from the total yield given by ball-of-fire photography. Such a procedure does not imply high accuracy, because of the large extrapolation required (to determine the proportionality constant required by the ball-of-fire technique) but it does offer an available alternate method.

2. The firm of Edgerton, Germeshausen, and Grier, Inc. is responsible for five distinct projects (3.1, 3.2, 3.5, 3.6, and 3.8) of the Scientific Photography program. The work loads imposed by these projects, however, are not capable of complete separation. Therefore, most of EG&G's personnel will equally devote their efforts to all projects. As a result, only those personnel whose responsibilities are clearly associated with a particular project are listed under the personnel requirement of that project. In addition, eleven civilians will be available in the forward area for support of all five projects, as follows:

[redacted]

Object of the Experiment:

To those interested in fallout hazards, tactical bomb delivery planning, or the planning for aerial collection of bomb debris, reliable answers to the following dependent questions are of paramount importance:

(a) What will be the maximum altitude of the top of the cloud, as a function of the yield of the weapon which produced it?

(b) What will be the size and shape of the cloud, as a function of (1) altitude, (2) time after zero, and (3) yield of the weapon?

(c) What is the vertical velocity of the cloud top, as a function of altitude and weapon yield?

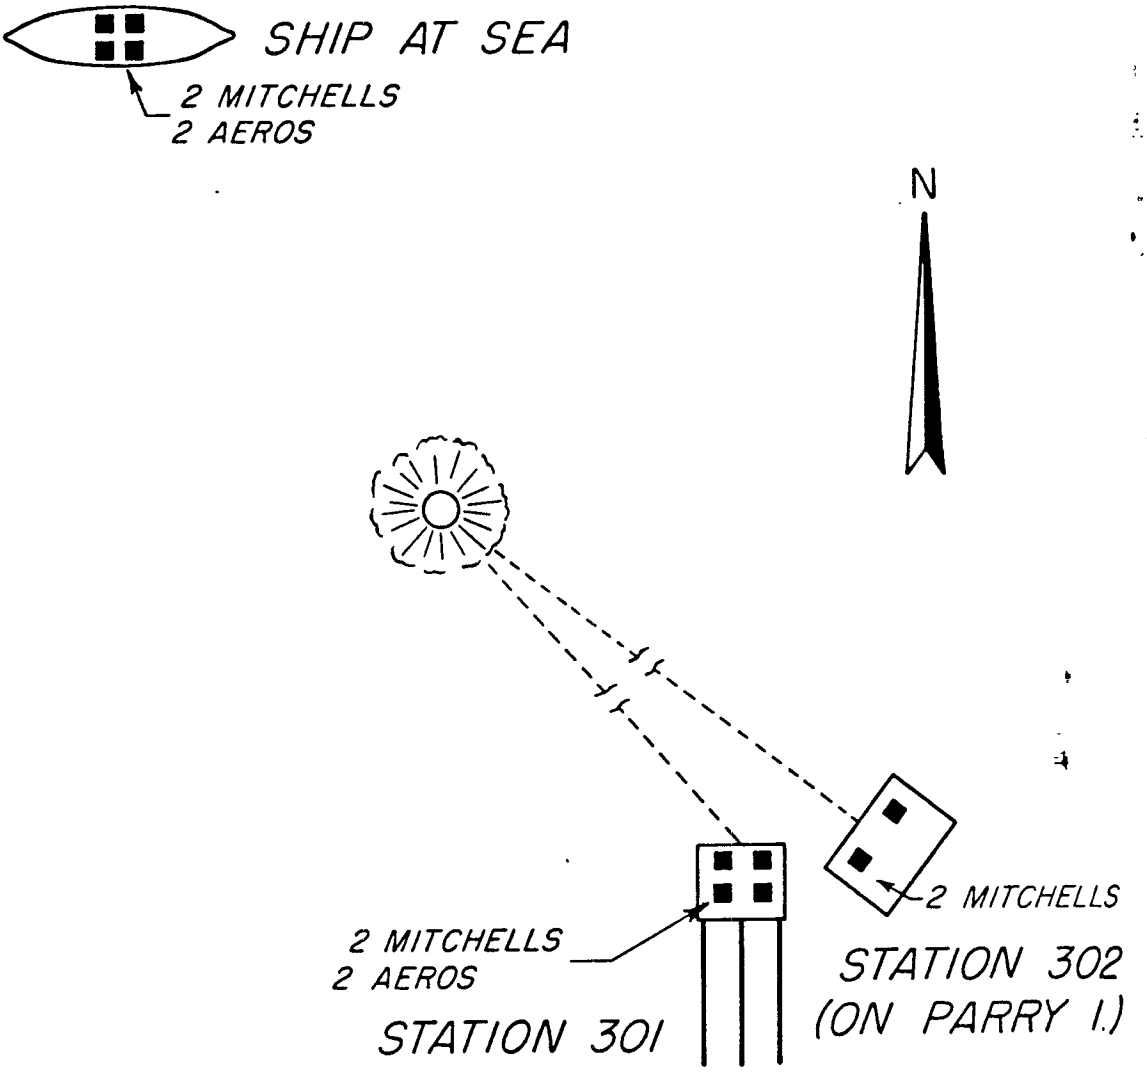
Unfortunately the complexity of the physical phenomena involved (for instance, turbulence and mixing) have so far precluded the existence of a theory adequate to answer these questions. It is in fact, most improbable that a complete theory will ever exist. In the face of this fact, two alternative approaches to the problem suggest themselves:

(1) By making radical simplifying assumptions, derive an approximate theory - perhaps keeping one or two adjustable parameters in the result. Then substantiate (if possible) the approximate theory with experimentally observed facts, making whatever parameter adjustment is necessary. If substantiation is impossible, select somewhat different simplifying assumptions and try again.

(2) Using curve fitting techniques, deduce the necessary functional relationships from experimental data. These functional relationships may suggest a simplified theoretical approach of the type mentioned above.

For one to have confidence in predictions or plans based upon the answers to questions (a), (b), and (c) above, both a reasonable approximate theory and experimentally observed facts with which to substantiate a theory must be available. One without the other is interesting and useful, but it does not inspire the user with confidence. In this case we have several approximate theories available, and are lacking in a sufficient amount of good experimental data. The method for obtaining such data is available, and has been used in the past. This method is to take photographs of the cloud throughout the period of its rise to maximum altitude. Prior to BUSTER-JANGLE,

[redacted]
LANL RC



However, such factors as poor lighting conditions, insufficient time resolution of photographic records, and obscuring cloud cover, made it extremely difficult to obtain the required documentation. The IVY cloud phenomena program is designed to extend this search for data, particularly in the high energy release range that is unavailable for all experiments.

Method and Procedure:

A. By obtaining photographs of the cloud, in a known field of view and at known times after zero, film analysis enables a time history to be drawn - not necessarily of the cloud itself, but of the cloud's projection on a plane perpendicular to the axis of the camera. The use of triangulation techniques (several cameras viewing the same phenomena - located on widely separated radial lines from zero), enables the position of the cloud in space to be determined with much greater accuracy.

B. For MIKE shot, eight Mitchell (~100 frames/sec) cameras will be operated - two operated in the fall-out-proofed structure on Parry island, two from the Parry photo tower, two from the photo platform on the Estes, and two from an airplane flying above Kwajalein. In addition, it is planned to operate four aero (~15 frames/sec) cameras - two from the photo tower on Parry, and two from a gyroscopically stabilized platform on the Estes. The cameras on Parry, of course, will be operated by remote control, and will hence obtain their records at the proper time regardless of photographic conditions. (Clouds obscuring the field of view, etc.) The others, however, will probably be hand operated in the hope that on-the-spot selection of exposure periods will enable at least a partial record to be obtained, even in the presence of local cloud cover.

For KING shot, two Mitchell and two Aero cameras will be operated (by remote control) in the Parry photo tower.

Object of the Experiment:

Laboratory design of a fusion bomb is strongly dependent upon the extraction of as much information as possible from each field experiment. The theoretician is fully as much interested in why a test model behaved as it did, as he is in how it behaved. As a result, the experimental program for MIKE shot includes a relatively large number of diagnostic experiments - each of which is designed to throw some light on the actual chain of events which immediately follow the fission phase. In some cases, completely independent experiments are designed to observe the same phenomenon, either directly or indirectly - thus increasing the probability of obtaining useful results.

selected f
middle, an
areas will
Bogallua s
will have

One interesting piece of diagnostic information is the temperatur distribution inside the gadget prior to disassembly, as the relative "success" of a fusion reaction is closely associated with temperature. This experiment is intended to supply some of that information in an indirect fashion.

Method and Procedure:

A. The time necessary for the explosion wave to traverse a known distance in metal is, of course, a direct indication of the speed of the wave. Knowledge of this, plus the known speed of a sound wave in a particular metal, enables one to deduce the "strength" of the explosion wave from hydrodynamic theory. This in turn is theoretically related to the temperature behind the shock wave in that region.

Three selected areas of the gadget case will be observed photographically by six cameras - the field of view of each camera being sufficiently large to include all of the three areas. In each area, two surfaces will be observed; the first being the outer surface of the case itself and the second being the outer surface of a one-inch-thick steel plate attached to the case.

The time difference between shock arrival at these two surfaces will then give the time required for the shock to traverse one inch of steel. The arrival of the wave at an observed surface will be indicated by a sharp rise in the light intensity seen thereon.

B. Six streak (fixed-film, moving image generated by rotating mirror) cameras, each having a time resolution of approximately 3 shakes (1 shake = 10^{-8} seconds), will be operated from a fall-out proofed shelter on Bogallua. The external areas of the gadget case

68

[redacted] [redacted]

...ted for observation are (1) Near the top, (2) Just above the ...t, and (3) Near the bottom of the assembly. The light from these ...s will be directed to a line of mirrors angling lagoonward on the ...ian side of zero, and thence reflected to the cameras. All cameras ... have a sufficiently wide field of view to see all mirrors.

DECLASSIFIED
LANL RC

71

[redacted]

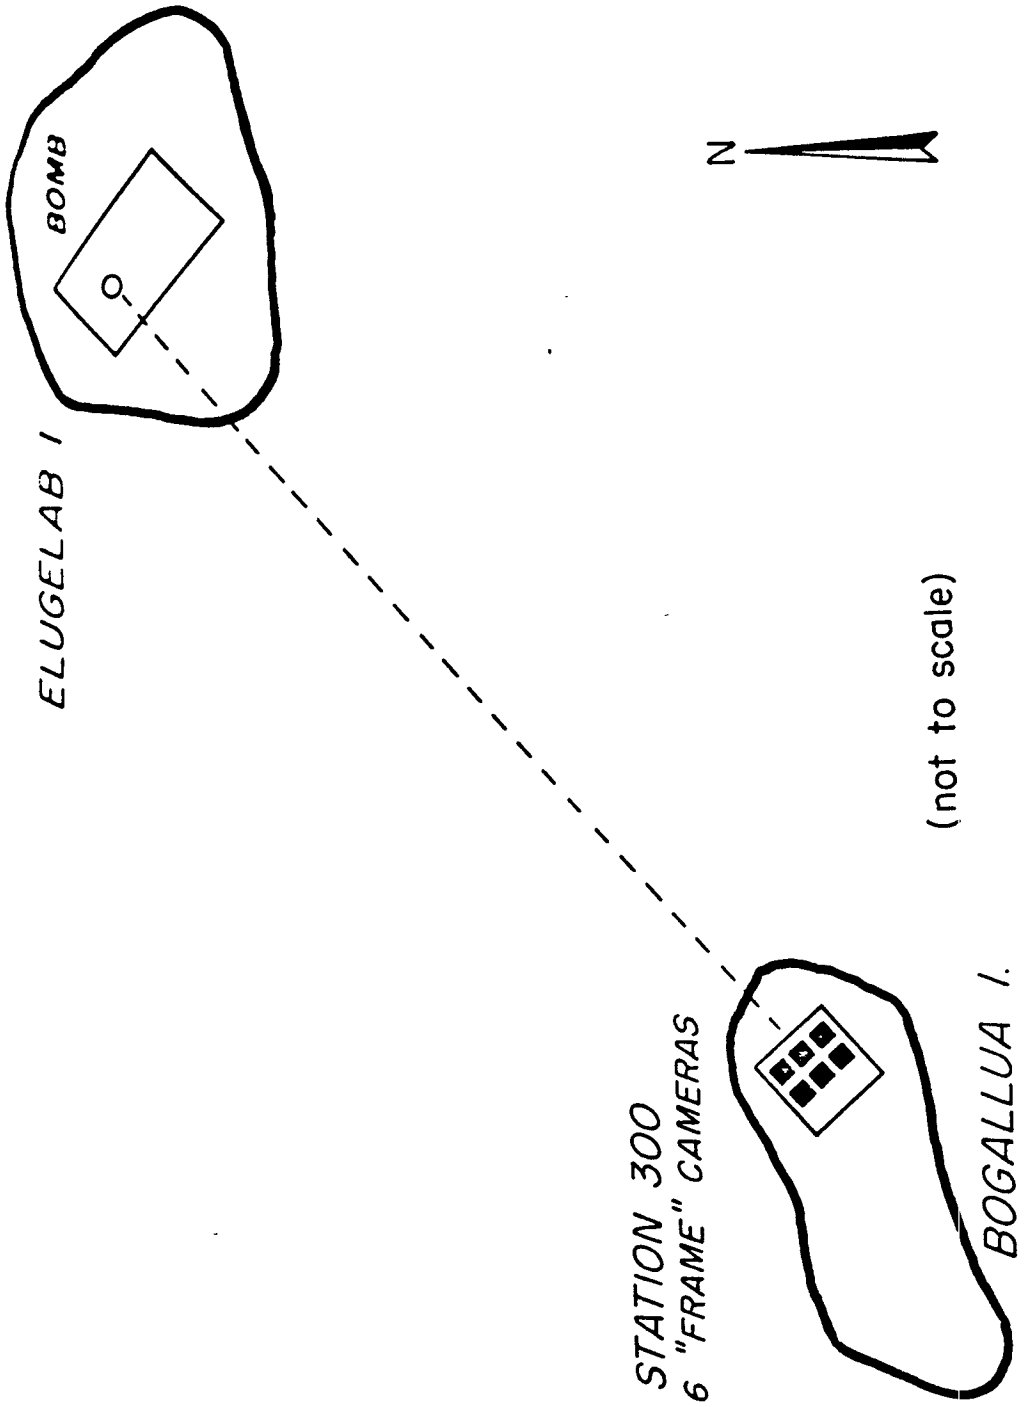
Object of the Experiment:

We have seen, in the discussion of Project 3.3, that several sweeping image ("streak") cameras will observe light intensity on the surface of the MIKE gadget case indirectly - by utilizing reflecting mirrors. This experiment is designed to supplement and extend such "early time" documentation by observing the case disassembly and initial fireball growth directly.

A detailed knowledge of how the gadget case disassembled is invaluable to those interested in internal temperatures, pressures, reaction rates, etc. The early formation of "jets" are also of great interest, as they are indicative of non-uniform expansion (or compression) and may explain the existence of temporary assymetries in the shock wave.

Method and Procedure:

A. The case will be observed directly with two groups of 3 cameras, the first group operating at a speed of 3.5 million frames per second and the second group operating at a speed of 90 thousand frames per second. The first group is designed to document the case disassembly, and the slower group will document the initial fireball development. The decreased time resolution of the second group will, of course, imply that records are taken over a longer period of time.



Since these cameras achieve their high time resolution by using the sweeping image technique (fixed film and rotating mirror), electronic timing devices must be used to close the shutters after the film has been swept once. Otherwise, multiple exposure would result. For lack of a better name, these cameras are called "frame" cameras.

B. The six cameras used in this experiment will be housed in a fall-out-proofed shelter on Bogallua - the same shelter as is used by Project 3.3.

45

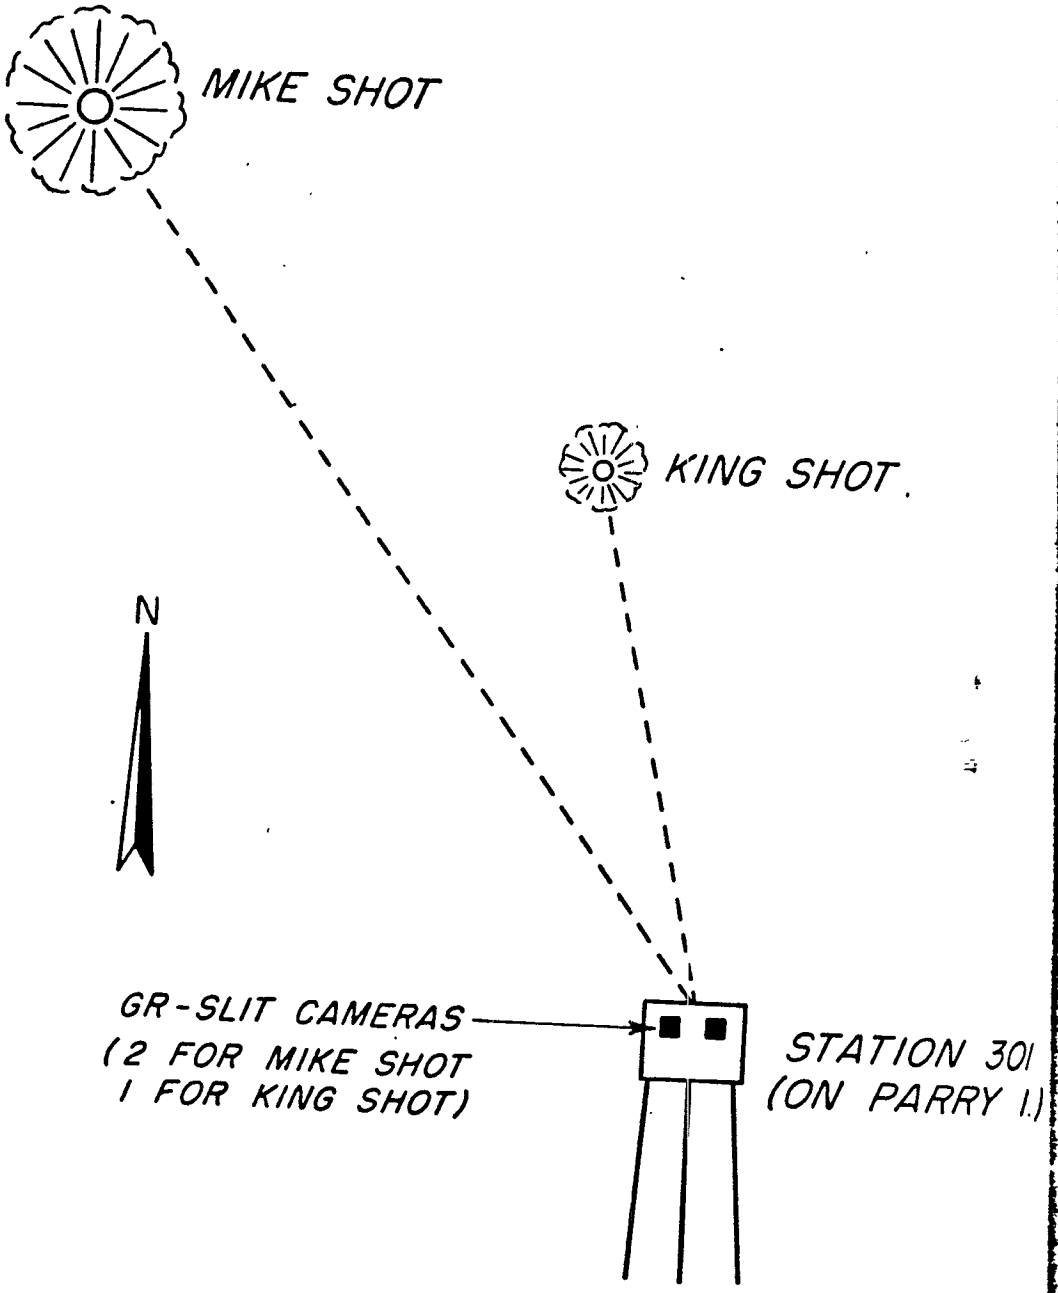
Object of the Experiment:

This project is included in the Scientific Photography program to augment the collection of data on illumination as a function of time from exploding atomic weapons. One value of such data is discussed under Project 3.6. Another value is the establishment of a fund of information with which to design and adjust photographic equipment being used under the light conditions generated by atomic bombs. The success of such projects as 6.2 and 6.4a is completely dependent upon good photographic records being obtained - which implies that such things as film sensitivity, shutter speed, and auxiliary lenses (filters) must be selected with great care. Knowledge of the light intensities that will be experienced is essential in making these selections.

Method and Procedure:

A. Perhaps the simplest and most direct technique for measuring overall illumination as a function of time from an atomic bomb explosion is afforded by a device known as the GR (General Radio - the manufacturer) "slit" camera. It consists, essentially, of a rectangular aperture in front of a moving photographic film. The aperture is covered with a strip of neutral density (ND) filter material* - the strip being constructed in such a way as to make available a wide selection of ND filters. That is, as the aperture is traversed, a small section is covered with an ND-0 filter** - the next small section is covered with an ND-1 filter, and so on. The net result is that the photographic record will consist of a series of parallel streaks (dark lines) on the negative. Each streak will have been made by the bomb light; attenuated a known amount by the ND filter in front of that portion of the film. Some of the streaks will be completely overexposed (or underexposed) over a portion of their length. The multiplicity of the filtering available insures us that an adequate readable record can be found somewhere on the film, even if the bomb light deviates strongly from prognostications.

* A neutral density filter is one which is not color sensitive - that is, it attenuates all visible light by the same amount.



** An ND-0 filter attenuates the light not at all. An ND-1 filter attenuates the light by a factor of 10. In general, an ND-X filter attenuates the light by a factor of 10^X.

The density (opaqueness) of a streak at a given point along its length can be determined in the laboratory with a densitometer, and this is a measure of the light intensity falling on the film at the time that point was opposite the aperture. By multiplying this light intensity by an appropriate factor (determined by the filter), one obtains the bomb light intensity at that time. By combining the above information with the known starting time and linear velocity of the film, one can construct the required curve of illumination-intensity versus time.

B. For MIKE shot, two GR-Slit cameras will be operated on the Parry island photo tower.

For KING shot, one GR-Slit camera will be operated on the Parry tower.

In each case, the cameras will be started by means of an electrical pulse (timing signal) supplied by EG&G.

Support Required:

* See note under "Remarks" of Project 3.1

Object of the Experiment:

As was mentioned in the discussion of Project 3.1, there exists a definite requirement for a device capable of measuring weapon yield during tactical operations. Ideally, such a device will be:

(a) Small, light, and self-contained.

(b) Sufficiently rugged to withstand normal operational use without impairment of its operation or accuracy.

(c) Capable of being operated by its user at a relatively great distance from the explosion.

(d) Capable of supplying its user with a yield number in a minimum of time.

(e) Simple to operate.

The Bhangmeter represents an attempt to develop such an ideal device. In its present form it is a steel box; eighteen inches long, twelve inches wide, and five inches deep - weighing approximately thirty pounds.

The theory behind its operation can be described as follows: The light intensity emanated from an atomic bomb explosion first rises to a maximum with extreme rapidity. It then falls quite rapidly to a minimum and rises again, somewhat less rapidly, to a second maximum, the magnitude of the second maximum being very much less than that of the first. After passing through the second maximum, it falls off rather gradually (on a millisecond time scale) to background values.

If one assumes that the first minimum is indicative of a mathematical "similarity"* condition, it is simple to show by means of hydrodynamic theory that the weapon yield is proportional to the cube of the elapsed time between zero and the occurrence of the first minimum. Conversely, to the extent that the first minimum is not indicative of a similarity state, the so-called "cube-root" scaling law will fail to hold. Also, analysis of the equations involved tells us that no true scaling law other than the above mentioned cube root law is possible. We are thus faced with the following alternatives.

* For a precise definition of similarity, the reader is referred to the Project Officer. For our purposes it will be sufficient to consider the term as meaning "the same, except for a constant factor throughout."

COPIED
LANL RC

(a) The first light minimum does label a state of actual similarity - therefore, the cube root scaling law must hold absolutely.

(b) The first light minimum does not label a similarity state at all - therefore no true scaling law exists.

The results of past experimental work are inconclusive. A large percentage of the experimentally determined light-minimum times give yield numbers within ten percent (the accuracy claimed for the Bhangmeter itself is 20%) of radiochemistry - a few do not. It is not felt however that case (a) has been completely denied as a possibility as there is a strong indication of color sensitivity in the light-intensity-measuring devices used. Careful laboratory analysis is indicated before final conclusions can be drawn. On the other hand, it appears that a rather good empirical fit can be made with past data by using something other than the cube root law. At first this may seem contradictory to both case (a) and (b); actually it is not. Case (b) does not deny the existence of any number of empirically determined scaling methods - it says only that no true law exists. A scaling law implies the invariance of a differential equation (or equations) under a given transformation- an empirically determined scaling method implies nothing but itself regardless of how useful it may be. Hence neither case (a) nor case (b) have been denied or substantiated.

Our problem then consists of continuing the development and calibration of the Bhangmeter, plus attempting to absolve anomalies in past (and perhaps future) data in such a way that either case (a) or case (b) above will be substantiated - and, if case (b) is substantiated, to find the best empirically determined scaling method available. Future users of the Bhangmeter will care little about the type of scaling used - as long as the results are sufficiently accurate (± 10%, probably) and dependable.

The inclusion of this project in Operation IVY will augment the above mentioned calibration, and hence continue what might be called the Bhangmeter feasibility studies, especially in the relatively high yield range.

Method and Procedure:

A. The Bhangmeter obtains the above mentioned elapsed time to first minimum for its user in the following fashion: A light-sensitive electronic valve observes the bomb light, the amount of current passing through the valve being proportional to the intensity of the light it sees. This current is used to deflect the sweep in a cathode ray tube so that a picture of the light intensity curve is drawn

on the retentive fluorescent screen of the tube. A Polaroid "Land Camera" photographs this picture and hence provides a permanent record. An electronic timer which interrupts the cathode ray tube sweep momentarily every millisecond is included, so the picture is made up of a series of dots rather than a continuous line The elapsed time is then obtained by counting the dots from the start of the curve to the minimum.

B. For MIKE shot, one Bhangmeter will be installed on the Parry island photo tower, and another will be installed on the "Estes". In addition, others may be placed at more distant stations.

For KING shot, Bhangmeters will be installed on the Parry island photo tower.

PROGRAM 3

SCIENTIFIC PHOTOGRAPHY

Project No: 3.7

Project Title: Preliminary Photographic Crater Survey.

Shot Participation: MIKE

Sponsor: DOD (USAF)

Project Officer:

Name: Lt. Col. James L. Gaylord
Address: Lookout Mountain Laboratory
8935 Wonderland Avenue
Hollywood, California

Phone: Hudson 2-1261

Conducting Agency: USAF Lookout Mountain Laboratory and Air Research and Development Command

Personnel Requirements in the Forward Area:*

	Approximate Number	From	To
Officer			
Enlisted			
Civilian			

Support Required: Part time use of the B-29 assigned to Documentary Photography coverage.

* Personnel for this Project are included in Task Unit 9 (Documentary Photography).

Object of the Experiment:

To obtain a preliminary photographic survey of the crater caused by MIKE shot, for use in the study of earth shock. It is also hoped that a correlation can be established between photographic evidence of surface perturbations and the fraction of the bomb's energy release that is "coupled" with the ground. Experience on previous tests has shown that early ground surveys of the crater are precluded by radiological hazards.

Method and Procedure:

A. A number of accurately surveyed ground points will be established close to Elugelab Island, with adequate marking of these points to assure contrast and definition when photographed. These positions must be so selected as to be easily distinguishable after the shot as well as before. Precise location of ground zero in relation to these positions is essential, and sufficient aerial photography of the shot island and adjacent islands prior to the explosion is planned to confirm the ground control.

B. The preliminary survey will be conducted from aircraft with vertical cameras as soon as practicable after the explosion of the MIKE device. The still cameras mounted in the documentary photography aircraft will be used only for oblique coverage on this project. Efforts will be made to obtain vertical and/or vertical stereoscopic photographs which will yield information on the size of the crater and the height of the material thrown out around the crater lip. Since considerable time must elapse before the crater can be surveyed in detail by personnel on the site, it is essential that the preliminary photographic survey yield as much data concerning the crater as is possible.

Remarks:

The experience of a similar project on Operation GREENHOUSE indicates that this photography should be done from an altitude of not less than 1000 feet. It was also found advantageous to process the film as soon as possible after the mission, in order that new photographs could be obtained in the event of equipment malfunction.

85

Object of the Experiment:

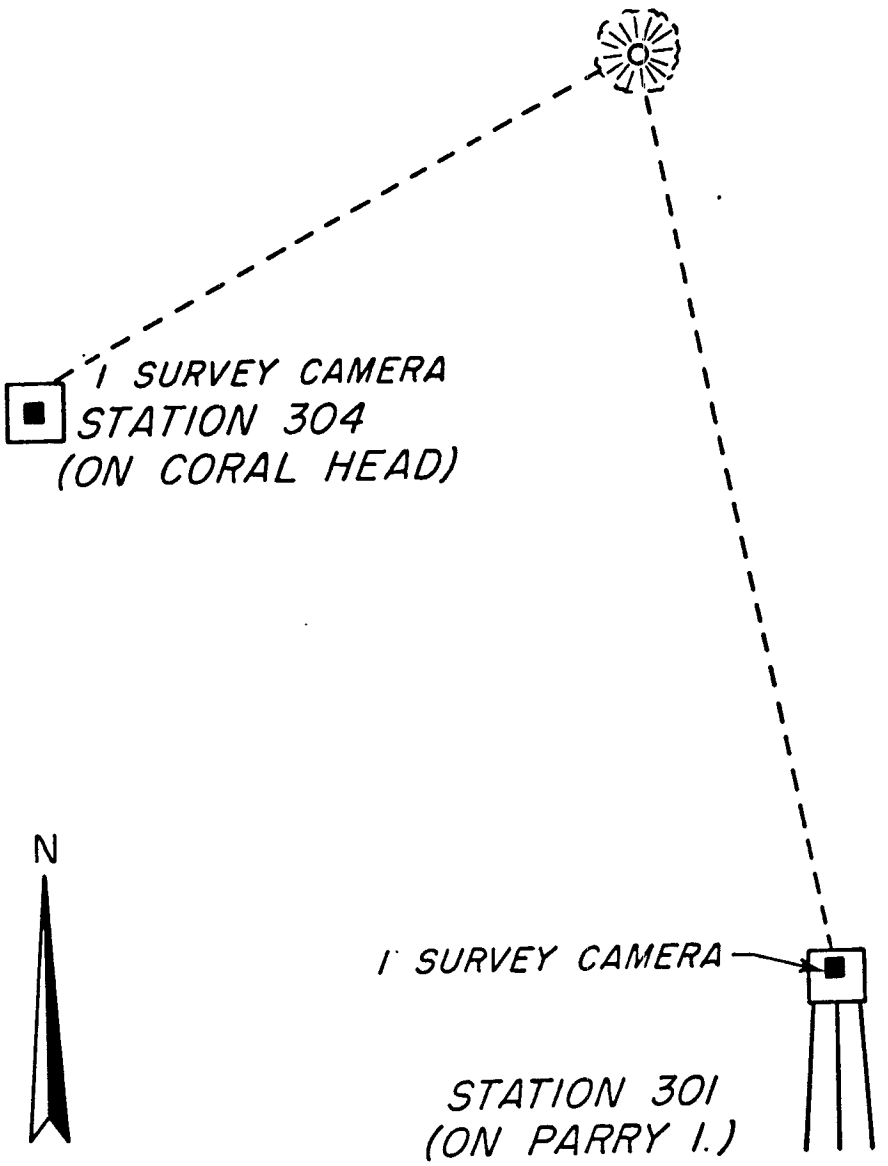
Experimental air bursts, such as KING shot, impose the unique problem of determining their actual burst position in space. Prior to the shot, of course, a ground zero is selected and the detonation mechanism of the bomb is set for a given height of burst. The combination of bombing inaccuracy and the inherent inaccuracies of the detonation mechanism, however, make it extremely unlikely that the burst will actually take place at the preselected point in space. On the other hand, the success of many experimental projects is dependent upon knowing the bomb zero point with good accuracy. As a result, a rather precise photographic technique is used to locate the position (in space) of the light flash which characterizes the exploding bomb.

Method and Procedure:

A. Once the procedure for conducting this project is outlined, the details of the experimental method are obvious - hence we shall proceed directly to a discussion of the procedure.

B. The proposed bomb zero point is 1500 feet above the ground and 5700 feet due north of station 250 on Runit island. The region in space which includes this point will be observed photographically by two survey cameras, one located on Coral Head and one located in the Parry island photo tower. In addition to seeing the light flash from the exploding bomb, each camera will see two fixed points - the positions of which (with respect to the camera) are known with great accuracy. The distance between the images of these points on the film supplies the film analyst with a simple and accurate distance scale, with which to locate the burst point with respect to the fixed points. Measurement of a given film will then locate the burst point in a plane perpendicular to the axis of the camera - and having two such location planes will allow the burst point to be located in space.

The success of this project depends upon accurate information as to the camera positions, as well as the positions of the above mentioned fixed points, hence very precise surveying techniques are essential. Images of the fixed calibration points are obtained on the films by time-exposure, the night before the shot, to lights located at those points. The films in these cameras are actually glass plates, since the experimental error would be increased by the shrinkage of ordinary film. The image of the bursting bomb is obtained as a small dark spot on the negative (and hence the measurement errors



are reduced) by greatly attenuating the bomb light with a strong ND filter (on the order of ND-9).*

Remarks:

1. The closer to proposed zero the bomb bursts, the more accurate is the location technique outlined above. This is because of the method used to obtain a distance scale on the film plate. The distance scale will be in error to the extent that the actual burst point is more or less distant from the camera than the fixed calibration points. The usual bombing error, however, is so small compared to the distance from zero to the camera that this effect is negligible.

* See the footnotes to the discussion of Project 3.5.

Support Required:

Object of the Experiment:

The flood of neutrons which emanate from an exploding atomic device is of great interest to workers in at least two independent fields - that of bomb design (and the associated diagnosis of bomb performance) and that of "effects on things" (materials and animals, in particular). The neutron measurements program of Operation IVY is designed to augment existing data on neutrons and to continue the development of field measurement techniques - in order that the ultimate goal of complete documentation of neutron economy will be closer. In addition, especially for MIKE shot, it is designed to supply diagnostic information as to the "modus operandi" of the device.

In part, one is interested in the distribution of neutrons with respect to time, distance, and energy. Knowledge of the time dependence is primarily a theoretical requisite, but knowledge of the distance and energy dependence is as important to the soldier in the field as it is to the scientist. The neutron intensity-versus-distance curve tells us the lethal range of a neutron, and the energy spectrum at a given distance tells us the amount of shielding necessary for protection - not only of men, but of critical materials.

DELETED

If one knew the total number of neutrons emitted by an atomic bomb at explosion time, and the energy of each, neutron diffusion theory could be used to compute the subsequent neutron "field", with respect to both distance and time. In essence, such knowledge would supply the "initial conditions" for a set of integro-differential equations - and relatively straight-forward theoretical techniques could be used from there on.

Unfortunately these initial conditions are not known, and the problem must be approached in reverse. By making various measurements in the neutron field, one attempts to gain sufficient information for a deduction of "what the initial conditions must have been".

Every neutron liberated by an atomic bomb is ultimately captured by some element in the surrounding medium (air, ground, etc.) Some will be captured before losing any of their energy - others will be

[redacted]

[redacted] only after losing some portion of their energy in one or more [redacted]. As a result, the existence of a neutron having energy E at a distance R from the bomb can indicate at least two possibilities:

(a) It may have left the bomb with energy E and traversed the distance R unmolested.

(b) It may have left the bomb with some energy greater than E and had its energy reduced by one or more collisions while traversing the distance R.

Each of these possibilities is associated with a definite probability of occurrence. Hence if one measures the total number of such [redacted] (energy E at distance R), diffusion theory can be applied in reverse to indicate their probable ancestry at the bomb. A multiplicity of such measurements taken at different distances and for different neutron energies allow one to build a more complete, as well as consistent, [redacted] of the above mentioned "initial conditions".

This project is part of a continuing program to determine the [redacted] distribution of low energy neutrons liberated by various sizes and types of atomic bombs.

[redacted] and Procedure:

A. Neutrons of energy in the range from thermal* to .25 electron volts (EV)** are essentially all captured by the element cadmium. Also, cadmium is quite transparent to neutrons of energy greater than .25 EV. These facts enable us to design a "target" which, when bombarded with neutrons of many energies, is capable of measuring the number of those neutrons in the energy range from .025 to .25 EV.

First we select an element which, upon being bombarded with neutrons, produces a radioactive by-product. Ideally, the element selected should be inert with respect to gamma radiation and the by-product should have a sufficiently long half-life to be amenable to laboratory analysis (counting) techniques. Two samples of this element are then prepared - one being coated with cadmium and the other left pure. These samples are together exposed to the neutron bombardment and subsequently placed in "counters" which measure the induced activity.

* Thermal neutrons are those with energies of the order of .025 EV.

** 1 EV = 1.602×10^{-12} ergs.

[redacted]

[redacted]

The difference in the induced activities of the two samples is then the amount of activity induced in the selected element by neutrons of energy in the range .025 EV to 0.25 EV. (This is usually referred to as the "cadmium difference"). Laboratory calibration of the element with neutrons of a known energy (for instance, as can be obtained with a Betatron) will then allow this cadmium difference to be interpreted in terms of numbers of neutrons (in the above mentioned energy range) striking a square centimeter of area of the "target" element.

This, in turn, finally allows one to deduce the total number of those neutrons which are existent (integral over time) at a given distance (the distance from zero at which the samples were exposed) from the particular bomb detonation. Such a measurement can be repeated at several distances to obtain an intensity-versus-distance curve for those neutrons.

The method outlined above is used in this project, the selected target elements being tantalum and gold.

B. For MIKE shot, pairs of tantalum and gold samples (one of each being shielded with cadmium at each station) will be placed on a line extending along the reef toward Bogallua. The first pair will be 100 yards from zero, and a pair will be placed every 100 yards from there to 2500 yards. Two sample recovery techniques have been proposed - one being to fasten the samples to a steel cable which can be hauled in after the shot; the other being to place the samples on fixed individual pylons and retrieve them after the shot by helicopter. In all probability, a combination of these methods will be used. After recovery, the samples will be shipped to Los Alamos for laboratory analysis.

For KING shot, the same technique will be used. The line of samples will start on the reef (300 feet from proposed ground zero) and extend down the center of Runit island to the region of the airstrip (7200 feet from proposed ground zero).

Remarks:

1. The samples must be collected as soon as possible after the shot, in order that the radioactive by-products will not decay any more than is absolutely necessary before laboratory analysis can be done. Also the near (to zero) sample containers are usually in extremely "hot" (radioactivity-wise) areas and may be "hot" themselves. Hence the recovery problems of this project are potentially very severe.

2. The above outlined technique only allows deduction of the [illegible] of neutrons in a very limited energy range. For the theoretical "inverse approach" to be of appreciable value, measurements must be made in other energy ranges, so that a much greater percentage of the total ancestor distribution can be deduced. Project 4.2 is devoted to such measurements for energies greater than 3 million electron volts (MEV). A secondary objective of this project will involve attempts to document energies between .25 EV and 3 MEV. The techniques required for such measurements are not yet proven, so this portion of the experiment is primarily a feasibility study. In particular, it is hoped that the high cross section exhibited by Indium, for neutrons of [illegible] EV, will be useful.

Object of the Experiment:

We have seen in the discussion of Project 4.1 the importance of obtaining as much information as possible regarding the distribution of neutron intensity with respect to distance and energy. This project is designed to extend the measurement started in Project 4.1, by documenting the flux of neutrons exhibiting energies considerably higher than .25 EV.

Method and Procedure:

A. The "cross section" of a substance with respect to a particular bombarding particle is a measure of the likelihood that the particle will react with the substance. A high cross section implies a high probability of reaction, and so forth. In general, the magnitude of this cross section is a function of the particle energy and type. As an example, consider the cadmium used in Project 4.1. We mentioned that cadmium absorbed essentially all neutrons having energies from thermal to .25 EV, and was "transparent" to those of energy greater than .25 EV. Cadmium thus has a very high cross section for neutrons in the .025 to .25 EV energy range, and a very low cross section for those of energy greater than 0.25 EV.

A threshold detector is a substance having an essentially zero cross section to particles of energy below a fixed level, and a finite cross section to particles of energy greater than that level. The fixed level is the threshold energy for that substance. Sulphur, iodine, and zirconium are examples of threshold detectors - each having quite different reaction characteristics and threshold energies. We shall discuss each of these in turn, with the view of indicating its usefulness to this project.

Sulphur (S^{32}) has a threshold energy of effectively 3 MEV. The reaction which takes place when sulphur is bombarded with neutrons of energy ≥ 3 MEV leads to the creation of a radioactive isotope of phosphorus (P^{32}). This active isotope in turn decays (with a 14.3 day half life)back to S^{32} by emitting 1.8 MEV beta rays. Thus, the specific beta activity of a sulphur sample measures the total number of neutrons with energies not less than 3 MEV that passed through the sample.

Iodine (I^{127}) exhibits a threshold energy of approximately 9.5 MEV. When it is bombarded with neutrons of energy greater than the threshold value, another isotope of iodine (I^{126}) is formed. The latter is radioactive, and decays (with a 13-day half life) to a stable isotope of Xenon (Xe^{126}) by emitting a 1.1 MEV beta particle

COPIED/DOE
ARN RC

and a 0.5 MEV gamma ray. Hence the specific activity (both gamma and beta) of the iodine sample is a measure of the total number of neutrons having energy in excess of 9.5 MEV which passed through the sample.

Zirconium (Zr^{90}) has a threshold energy of effectively 12.5 MEV. This reaction, upon bombardment with neutrons of sufficiently high energy, produces atoms of Zr^{89} - a radioactive isotope of zirconium. This in turn decays (with a 78-hour half life) to a stable isotope of yttrium (Y^{89}) by emission of a 1 MEV gamma ray. The specific gamma activity of the zirconium sample is then a measure of the total number of neutrons (of energy >12.5 MEV) which passed through the sample.

An experimental procedure is thus indicated. Let us place samples of each of the above elements at some fixed distance from the bomb. Post-shot analysis of these samples will then supply three points on the curve of E (neutron energy) versus N(E), the total number of neutrons with energy at least as great as E. This curve is, of course, associated with the above mentioned distance. A family of such curves can be obtained by placing sets of samples at various distances. From such a family other curves can be derived - for instance those relating N(E) to distance, a different curve being drawn for each value of E.

B. For MIKE shot, sulphur, zirconium and iodine samples will be placed at the same positions mentioned under Project 4.1 (MIKE shot). In addition, a few zirconium samples may be placed on Elugelab - in line with the collimator holes mentioned under Project 2.3 - out to a distance from zero of approximately 800 yards. The placement of the latter is dependent upon space availability, as the collimation may be sufficiently "tight" to forbid extra material in the line of sight. The sample recovery and shipment (to the Los Alamos laboratories) procedures will be identical to those outlined for Project 4.1. For KING shot, sulphur samples will be placed at the same positions as the tantalum samples mentioned under Project 4.1 (KING shot).

Remarks:

1. The above discussion of sulphur, iodine and zirconium as threshold detectors has been over-simplified in the interests of brevity. In actuality, the specific activity of a sample may not be completely neutron-induced. Both iodine and zirconium also react to gamma rays in a very similar fashion. Hence the experimenter must separate the neutron-induced and the gamma-induced activities. One method of doing this is to duplicate such samples in the experimental set-up, one of each pair being surrounded by lead - lead having a very high cross

COPIED/DOE

section for gamma rays and a very low cross section for neutrons. The difference in specific activity of two such samples is then the activity induced by the gamma rays, etc. The reader is referred to the Project Officer for details of this and other difficulties.

2. In addition to the above, it may be possible to obtain more points on the curve with the following threshold detectors - lack of documentation for which forces their use to be classified as feasibility tests:

(a) Neptunium (Np^{237}) with a .5 MEV threshold for fission.

(b) Uranium (U^{238}) with a 1 MEV threshold for fission.

(c) Arsenic with two thresholds, one at 10.5 MEV and one in the thermal range, the results of which can be separated with special analysis techniques.

COPIED/DOE

Object of the Experiment:

The discussion of Project 4.1 pointed out the desirability of obtaining the total neutron spectrum (numbers of neutrons at every energy level) versus distance. However, the techniques of Projects 4.1 and 4.2 do not allow a determination of the entire spectrum. This project makes use of an experimental technique which, if successful, is capable of much more extensive documentation of the neutron energies existent at a given distance.

Method and Procedure:

A. Certain elements, upon neutron bombardment, undergo an (n,p) reaction. That is, the absorption of a neutron is accompanied by the ejection of a proton, the energy of which is proportional to the energy of the absorbed neutron. If the proton is allowed to travel through a photographic emulsion, it will produce a "track" of ionized particles and hence a track of "exposure". Upon development, the photographic negative will exhibit a dark line, the length of which is proportional to the proton energy. As a result, laboratory calibration of this technique allows the measurement of the resulting line in the negative to be interpretable as the energy of the incident proton.

This technique has a number of serious disadvantages, however. First, the film must be adequately shielded from both neutrons and gamma rays, as both are capable of producing "exposure" of the emulsion. Secondly, the proton source is also sensitive to gamma rays, and must be shielded from them if the experimental record is to be useful as a neutron indicator.

These difficulties are met, at least partially, by heavy shielding for the assembly (proton source and photographic plate) and strong collimation for the signal - with lead in the collimation line to keep the gamma rays away from the proton source. The necessary collimation creates more disadvantages, however. The experiment cannot be conducted on air drops because of the uncertainty in burst position, and the "good geometry" results are not applicable to the needs of those interested in the biomedical effects of neutrons. After all, it is most unlikely that the soldier in the field would be exposed to an atomic bomb in a collimated geometry.

B. For MIKE shot, one nuclear emulsion camera will be operated at 1300 yards from bomb zero. This is primarily a feasibility test for the equipment, as the gamma-ray level at such a distance from the gadget will be sufficiently high to make film-fogging marginal.

COPIED/DOE

[redacted]

The camera cannot be moved further away, however, as the neutron signal strength at that distance is marginal (for obtaining a usable experimental record) on the low side.

Remarks:

At first glance, it might appear that the disadvantages associated with this experiment far outweigh the advantages to be gained from its success. This is not the case, however, as the spectrum information it may obtain would be of great theoretical value. Also, it can be simply and cheaply done with reclaimed GREENHOUSE equipment that has been kept in storage on Parry Island.

Object of the Experiment:

The neutron detection methods outlined in Projects 4.1 and 4.2 are essentially time integrating, and offer no information as to the time distribution of the original flood of neutrons. This project is designed to gain information as to the total number of arriving neutrons versus time at given fixed distances from bomb zero. The device which accomplishes this purpose is called a "fission-catcher camera" and its method of operation is discussed below.

Method and Procedure:

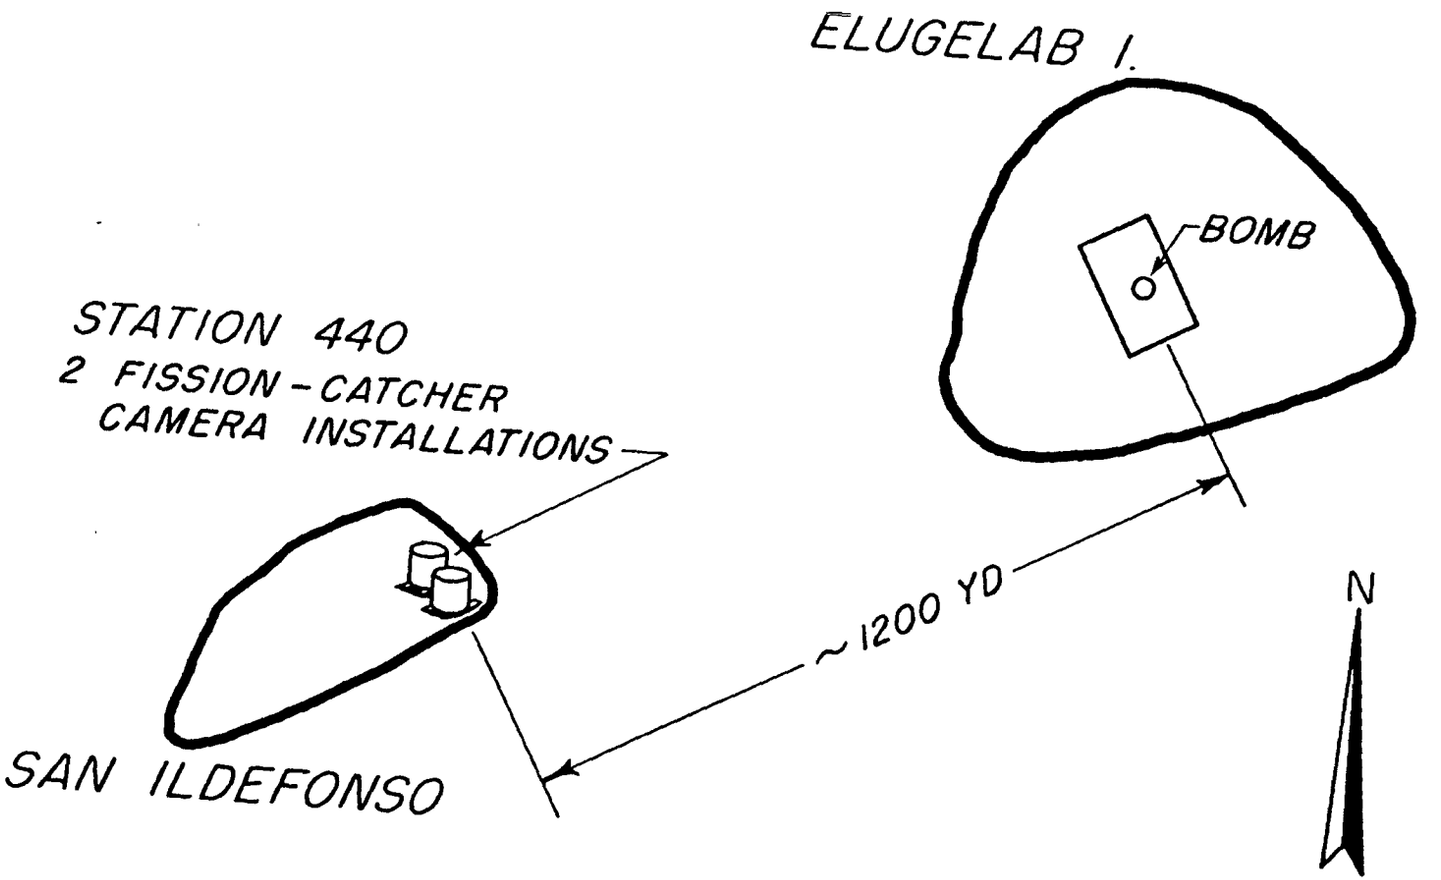
A. The fission-catcher camera consists essentially of a thin foil of fissionable material, behind which a cellophane strip is moved at a known rate. If the fissionable material is subjected to bombardment by neutrons of the proper energy, some of its atoms will undergo fission, and the by-products of these fissions will be thrown out as fission fragments. The fragments will be picked up by the moving cellophane strip, and their position on the strip will be a measure of when they were created. Since many fission by-products are radioactive, their presence on the strip can be detected by laboratory "counting" techniques. Hence by measuring the activity of the cellophane strip as a function of distance along the strip, one can, by using the known strip velocity and starting time, deduce the period of time over which fission producing neutrons arrived at the camera.

B. For MIKE shot, three fission catcher cameras will be located on San Ildefonso island approximately 1200 yards from zero. Foils of both uranium 235 and uranium 238 will be used as the fissionable material, the U^{235} being used both with and without cadmium shielding.* U^{235} has a thermal ($\sim$.025 EV) energy threshold for the fission reaction, and U^{238} has a similar threshold at 1 MEV.** Analysis of these cellophane "films" should then supply us with the following information:

(a) The time distribution, at 1200 yards from zero, of the neutrons in the energy range from 0.25EV to 1 MEV.

(b) The time distribution, at 1200 yards from zero, of those neutrons having energies in excess of 0.25EV.

* See the discussion of Project 4.1



** See the discussion of Project 4.2

CONFIDENTIAL
LANL RC

(c) The time distribution, at 1200 yards from zero, of those neutrons having energies in excess of 1 MEV.

In each case, these measurements will start at approximately 1 millisecond after zero and continue for 30 seconds.

For KING shot, an identical installation will be made on the north end of Runit island.

///

Object of the Experiment:

In the field of atomic weapons effects, knowledge of the gamma radiation dose resulting from a bomb detonation - as a function of distance, energy release, time and weapon type (i.e., fission or thermonuclear) - is of obvious importance. Since a non-negligible fraction of the total energy involved is released as gamma radiation of various energy levels, we have a serious personnel hazard assured for some distance from bomb zero. The more knowledge we possess about this hazard, the better we can plan for defense against (and tactical use of) atomic weapons. As a particular example, consider the problem of telling the foot soldier how to prepare a fox hole in such a way that he will most efficiently utilize the time available to him in obtaining protective shielding from gamma rays. As another, we have the problem of where to plan the concentration of disaster relief team efforts for civil defense. This experimental project is part of a continuing program, the purpose of which is to obtain as much documentation as possible of the gamma radiation fields established by exploding atomic weapons. In particular it is designed to supply information as to the total gamma dose received by points located at various distances from bomb zero.

Method and Procedure:

A. It is common knowledge that photographic (silver halide) emulsions react to light in such a way that subsequent chemical reduction (development) of the emulsion causes opaque deposits of metallic silver to be produced - the relative opacity (density of silver deposit) being proportional to the original light intensity. Such a phenomenon might supply an experimental method for determining the strength of a light source, by carefully calibrating the emulsion, development technique, and negative density measurements - and by using known attenuators for very strong sources.

Consider, however, the fact that visible light represents but one small portion of the electromagnetic radiation spectrum. Other portions of that spectrum; for instance, X-rays and their more energetic brothers gamma rays, are capable of producing the same reaction in the silver halide suspension. Hence we have modern X-ray photography - and the film badge dosimeter.

The film badge dosimeter consists of a small packet containing several strips of photographic film - the packet being made light-tight to insure that "exposure" is due only to penetrating radiation. Quality control in the film manufacturing, and laboratory calibration of samples from each film batch used, insure that the field exposure of a packet

CONFIDENTIAL

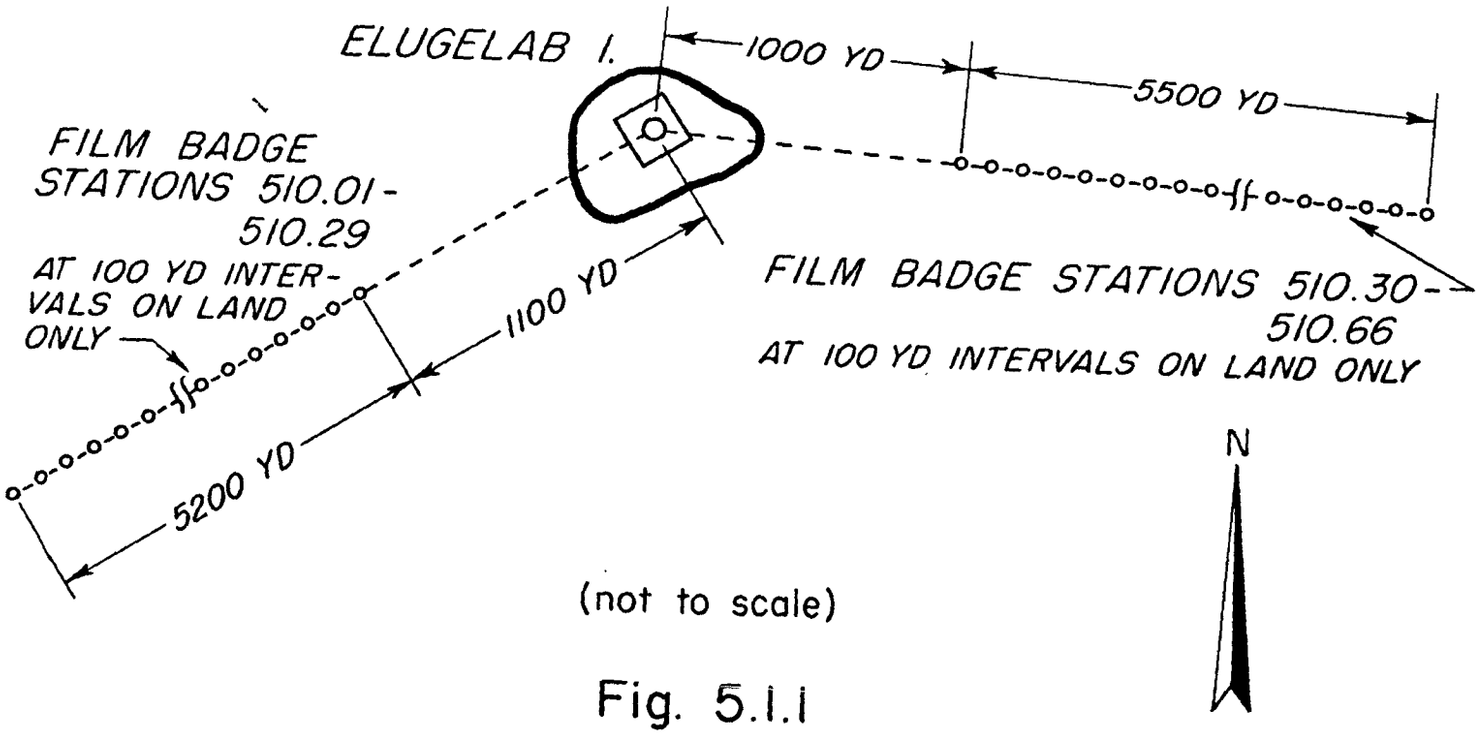
COPIED/DOE
LANL RC

...l be interpretable directly in terms of roentgens of gamma ray dose ...eived.

After the badge has been exposed, the analysis technique consists ...f first developing the film under carefully controlled conditions ...that is, conditions precisely like those with which the film was cali...rated), then measuring the opacity of the negative with a precision ...ensitometer. The densitometer measurement will be interpreted as so ...ny roentgens by the above mentioned laboratory calibration.

Exposure of the film, of course, tells us only that one or more ...amma photons were there. It cannot, in itself, tell us when. Hence ...e film is a time integrating device, and measures only the total ...amma dose received by it from the time it was made until the time it ...as developed. This fact indicates the absolute necessity of adequate...y shielding unexposed packets from extraneous radiation sources (for instance, fallout).

Photographic film, like all other gamma ray detectors, is somewhat energy sensitive - that is, the degree of "exposure" due to gamma ray passage is somewhat dependent upon the energy of the gamma. This effect, however, is essentially a calibration problem, and need not be considered herein. For such details the reader is referred to the Project Officer. For all practical purposes, one can give the final result of this measurement as so many roentgens of gamma - of energy sufficiently great to penetrate the protective covering of the packet.



The inclusion of several strips of film in each packet is an economy measure. The measurement of a fifty roentgen dose is more efficiently accomplished on a film strip that is strongly exposed by one hundred roentgens than it is on one which requires one thousand roentgens for strong exposure - the contrast between the correct densitometer reading and one slightly incorrect being much easier to detect. Hence the inclusion of only one film strip per packet would require several different packet models for the various distances from bomb zero (likely gamma exposure ranges) of interest. Packet standardization, in such a way that each packet is capable of use at any measurement station, effects an obvious logistical simplification.

B. For MIKE shot, two measurement lines will be established - one from Elugelab to the far end of Bogallua, and one from Elugelab to the far end of Engebi. The packet positions will be on land only, and will be spaced at one hundred yard intervals insofar as possible. Three film badges will be placed at each position, the first of which remains openly exposed to radiation until recovery. The second and third badges will be openly exposed initially, but will later drop into prepared shielded positions - the second dropping 0.2 seconds after the explo-

sion, and the third dropping 60 seconds later. In this fashion, a crude time resolution of the total dose will be obtained - providing the shield corrections can be adequately made. In particular, the spreading of contamination by a "base surge" or "dust skirt" may be documented in this fashion.

For KING shot, a line of film badge stations will be placed down the middle of Runit - spaced at approximately one hundred yard intervals. Each station will consist of a post to which one or more film badges is attached. All badges will be openly exposed until recovery.

CONFIDENTIAL
SECRET

Object of the Experiment:

Consistent with the idea of eventually having complete documentation of the "field variables" associated with an atomic weapon detonation, this project is intended to measure the time dependence of gamma ray intensity (at certain fixed distances) from shortly after zero time to plus thirty seconds.

The gamma rays which are emanated from an exploding atomic bomb fall into two distinct classifications - "prompt" and "delayed". The prompt gamma rays are those created during the reaction time of the bomb - this time being dependent upon the bomb model, but usually being some fraction of a microsecond.

The delayed gamma rays come from two quite distinct sources, each source contributing approximately one-half of the total:

(A) Those liberated by the decay of the active fission fragments, their time dependence depending upon the fate of the fragments - when they are swept up by the rising fireball, or where they are deposited on the ground.

(b) Those arising from (n,γ) reactions in the soil and in the air around the bomb.

In any above-surface burst the vast majority of fission fragments will be carried up by the fireball; hence the greater portion of delayed gamma radiation occurs during the first few seconds after the explosion, although weak radiation may continue for a long time because of a few active fragments being deposited in the surrounding soil.

The time dependence of the prompt gammas is documented by the "Alpha" experiment, and will not be considered here. This experiment is designed to start at 0.2 microsecond (μs) for MIKE shot (1 millisecond (ms) for KING shot) and extend for approximately 30 seconds - thus measuring the time dependence of the major portion of the delayed gammas.

Method and Procedure:

A. The detection method used herein is essentially the same as that used in Project 2.1a. A "phosphor" (substance which fluoresces under gamma ray bombardment - to produce a light signal, the intensity of which is proportional to the intensity of the incident gamma radiation) observes the bomb, and is itself observed by a photocell (current

generator - the magnitude of generated current being proportional to the intensity of the light signal it "sees"). The current signal from the photocell is converted to a voltage signal in a so-called "logarithmic attenuator" and applied to the deflection plates of an oscilloscope. The timing equipment is included in the horizontal deflection plate circuit of the scope in such a way that a given horizontal deflection of the electron beam is uniquely associated with a given elapsed time from zero. Hence the scope trace is a gamma intensity versus time record, the vertical scale of which is not gamma intensity itself but a known function of the gamma intensity - the known function being supplied by the experimentally determined characteristics of the logarithmic attenuator.

The logarithmic attenuator is an electronic device which, upon receipt of a signal of magnitude M, passes on a signal whose magnitude is proportional to log M. Hence it passes on small signals with little or no attenuation, whereas it attenuates large signals a great deal. Such a device is necessary in this experiment because of the tremendous range of gamma intensities involved. Since a given oscilloscope has a limited intensity range, direct recording of all gamma intensities involved herein would require a prohibitive number of scopes. The use of the above mentioned attenuator allows the use of only a few scopes, each covering several decades (powers of ten) of gamma intensity.

B. For MIKE shot, gamma intensity versus time measurements from 1 ms to 30 seconds (covering 6 decades of intensity) will be made on four islands - Cochiti, San Ildefonso, Bogombogo, and Ruchi. Hence four points will be obtained on the gamma intensity versus distance curves - each curve being associated with a given elapsed time after zero. In addition, on Ruchi island, measurements will be taken from 0.2 to 1000 μs, covering approximately 8 decades of intensity.

For KING shot, three measurement assemblies will be placed on Runit - at varying distances from bomb zero. The time coverage here will be from 1 ms to 30 seconds, and approximately 6 decades of signal will be recorded.

Remarks:

1. The retentive face of a cathode ray tube is caused to fluoresce by incident ionizing radiation - just as it is by the electron beam generated within the tube. Such a phenomenon can cause loss of experimental measurement, if it occurs during the time that a desired trace is being generated and photographed. As a result, recording oscilloscopes near the exploding bomb must be shielded from ionizing ra-

diation rather thoroughly.

As a result of this, the usual gamma-versus-time station consists of a hole in the ground - some 18 to 20 feet deep - at the bottom of which the recording equipment is placed. The hole is filled with water to obtain extra shielding, and the detector is placed above the surface of the ground. Hence the only outward manifestation of the stations existence is a bell shaped aluminum object (the detector cover) sitting on a steel plate (the hole cover). For this project, all stations not on Ruchi island will be as described above.

The Ruchi station will consist of a small blockhouse, in which a number of detectors for nearby recording equipment will be placed. This more complicated installation is made necessary by the greater time resolution (and attendant complexity of instrumentation) required of the Ruchi measurements.

2. The Ruchi blockhouse will be supplied with a timing signal by EG&G, to actuate the recorders. The self-contained units will be actuated by the "blue boxes".

LANL FRC

[redacted]

Object of the Experiment:

The "fall-out" of radioactive particles from an atomic cloud presents a problem, the solution of which is potentially important to every living thing on our planet. Because of this phenomenon, a bomb burst over Nevada may require the evacuation of areas in another state - or a bomb burst over the enemy may endanger friendly troops many miles away. Of even more immediate interest to us at this time, MIKE shot may constitute a hazard to Runit island, Kwajalein, or perhaps even Oahu.

The winds of our atmosphere are primarily responsible for this ability of an atomic bomb to threaten at great distances. As a result of this fact, every experimental detonation made by this country to date has had its firing scheduled by the vagaries of nature - to minimize the possibility of hazardous fall-out. In time of war, however, (and particularly where the tactical deployment of atomic weapons is concerned) it may be necessary to forego a minimizing procedure in favor of a calculated risk - for defensive planning as well as offensive. Hence a relatively complete understanding (or a proven sufficiently accurate approximation thereto) of the fall-out mechanism is essential. A calculated risk is unworthy of the name if the risk cannot be calculated.

To better understand the above statements as to the importance of understanding fall-out, and to gain a feeling for how documentation of the phenomenon can be made more feasible, let us briefly consider a qualitative picture of what fall-out is and does.

As we mentioned in the discussion of Project 5.2, a vast majority of the radioactive fission particles are swept up to altitude by vertical winds - the winds being created by the rising fireball. These particles are of many types, and cover a wide range of sizes (for instance from a small fraction of a micron (μ)* to 1 millimeter (mm) in radius). They produce ionizing radiation of half-lives** ranging from a fraction of a second to thousands of years. The maximum altitude to which a particular particle is carried is a function of its size and the average vertical wind velocity to which it is subjected -

* 1 micron = 10^{-6} meters

** The half-life of a radioactive source is the amount of time necessary for it to decay to one-half its original strength.

CORNER/DOE
LANL RC

and hence of the yield of the weapon. After this maximum altitude is reached, the path of the particle is affected by the downward pull of gravity and whatever forces the atmospheric air motions (winds - both vertical and horizontal) may impose on it.* Hence its path in space will vary from nearly a simple parabola to extremely tortuous curves that defy analytical representation.

Regardless of what such a path may be, however, common sense tells us that it will intersect the ground sooner or later - sooner for large particles and later for small particles. After reaching the ground, a particular particle constitutes a personnel hazard - the magnitude of the hazard depending upon:

(a) The type of decay radiation produced by the particle - gamma, beta, or alpha, for instance.

(b) The energy of the decay radiation, which determines its effective range.

(c) The time after zero, which determines the source strength.

The ultimate theoretical goal in this field is the development of an adequate theory for prognostication of the fall-out-induced dose rate at any point. This can be naturally separated into two distinct problems, as follows:

(a) The problem of deducing particulate fall-out for a given point, and

(b) The problem of deducing the dose rate that will be experienced due to exposure to the above mentioned particles.

The second of these is adequately solved by using an empirically determined average decay rate for fission fragments - namely, that the dose rate is proportional to the inverse 6/5 power of time.

* Unless the particle is sufficiently small to undergo "Brownian movement". In this case, the dominating factor in its motion is bombardment by molecules of air, and its path in space will be dictated by chance. For the sake of simplicity, we shall ignore these particles (radius < approx. $1/2\,\mu$), although it is by no means clear that such a simplification is justifiable from the viewpoint of contributing a negligible fraction of fall-out-induced radiation hazard.

The existence of the second, however, implies that we must know when the particle arrived at a point - the mere fact that it did arrive is not enough. A simple theory explaining the latter phenomena has been evolved, but it requires extensive corroboration and calibration before it can be used with confidence. Prior to BUSTER/JANGLE, the necessary experimental data was not available - since all fall-out measurements were time-integrating (for instance, film badges). This project is intended to further the documentation (started in conjunction with Nevada tests) of fall-out intensity versus time at various fixed points.

Method and Procedure:

A. The instantaneous dose rate at a given point will be measured with an ionization chamber - a device which produces a current signal upon the passage of ionizing radiation. A permanent record is obtained of this instantaneous measurement by using the current signal to drive a pen on a Esterline-Angus (or its equivalent) recorder. Measurement of the pen trace thus obtained will furnish radiation intensity versus time data - the lateral displacement of the pen being proportional to radiation intensity, and the longitudinal position of a point on the paper being a measure of time after zero.

B. Recording devices, of the above mentioned type, will be installed on Bogallua, Rigili, Parry, Biijiri, Engebi, Runit, and Bogon islands. The records from Engebi and Bogon will be telemetered to Parry, in order that the initial recovery teams (on Parry) may know the personnel hazard existent in the northern part of the atoll at that time. All units will be self-contained, and actuated by time clocks.

In addition, it is planned to install such monitoring devices on some ten other atolls in that portion of the Pacific.

[redacted]

127

[redacted]

Object of the Experiment:

In order to better predict fall-out patterns and probable external and internal hazards to personnel from radioactive fall-out, previous atomic weapons tests have mounted experiments to measure fall-out. As a result, after the SANDSTONE tests a secondary fall-out was reported at Kwajalein (400 miles distant) on YOKE plus 1 day. This fall-out occurred as radioactive rain which fell intermittently during a period of about 10 hours. The maximum activity reported was 6 mr/hr on exposed cloth and tent sides and 10 mr/hr in dried puddles. At Operation GREENHOUSE following DOG shot, a fall-out occurred over the southern half of Eniwetok Atoll. The fall-out on Eniwetok Island started approximately three hours after the shot and continued to build up for a few hours, reaching a peak in excess of 40 mr/hr by mid-afternoon. No secondary fall-out was observed through D plus 6 days. Within a few hours after EASY shot, a fall-out occurred which was restricted to the northern islands of the atoll, near Engebi. A small secondary fall-out occurred on E plus 1 day which was observed only on Aniyaanii, Parry and Eniwetok.

If the yield on MIKE shot approaches that which has been predicted, the cloud can be expected to rise considerably higher than that from any previous test. The gathering of fall-out data from this shot is therefore a logical extension of previous fall-out documentation. The data collected will have direct application in the appraisal of potential health hazards to personnel from external and internal exposure to the fall-out products. It will also furnish additional information for predicting fall-out patterns from other atomic detonations.

This experiment has been designed to accomplish the following objectives:

A. To extend the measurement of fall-out distribution and magnitude following MIKE shot to distances greater than those being documented by Project 5.3. For the most part, this will involve instrumentation of the sea areas around Eniwetok Atoll.

B. To determine, at a limited number of close stations, the rate of arrival of inert liquid or solid materials and associated radioactive materials.

C. To obtain data on size distribution and chemical nature of the active fall-out particles.

COPIED/DOE
LANL RC

D. To correlate the fall-out pattern obtained with that predicted from a knowledge of meteorological conditions and atomic cloud behavior.

E. To calculate fall-out-induced radiation intensities (versus time) and total dose.

Method and Procedure:

The instrumentation to be utilized in securing the necessary data will include the following type of collecting devices:

Type A — An integrating collector for both liquid and solid fall-out, comprising a collecting area funneling into a flask. The flask is so designed that it can be removed from the collector, sealed and shipped.

Type B — A liquid rate collector consisting of a modified recording type rain-gage. There will be two models of this instrument, one for recording over a period of one week and one for recording over a period of six hours.

Type C — A differential fall-out collector which separates the liquid fall-out with respect to time of arrival at the station.

Type D — A differential fall-out collector which separates the solid fall-out with respect to time of arrival at the station.

Type E — Greased plates which will be replaced each 24 hours for a period of approximately one week after shot time.

The six-hour Type B collectors and Type D collectors will either be started manually or with blue boxes, depending upon their proximity to the weapon.

The land-based station array within the Atoll will consist of the following:

Land Station	Collecting Devices				
	Type A	Type B	Type C	Type D	Type E
Bogallua	1	1	1	1	
Engebi	1	1	1	1	
Yeiri	1	1	1	1	
Piiraai	1	1	1	1	
Runit	1	1	1	1	
Aniyaanii	1	1	1	1	
Parry	1	1	1	1	1
Eniwetok	1	1	1	1	1

It is currently planned that Type D and E collectors will be employed on certain islands outside the atoll. The exact islands to be used will be determined at a later date. Station installation at a selected island outside Eniwetok Atoll can be accomplished by a team of no more than two men - in a maximum of 24 hours. Subsequent operation of the station might be accomplished by personnel permanently assigned to that area - since it would require only 5 man-minutes per day during the period of interest.

It is also planned to use a number of anchored rafts as instrument stations within the lagoon. These raft stations will be assembled on land and towed to anchorage location.

Stations equipped with Type D and E collectors will be established aboard at least one vessel of each task force unit. This equipment can be delivered to the ship well in advance of proposed operations, and, where Project 5.4a personnel are not present, simple operating instructions will be issued to the ship's force.

(2) Rad-Safety monitors for survey recovery operations.

CONFIDENTIAL

Object of the Experiment:

At Operations SANDSTONE, GREENHOUSE and BUSTER/JANGLE, the Chemical Corps secured a great deal of data on the distribution of particulate matter in atomic explosion induced radioactive clouds. At Operations SANDSTONE and GREENHOUSE much of this data was obtained by using samplers on drone aircraft. It was used in determining the predominant sizes of gross and radioactive particulates, particulate activity per unit volume of the cloud, specific activity of particulate matter, fractionation of radionuclides with particle size, gross weight of fall-out per unit area as a function of distance and airborne activity contours in the area of cloud travel.

The object of this experiment will be to obtain the following specific data from the clouds produced by Operation IVY atomic detonations:

a. Total activity in the particulate material.

b. Rate of fall-out and the fall-out pattern on land areas of Eniwetok atoll.

c. Determination of the airborne concentration of the radioactive particulate matter near ground level over land areas of Eniwetok atoll.

d. Determination of size distribution of gross and radioactive particulate matter.

e. Distribution of activity with particle size.

f. Determination (with radiochemical techniques) of the presence of selected fission products in the particulate matter.

g. Determination of the adequacy of aerial survey systems in assessing the ground contamination situation.

These data will supplement the previous atomic bomb phenomena observations in the determination of the following:

a. The hazard to personnel resulting from residual fall-out and airborne activity.

b. The contamination of areas and structures.

c. The development of decontamination measures.

DOE

Method and Procedure:

The collection of the necessary samples will be accomplished by sampling aircraft for air samples and the Intermittent Fall-Out Sampler and Electrostatic Precipitator for ground samples. These methods and equipment will be discussed in detail below:

Air Sampling - Air sampling aircraft will collect a total sample of gaseous and particulate material from the cloud for the purposes of Project 7.3 and this project. This project will analyze the particulate sample for cloud particle size and distribution. The sampling will be accomplished by F-84G aircraft, each being equipped with a cloud sampler. The latter will be installed in the nose of the aircraft with a probe extending forward of the nose through a gunport. The probe contains a solenoid operated valve and is attached to a flexible plastic bag. Initially the bag will be deflated and the valve closed. Upon entering the cloud following the detonation, and at a given radiation level, the pilot actuates a switch opening the solenoid valve. The probe samples the air isokinetically, to fill the bag within approximately ten seconds. The gas sample is subsequently pumped out through a filter into shipping bottles. Both bag and filter will finally be shipped to the ZI for detailed particulate analysis.

Intermittent Fall-Out Sampler - The intermittent fall-out samplers will be located on various islands of the atoll, and will operate in such a way as to document fall-out as a function of time. These samplers will be designed to the following specifications:

a. Initially water-tight to prevent entry of water.

b. Equipped with a Blue-Box with a time delay relay to start the sampling cycle at H-hour plus 5 to 10 minutes.

c. Total sampling time of six (6) hours.

d. The unit will sample fall-out intermittently, with a time interval between sample collections of fifteen minutes.

e. Battery, or spring-wound motor, operated.

f. Sampling surface readily removable from the equipment to facilitate shipment.

It is planned that one of these Intermittent Fall-Out Samplers will be located on each of the following islands of Eniwetok atoll:

Bogallua	Rojoa
Bogombogo	Aaraanbiru
Ruchi	Piiraai
Bogon	Runit
Engebi	Aniyaanii
Muzin	Japtan
Kirinian	Parry
Bokonaarappu	Eniwetok
Yeiri	Igurin
Aitsu	Giriinien
Rujoru	Rigili
Eberiru	Coral Head
Aomon	Artificial Island
Biijiri	

Duplicate stations will be established at Engebi, Eberiru, Runit, Japtan, Parry, Eniwetok, Giriinien and Rigili.

Electrostatic Precipitator - These will collect samples of airborne particulate material. Each precipitator is self-contained and similar to a portable electrostatic precipitator developed and manufactured by Mine Safety Appliance Company. The collecting surface will be modified to include electron microscope screens for particulate analysis. Such units will be located on Engebi, Eberiru, Biijiri, Runit, Japtan, Parry and Eniwetok.

Aerial Survey - These data will be obtained with survey meters in light aircraft or helicopters,with detailed data being taken with survey meters equipped with recorders. It is planned that these data be taken by a Rad-Safety monitor in each aircraft and made available to this project. Detailed information is required on the altitude, flight path, air speed, estimated ground speed, location relative to the ground, etc., to permit interpretation of the graphical data.

Object of the Experiment:

A complete understanding of blast phenomena involves many problems - very few of which can be adequately treated with theoretical methods alone. To the bomb design theoretician, knowledge of the free-air* pressure field that would be established in a homogeneous atmosphere by a given atomic explosion is sufficient. Such knowledge would imply an understanding of how the explosion energy is partitioned (between the various energy transport mechanisms) and how at least part of that energy is propagated. In the strict sense, the phrase "field variable" means just that when applied to pressure. Since no such homogeneous atmosphere exists, however, and we see that pressure can never be studied as a field variable in the strict sense, it seems logical to study pressure fields that have been perturbed only by atmospheric inhomogeneities. The discussion of Project 6.2 is devoted to explaining the proposed contributions of Operation IVY to such studies.

The next step in complexity involves studying the pressure field, near a reflecting surface, in order that one may understand how such a surface perturbs the field - as a function of pressure, time, characteristics of the reflecting surface, and characteristics of the atmosphere above the surface. This project is designed to augment the existing fund of experimental data on the latter - by measuring pressure as a function of time, on or near the earth's surface, at various fixed points around Eniwetok atoll for shots MIKE and KING. The value of such data to those interested in Weapons Effects is clear, since most objects that one might wish to destroy with (or protect from) an atomic bomb are located on or near the surface of the earth.

Method and Procedure:

A. One device which measures the instantaneous incident pressure is known as a Wiancko gauge. This instrument makes use of the pressure-induced deformation of a twisted "bourdon" tube to vary the inductance of a coil - thus generating an electric signal, the magnitude of which is proportional to the instantaneous value of the incident pressure. A permanent record of the signal is made electronically, either on magnetic tape, photographic film or paper. Each gauge thus supplies a record of pressure versus time at its location - and a pressure versus distance record is obtained by placing gauges at a number of different positions.

To obtain information as to azimuthal variations in the field, gauges are located on different radial lines from zero. To separate "surface" effects from the records, the gauges are mounted a few feet above the ground on small towers. When the latter is not feasible, the

* See the discussion of Project 6.2.

gauges are mounted flush with local surfaces (ground baffles).

B. For MIKE shot, Wiancko air pressure gauges will be placed at thirteen positions around the eastern side of the atoll, as follows:

Station Number	Island	Dist.from Zero (ft.)	Type of Gauge Mount
614	Teiteiripucchi	4422	Ground baffle
615.01	Bogairikk	5900*	Ground baffle
616.01	Bogairikk	5900*	Ground baffle
615.02	Bogon	8250**	Ground baffle
616.02	Bogon	8250**	Ground baffle
610	Site Noah***	11490	15 foot tower
611.01	Engebi	15900	15 foot tower
611.02	Muzin	21412	15 foot tower
611.03	Bokon	30130	15 foot tower
611.04	Aomon	47574	15 foot tower
612.01	Parry	-	15 foot tower
613.01	Aitsu	-	10 foot tower
613.02	Runit	74884	10 foot tower

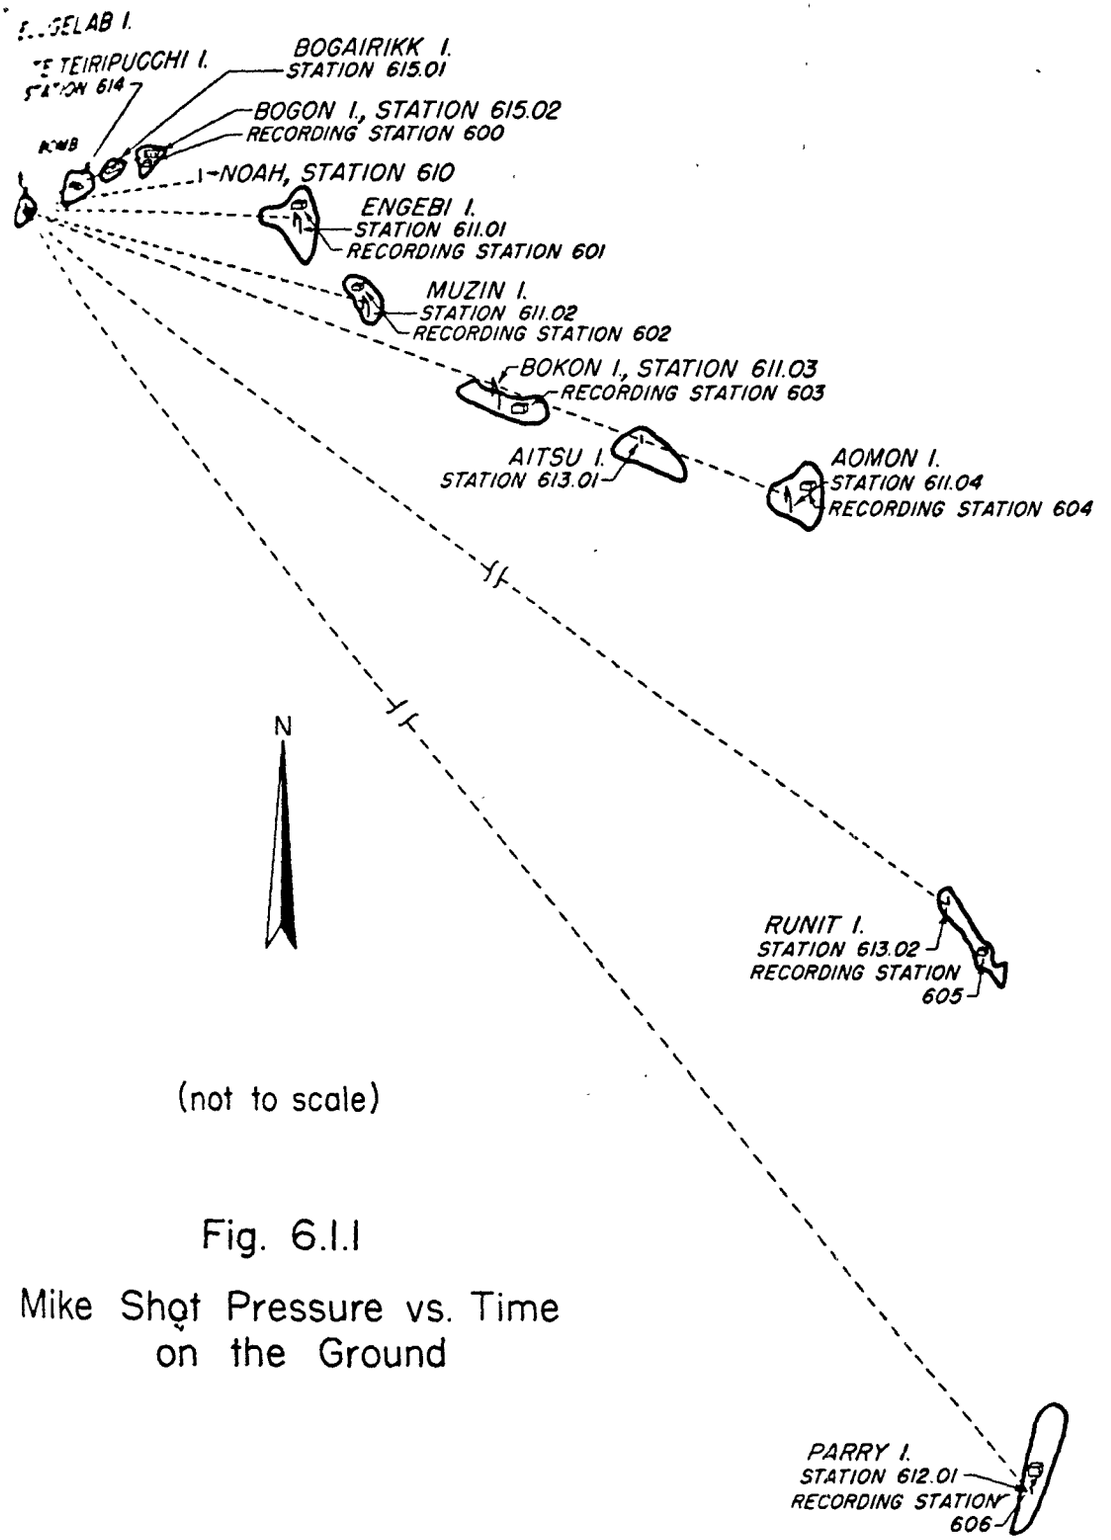
In this way, an estimated peak pressure range of from 0.8 to 300 pounds per square inch (psi) will be covered. The recording will be accomplished in the following stations:

Station Number	Island	Type of Structure
600	Bogon	New concrete blockhouse
601	Engebi	GREENHOUSE station 301J
602	Muzin	" " 301H
603	Bokon	New concrete blockhouse
604	Aomon	GREENHOUSE stations 132a & b
605	Runit	" " 55
606	Parry	New wooden blockhouse

In every case, signal wiring is being kept to a minimum, both by recording at the nearest available recording station and by careful selection of gauge locations.

* Different radial lines.
** Different radial lines.
*** This is a small artificial island on the reef between Bogon and Engebi.

For KING shot the same type of gauge will be used, and two measurement lines will be established - one over water and one over land. For the former, the gauge mounts will be 15 foot towers, located at 2500, 3000, 4000, 5000, 6000, 7000, 10,000, and 15,000 feet from bomb zero. The line will extend along the reef to the south, an attempt being made to keep each instrument at least one hundred yards from land - in order that the measurements may be more nearly "over water". The land line will be established on Runit, and will consist of the following:



Station Number	Distance from Zero (ft.)	Type of Gauge Mount
6101.01	3000	Ground baffle
618	5000	15 foot tower
6101.02	5000	Ground baffle
619.01	7000	15 foot tower
6101.03	7000	Ground baffle
619.02	9678	15 foot tower
6101.04	9678	Ground baffle

Recording of these measurements will be accomplished in station 605. In addition to the above, one gauge will be mounted (on a 15 foot tower - station 612.02) on Parry - the measurements of which will be recorded in station 606.

Remarks:

The Proving Ground Department of Sandia Corporation is responsible for four distinct projects (6.1, 6.3, 6.5, and 6.7b) of the Blast Measurements program. The work loads imposed by these projects, however, are not separable. As a result, the Sandia Corporation personnel under Mr. Lenander's supervision will devote their efforts to all projects equally. In lieu of listing personnel requirements for the individual projects, the following table is presented; to represent the total proposed forward area requirements for the above mentioned four projects:

Officer	Enlisted	Civilian	From	To
		2	M-130	M/7
		1	M-99	M/7
		3	M-59	M/29

Object of the Experiment:

One of the most perplexing problems in the field of atomic weapons effects is the obtainment of an accurate and complete free-air over-pressure versus distance curve. By complete we mean a continuous record of pressures from the relatively high (hundreds of pounds per square inch) to the very low (a fraction of a pound per square inch). Over-pressure, of course, is defined as absolute pressure less ambient pressure - and the term free-air implies the true absolute pressure existent at a point in the atmosphere, in the absence of such perturbing factors as measuring instruments, structures, aircraft, or the earth's surface.

Unfortunately, the hydrodynamical equations which describe this phenomenon completely can be written but not solved. An approximate solution has been obtained with IBM machines, under the simplifying assumptions of a homogeneous atmosphere and no radiative transport of energy - this solution, however, is of maximum value only when supplemented with experimentally determined facts, as it tells us nothing about the attenuation of the shock strength with passage to altitude.

The obtainment of such experimentally determined facts is fraught with difficulties, as will be seen from an examination of our definitions above. First one must develop an instrument which will document the passage of the shock wave without disturbing that passage in any way, otherwise the measurements will not be true "free-air". Then a system must be evolved for fixing these instruments at known positions in space.

The importance of having the above mentioned pressure versus distance curve cannot be overemphasized. For instance, in the field of atomic weapons effects alone, the correct answers to the following questions would come much closer to being a reality:

(1) What is the minimum safe target approach distance for a dropping aircraft, as a function of target altitude, aircraft altitude, and energy release of the weapon?

(2) What accuracy is required for the optimal use of atomic warheads in anti-aircraft projectiles, as a function of target altitude, target velocity, probable target dispersal (tactical deployment of aircraft formations), and energy release of the warhead?

(3) What is the optimal bomber formation for effective deployment against an enemy target which may be defended by atomic anti-aircraft projectiles?

At the present time, these questions (and many others, closely related) can be answered in an approximate way only - by making many simplifying assumptions. The availability of good free-air pressure versus distance information will decrease the number of those assumptions by at least one. This experiment attempts to supply some of this information, by employing an "ingenious device" to partially circumvent the experimental difficulties mentioned above.

Method and Procedure:

A. One method of labeling the atmosphere is supplied by smoke puff photography. A puff of smoke is placed in the atmosphere - in some region of interest (the placement procedure will be discussed below). A motion picture camera has been previously aligned in such a way that the puff is well within its field of view, and the camera has been supplied with a device for placing timing "pips" on the film. Subsequent photography of the puff, and film analysis procedures, will supply the experimenter with a time history of the puff's motion and perturbation.* Use of one camera, of course, will only document the projection of the puff on a plane perpendicular to the axis of the camera. If one places the puff in a known plane initially, however, and makes wind corrections, a reasonable approximation to the three dimensional path of the puff can be obtained.

Such a method should supply us with the following information, with fair accuracy:

(a) The elapsed time from zero to the arrival of the shock at the puff. This combined with the Eulerian coordinates of the puff at that time (obtained from film analysis) will supply a point on the free-air shock time of arrival curve.

(b) The motion of the puff after passage of the shock. Such "mass motions" are theoretically associated with the variation of shock strength with time, and hence with the variation of shock overpressure with time in that region. This represents the primary measurement of the project.

* The puff itself may be thought of as a point in the Lagrangian coordinate system, and the technique outlined herein is a method of associating this Lagrangian point with both time and the Eulerian coordinate system.

B. For MIKE shot, low altitude (~ 400 feet) labeling of the air will be accomplished with exploding mortar projectiles. The distances from zero will be similar to those chosen for the Wiancko gauges of Project 6.1 - the actual positions, however, are quite different. Most of the mortars will be mounted on ten foot square rafts and placed in the lagoon, to allow photography from stations on the eastern side of the atoll. The four close-in mortars will have their firing mechanisms actuated with EG&G timing signals - the remainder will be actuated by means of "blue boxes". The mortar-produced puffs will be photographed by ten Mitchell (100 frame/sec) cameras - from vantage points on Engebi, Rojoa, Runit, and Parry. These cameras will be mounted in individual shielded steel boxes on concrete pillars.

In addition, the air will be labelled with smoke at ten altitudes above the bomb (5000, 6000, 10,000, 11,000, 15,000, 16,000, 20,000, 21,000, 25,000, and 26,000 feet) by means of bursting shells from guns. The guns will be placed on Engebi, and the bursts will lie on a line defined by the intersection of the following planes:

(1) A plane such that a horizontal line in that plane is perpendicular to the line from zero to the photo station on Rojoa. This plane makes an angle of 60 degrees with the horizontal, passing through zero and leaning toward Rojoa.

(2) A plane such that a horizontal line in that plane is parallel to the line from zero to the Rojoa photo station. This plane makes an angle of 75 degrees with the horizontal, passing through zero and leaning toward Bogollua.

The ten guns will be placed on Engebi, each gun assembly being mounted on a concrete pad (10 feet square and 8 inches thick). Since the lowest burst height is 5,000 feet, the choice of the above line (along which the bursts will lie) implies that no gun is aimed toward the bomb. If the velocity of a projectile be wrong, the nearest possible approach to the bomb is 1,000 feet. All guns will be fired with timing signals furnished by EG&G. The gun-produced puffs will be photographed by five Mitchell (100 frames/sec) cameras, from the photo station on Rojoa.

For KING shot, only the low altitude (~ 400 feet) air labeling technique will be used. Eight mortars will be placed on a line running approximately northwest from ground zero - the nearest being at 4,000 feet and the most distant being at 15,000 feet. The puffs will be photographed by Mitchell cameras from the Rojoa photo station.

Remarks:

1. A fundamental difficulty with this measurement is the fact that cloud coverage may result in complete failure to obtain data. Since this method is the simplest known way to obtain the information sought, however, it is felt that the chance is worth taking.

2. It should be clearly understood that high orders of accuracy in the obtainment of free-air pressure information are not essential to the present day "effects on things" planning. This is due to the fact that the response of the "things" to those pressures is not well understood. Such a fact, however, does not preclude the desirability of understanding the pressure field about an atomic bomb explosion as completely as possible. Future developments in the field of structural analysis may well make highly accurate pressure knowledge necessary.

COPIED/DOE
LANL RC

Object of the Experiment:

The static pressure experienced by a fixed point in the blast field exhibits the following qualitative variation with time:

(a) Prior to shock arrival it remains relatively constant at its ambient value.

(b) Passage of the shock wave is accompanied by an abrupt pressure rise to some peak value. This peak value is determined in part by the distance from bomb zero and the energy release.

(c) After the shock passes the pressure falls (in something like an exponential fashion) with time from the above mentioned peak to below-ambient values. It subsequently passes through a minimum, and finally approaches the ambient value from below.

For a given point in space, the period during which the pressure is greater than ambient is known as the "positive phase" - and the period during which the pressure is below ambient is known as the "negative phase". The positive phase is characterized by a wind blowing radially outward (from zero) and the negative phase is characterized by a wind blowing radially inward toward zero. These are the shock winds. Material velocity behind the shock (one of the parameters entering into the equations used to describe shock propagation) is another name for the shock wind in that region.

The rising fireball creates a tremendous "updraft" in the vicinity of bomb zero. Such a vertical motion of an air column creates a low pressure region near the base of the column. This in turn causes outside air to flow into the lower portion of the column. The latter is called the "afterwind".* For a sufficiently small burst height (above the earth's surface), the above mentioned column rests on the ground - and the afterwind includes horizontal components at ground level, directed toward ground zero. The mechanisms which create an afterwind on the one hand and a "fire-storm"** on the other hand are essentially the same.

* The term "afterwind" may also be used to include the shock winds of the negative phase. In this case, the phrase "shock wind" applies only to the radially-outward winds associated with the positive phase.

** Similar to that following the Hiroshima detonation.

When an object is placed in a moving fluid, such as air, the pressure to which the object is subjected consists of two distinct components - the static pressure and the dynamic pressure. The former is the pressure that the object would "see" if it were moving with the fluid - the latter is the additional effective pressure on the object, produced by the fluid velocity. Which of these components is the larger depends on the particular conditions - and each is capable of destruction, as an inanimate object has no way of differentiating between them. Thus the above mentioned winds are potential destructive forces, and are worthy of study as such.

The ambient (unshocked air) sound velocity, the material velocity behind the shock, and the sound velocity behind the shock are all parameters which occur in theoretical shock wave descriptions. As a result, their experimental documentation for an actual wave is very valuable to a complete description of the phenomena associated with the wave.

The objectives of this project are thus seen to be two-fold, as follows:

(a) The measurement of shock winds and afterwinds at various distances from ground zero.

(b) The measurement of sound and material velocities, both prior to and after shock arrival, at various distances from ground zero.

Method and Procedure:

A. At this writing, feasibility tests of several instruments are being conducted at the NTS. Final decisions as to which of these instruments will be used for IVY will be forthcoming on or about 15 June. Among those instruments being considered are the following:

(a) A double-ended pitot head assembly. This instrument measures both total (static plus dynamic) and static pressures. It is made double-ended in order that both the positive and negative phase winds can be documented. Its mode of operation is identical to that of any aircraft pitot head.

(b) A so-called Sonic Interferometer. This instrument assembly consists of a pulsing mechanism, two sound wave generators, two receivers, a timing oscillator, an interval timer, and recording equipment. That portion of the assembly which actually is subjected

[redacted]

to the blast wave is mounted on the cross bar of a "goal post" type tower, some 15 feet above the ground. The two sound wave generators are located at the center, and one receiver is attached to each end, of the bar. The goal post is oriented in such a way that the bar makes a 45 degree angle with the oncoming blast wave. Hence one receiver is upstream, and the other is downstream, of the transmitter head. The remainder of the assembly (pulsing mechanism, timing devices, and recording equipment) is mounted in a nearby recording station, to and from which the necessary signals can be carried by wires.

In brief, operation of the above instrument is as follows:

(1) The timing oscillator (set for 250 signals per second) triggers the pulsing mechanism and the interval timer simultaneously.

(2) The pulsing mechanism feeds a pulse to the transmitter head, which in turn generates two sound waves.

(3) Upon detection of a sound wave, a receiver notifies the interval timer and its associated recording equipment.

The basic data obtained by the instrument consists of elapsed time measurements - from the electronic initiation of each signal to its recording after detection by both receivers. Calibration allows these measurements to be interpretable in terms of the sound wave transit times over both upstream and downstream air paths. The latter information can in turn be theoretically related to both local sound velocity and wind velocity.

and i
measu
stati
locat

(c) Kiel-meters and Q-tubes. These instruments are commonly used for wind tunnel pressure measurements. Their operation is based on an application of Bernoulli's principle.

(d) A device known as the Sonic Anemometer, the name being derived from the fact that it is a wind velocity measuring instrument which probes the velocity field with sound waves. This interesting device, which was designed and developed by Group J-10, of LASL, measures the elapsed times between the creation of a sound wave

The
yet

one
and

COPIED/DOE
LANL RC

[redacted]

CONFIDENTIAL

(by a spark gap) and its arrival at two microphones. The path lengths in air (from spark gap to each microphone) are identical in length and oriented differently with respect to a radial line from bomb zero. The difference in wave arrival times, at the two microphones, is a measure of the relative motion of the air through which the wave passed - and hence of the local wind velocity. The time required for a wave to traverse a given path is a measure of the average sound velocity over that path.

A typical installation consists of a 24 inch (diameter) hole in the ground (16 feet deep) - around the mouth of which three steel pipes extend vertically some six feet above the ground. The pipes are located at the vertices of an isosceles right triangle, the altitude of which is perpendicular to a radial line from ground zero. The microphones are located at the tops of the pipes at either end of the triangle base, and the spark gap is located at the top of the pipe remaining. The air paths are thus the equal sides of the triangle - each being approximately one meter long. The electronic equipment, including a dual-trace recording oscilloscope, and a Warrick high speed camera which provides permanent records by photographing the scope face, are mounted in the hole - cheap shielding from ionizing radiation thus being obtained.

B. For MIKE shot, Group J-10 of LASL will measure both sound and inward directed wind velocities - using Sonic Anemometers. These measurements will start at the end of the positive phase (at a given station) and extend for approximately ten seconds. The instrument locations will be as follows:

Station Number	Island	Distance from Zero (ft.)
630.01	Engebi	19363
630.02	Kirinian	24104
630.03	Bokon	30764
630.04	Biijiri	51008

The possible participation of this group in the KING shot program is as yet unsettled.

The Proving Ground Department of Sandia Corporation, using one or more of the other instruments mentioned, will also measure sound and wind velocities for both MIKE and KING shots. Their instruments

COPIED/DOE

will be mounted on, and the recording for them will be done in, Project 6.1 stations* (15 foot towers and associated recording stations) - on Bogairikk, Bogon, Engebi, Muzin, Bokon, Aomon, Parry, and Runit. The two closest stations will not measure wind velocity directly, because of its great magnitude, but will measure pressure differences along a shaped surface - from which the wind velocity can be calculated. Shaped surface designs are not yet available, but they will probably be concrete walls 5 to 10 feet high and 20 to 30 feet long.

Remarks:

Major Jack E. Whitener, of LASL, is the Project Officer for the Sonic Anemometer portion of this experiment. For those interested in contacting him for additional details of his work, we offer:

Address: P. O. Box 1663
Los Alamos, New Mexico

Phone: 2-2766

* This includes the Sonic Interferometer goal posts - stations 611.01, 611.02, 611.03, 611.04, 619.01, and 619.02.

159

Object of the Experiment:

As a continuation of the studies outlined under Project 6.4b, this project is designed to document water surface motions within the lagoon.

Method and Procedure:

A. Both the wavelength and amplitude of lagoon water waves will be observed photographically. To make such a technique feasible, the water surface will be labelled with floats. Each float will be located within the fixed field of view of a Mitchell (~100 frames/sec) camera. Subsequent film analysis will allow the construction of a position-versus-time function for each float - and hence for those water surface points.

B. The fields of view of those Mitchell cameras arranged to observe mortar-produced smoke puffs (see Project 6.2) will include the water surface. Hence ten film records can be obtained for this project by the proper location of floats alone. In addition, to obtain further coverage, three Mitchells will have a primary mission of obtaining records for this project. The latter will be mounted in individual shielded steel boxes on concrete emplacements. One each will be located on Engebi, Runit, and Biijiri.

The above instrumentation will allow documentation of lagoon water surface motions in the vicinity of Parry, Runit, Rojoa, and Engebi.

161

Object of the Experiment:

MIKE shot is expected to produce rather substantial waves on the surface of the surrounding water. This project is designed to document:

(1) The characteristics of the waves produced (number, height, period, length, and velocity).

(2) The amount of blast energy being transferred into wave-making.

(3) The nature of propagation and refraction of seismic-like waves over large areas of ocean.

Although many experiments which give a reasonably good picture of explosion-generated waves have been conducted, they have been for comparatively uncomplicated conditions. The principal problem is to ascertain the means by which energy is transferred from the explosion to the water (the impedance match). Such a problem is particularly difficult in this case because we have no comparable experiments upon which to base an estimate. For example, the "Seal" experiments by Leech indicated that there is a second critical depth, close to the water surface, at which a remarkably high percentage of blast energy goes into wave energy. In fact, the use of near-surface explosions is a promising means of deluging an enemy beach prior to an amphibious assault. This would lead one to assume that the MIKE waves will be high. On the other hand, the fact that the actual explosion will be over land suggests a poor impedance match and a low transfer of energy to wave making. There are at least six means by which waves may be produced:

(1) The existence of a high pressure area of considerable duration over the water surface near ground zero will give an initial outward impulse to the surrounding water.

(2) The pressure and tremendous heat will create a crater, the collapse of which may cause a second wave to start outward.

(3) A submarine landslide may be started by the blast, resulting in a tsunami (tidal wave) which, though a secondary effect, might make large waves at a distance.

(4) The air-pressure wave travelling across the water surface may be accompanied by a water wave of equal velocity.

(5) There may be a mass of rock and material lifted from the crater which will fall back into the sea - thus creating waves.

(6) Because of the assymmetry of the situation, with the shallow

lagoon (150 ft.) on one side and the deep ocean (12,000 ft.) on the other side, it is probable that the water crater will be much larger on the ocean side and that its collapse may throw a great mass of sea water into the lagoon - thus creating a secondary wave source.

Another very important, and highly indeterminate, fact is that under such circumstances these waves are likely to be of low amplitude in the deep ocean but may peak-up very considerably upon arriving at distant shores.

The value to the sciences of geology and geophysics of instrumenting a controlled seismic sea wave, perhaps the only one in history, can well be imagined.

Method and Procedure:

Waves are to be measured at four general types of locations:

1. In Eniwetok Lagoon.
2. In the open ocean nearby (undisturbed).
3. On the shores of islands at moderate distances (subject to some refraction and diffraction).
4. At great distances which are highly modified by the configuration of the bottom and the juxtapositions of islands.

The following specific locations and instruments have been chosen which, it is believed, will give the most satisfactory records of such waves:

(1) On Eniwetok island a shore recording station will receive electrical impulses thru a submarine cable from a pressure pick-up in about 60 feet of lagoon water. This is a tried and true instrument combination which has been used successfully in the past for measuring ocean swell.

(2) To the north of ground zero there are no suitable (nearby) islands at which the above "standard" instruments can be used. It is necessary, however, to measure waves reasonably close to ground zero in deep water. For this, a radical departure from previous methods of instrumentation will be required. A deep-sea mooring which utilizes the tops of undersea mountains (at 26 and 72 miles) will be tried; these flat-topped seamounts rise from 12,000 feet of water to within 4,000 feet of the surface and are thus in comparatively shallow water. A taut-line mooring with an underwater buoy for a pressure pickup station, connected by slack line to a spar-buoy containing the recording elements, will be used. Although this scheme is as yet untested, we believe it will be successful; and the eventual value of such an instrument-placing technique in undersea warfare can scarcely be overestimated.

(3) An installation on the seaward side of the westernmost islands of Bikini atoll, similar to that at Eniwetok, is necessary to measure waves at the third type of location. Here the first record of shoaling waves will be taken; diffraction will be measured and perhaps some indication of energy transfer can be obtained. Bikini will also have shore-recording wave meters cable-connected to pressure pick-ups in shallow water.

(4a) In order to measure waves at greater distances (500 - 2000 miles) a simple water-level recorder will be used which can be mounted on existing pier pilings. This instrument measures the differences in elevation of the water surfaces in two adjacent pipes which are suitably damped to exclude low frequency waves. Such installations are planned for Hawaii, Truk, Wake, and Midway.

(4b) It is quite possible that the MIKE-produced waves will be picked up by the U. S. Coast and Geodetic Survey recording-tide gauges which are distributed throughout the Pacific islands; copies of their records will be requested for study.

The University of California wave recorders on Guam, although not tuned for exact frequency response, will almost certainly get some sort of a record. These instruments will be operated continuously during the time at which waves may arrive at Guam.

Remarks:

As an aid in correlating water wave motion (and formation) with atmospheric pressure variations, microbarograph measurements may be made at Truk, Guam, Midway, and Wake islands. Such measurements would determine perturbation pressures established in the upper atmosphere by the nuclear detonation.

Each station would consist of two microbarophones installed on a radial line from Elugelab - the phones being approximately two miles apart. Measurement of the elapsed time between signal arrival at the two observation points allows a calculation of the angle from which the signal is coming.

It was originally planned that the Proving Ground Department of Sandia Corporation would make these measurements. Economy considerations, however, make it highly desirable that the Scripps Institution of Oceanography take the responsibility for them as a part of the parent project. At this writing, a final decision on this matter was not available.

Object of the Experiment:

Of the total energy released by an atomic explosion, an indeterminate percentage is transported (radially outward from bomb zero) by the ground. The magnitude of this percentage is dependent upon the impedance match between the ground and the weapon during reaction time. For a high air burst, the impedance match is obviously poor, and the percentage is essentially zero. For a deep underground burst, conversely, it is 100%. Low air bursts, surface bursts, and shallow underground bursts represent intermediate situations.

The transport of this energy by the ground is evidenced by earth accelerations and resulting motions. Documentation of these as a function of distance from bomb zero may make possible the theoretical deduction of how much energy was ground-transported. This project is designed to supply such documentation. Data from the pre-shot seismic surveys and earth attenuation measurements of Program 11 will aid in the analysis and interpretation of results obtained herein.

Method and Procedure:

A. The basic instrument to be used for these measurements is a Wiancko accelerometer. An acceleration along the axis of the instrument causes unbalance of a mass-loaded lever arrangement. This in turn causes the inductance of a coil to be varied - which generates an electric signal. Laboratory and field calibrations allow the magnitude of the generated signals to be interpretable in terms of the instantaneous accelerations. These accelerations can be integrated; once to obtain velocity, and twice to obtain displacement.

Each measuring station will consist of three such accelerometers mounted in the ground, with mutually perpendicular measuring axes. The earth acceleration will therefore be measured in three components. The depth of the accelerometer mounts will depend upon local conditions - depth of the base rock foundation, if any, etc.

B. Measuring stations will be established on Parry, Biijiri, Bokon, Muzin, Engebi, and Bogon. Exact locations and individual station details are not available at this writing.

COPIED/DOE
LANL RC

169

[redacted] CONFIDENTIAL

Object of the Experiment:

This project is designed to supplement the data obtained by the Sandia Corporation under Project 6.7b, by making a limited number of peak water pressure measurements along a line from ground zero through the center of the lagoon. In addition, the pressure-time history of the underwater shock wave, in the deep water immediately outside the reef northwest of the shot island, will be obtained. The data obtained may be of importance in determining the energy "coupling" coefficient*, as well as in predicting the effects of similar releases of energy on underwater ordnance and on vessels.

Method and Procedure:

A. A minimum of four pressure measuring and recording systems ("Tuna Cans") will be moored below the surface of the deep water immediately adjacent to the reef northwest of Elugelab. Each buoy for supporting the pressure pick-up is a completely independent unit containing the necessary power supply and recording system for the pressure-time instrumentation. A complete unit will weigh approximately 7½ tons. Pressure gauges will be suspended from the mooring cable at various depths to 2000 feet. In addition, suitable mechanical underwater pressure gauges will be utilized.

B. Scripps Institute of Oceanography vessels will position and permanently moor the pressure measuring instruments and the "Tuna Cans" during their operation in the Eniwetok area; then retrieve the records, and later the units intact, after the shot. A team of approximately six Navy scientists who have been doing underwater explosion research will be organized to accomplish the field work and analyze the data from this project. They will be based on the Scripps vessels.

The three outermost "Tuna Cans" will have surface buoy telemetering equipment (seven channels each), the signals of which will be relayed, by an airborne pick-up and relay telemetering station, to a ship plotting station. The aircraft involved has been requested and will probably be a P2V, whose position at shot time will be more than 2000 feet above the evacuation fleet.

* This is the ratio of energy transferred into the water to total energy incident upon the water.

COPIED/DOE
LANL RC

Remarks:

The Sandia Corporation will place six underwater pressure gauges in the shallow water on the lagoon side of the shot island, under Project 6.7b, the data from which will be coordinated with the above.

Object of the Experiment:

As a continuation of the underwater pressure field studies*, this project is designed to measure the pressure as a function of time in the shallow water of the lagoon. Various distances from bomb zero will be instrumented, in order that pressure attenuation with distance can be documented. These measurements are not considered worthwhile for KING shot. Since it is to be an air burst, one expects a poor impedance match between water and exploding weapon, with a correspondingly small amount of energy being transported by the water.

Method and Procedure:

A. The basic instrument to be used herein is a Wiancko gauge**. modified for underwater use.

B. These gauges will be placed in the lagoon, 1/4 to 1/2 mile from land. The actual locations will be off Parry, Biijiri, Engebi, and Bogairikk. Recording of the data obtained by these instruments will be accomplished in nearby Project 6.1 recording stations, using standard equipment.

COPIED/DOE
LANL RC

COPIED/DOE
LANL RC

Object of the Experiment:

This project is designed to make special observations, at several SOFAR (Sound Fixing and Ranging) stations in the Pacific (and possibly Atlantic) area, of acoustic signals propagated in deep water. It is believed that the MIKE shot yield can be crudely estimated from the characteristics of the received signal. It was demonstrated during Operation SANDSTONE that the relative yields of shots XRAY, YOKE, and ZEBRA could be established in this fashion. The poor impedance match (between ocean mass and exploding weapon) characteristic of an air burst will probably preclude the reception (at great distance) of such signals for KING shot.

Method and Procedure:

A. SOFAR is a method of detecting, and recording the characteristics of, acoustic signals propagated in a water layer which is approximately 500 fathoms under the ocean surface in the Pacific and 700 fathoms under the surface in the Atlantic. The transmission of sound waves in this layer is extremely efficient, apparently because of a temperature inversion at that depth. In fact, for MIKE shot, it is expected that the signal will travel through the layer around the tips of both Cape Horn and the Cape of Good Hope.

B. Navy SOFAR and SOFAR Research Stations, presently operating in the Pacific and Atlantic areas, will be used for special observation and analysis of the acoustic signals received during the shot period of Operation IVY. Installation of new pressure pick-ups and recording systems is being expedited at these stations. A specially trained observer will be attached to the normal staff of each of two such stations, to insure that observations are properly made and to analyze the available data. No new SOFAR stations will be established.

Object of the Experiment:

In the discussion of Project 6.2 we pointed out the difficulty of measuring a blast parameter without perturbing the flow with the measuring instrument. We also indicated one approach to a solution of the problem posed by such a difficulty; namely, the "probing" of the blast field with particles so small that their presence in the flow would cause little or no perturbation. Under Project 6.3 we discussed a second approach to the solution - the use of sound waves to probe the field.

The probing method used herein is a continuation of the first approach, in that even smaller (than the smoke particles of Project 6.2) particles are used. This project is designed to document the air density at various fixed points in the blast field - prior to, during, and subsequent to the passage of the shock wave. Knowledge of the air density alone is insufficient to describe the shock wave development completely. Since all the blast parameters (pressure, temperature, density, velocity, etc.) are related theoretically by well substantiated expressions, however, the measurement of any one is useful in the determination of others. Also, if we measure more parameters than are necessary to make the equation system determinate, the obvious advantage of being able to cross-check our results is available to us.

Method and Procedure:

A. In addition to its function as a blast parameter, density controls the transmission properties of air - for both particulate and electromagnetic radiation. That is, the mean free path* of gamma-rays, neutrons, beta-rays (electrons), etc. in air is a function not only of their energy but also of the air density. In other words, the cross section** of air with respect to radiation of a given energy varies with air density. In particular, an increase of air density implies greater attenuation with distance (shorter mean free path - higher cross section) to radiation of a given energy level.

To accomplish its purpose, this project utilizes a device known as the Beta-ray Densitometer, the latter being designed to take advantage of the above mentioned variation of cross section with

* See page 8.1.3

** See page 4.2.2

COPIED/DOE
LANL RC

180

sity. In brief, its method of operation is as follows: A beta-ray source of known intensity is observed by a phosphor-photocell type of detector, the separation between source and detector being ~ 50 cm. An air density increase (decrease) over the path between source and detector causes a decrease (increase) in the intensity of beta radiation incident upon the phosphor - which in turn causes a decrease (increase) in the light output by the phosphor. The latter leads to a corresponding decrease (increase) in the current signal generated by the photocell. The current signal is used to perturb an electron beam in a cathode-ray tube, and the primary datum generated by the instrument is a photographic record of the tube face. Laboratory calibration of the assembly allows analysis of the above mentioned film to be interpretable directly as air density versus time along the path.

B. For MIKE shot, four Beta-ray Densitometers will be used, one on each of the following islands: Engebi, Kirinian, Bokon, and Aamon. The distances from bomb zero to these stations will be approximately 20,000, 25,000, 30,000, and 50,000 feet respectively.

At present, it is planned to use two densitometers for KING shot - both of which will be located on Runit. Detailed planning for this phase of the operation is not complete at this writing.

Remarks:

(1) The density versus time information obtained herein should be valuable as a data-interpretation aid for Project 5.2 (Gamma Intensity as a Function of Time). At a given instant of time the density contour between bomb zero and any fixed point in space will affect the gamma radiation incident upon the point. Hence humps or troughs in the gamma intensity versus time curves may be explainable in terms of shock wave position (and attendant air density variations) relative to the gamma detectors.

(2) For the primary data of the densitometer to exhibit high signal-to-noise ratios, the instrument must be located such that:

(a) The density variations experienced during and subsequent to shock passage are relatively high.

(b) The magnitude of the extraneous (to this experiment) light signals generated in the phosphor by incident gamma radiation and neutrons must be relatively small.

COPIED/DOE
LANL RC

Hence we must place the station so close to the bomb that the shock strength is not too low when it reaches the instrument, yet sufficiently distant that the gamma-ray and neutron flux will be adequately attenuated. For small weapons, these conditions are mutually exclusive - for large weapons the situation is much better. The reader interested in determining why this is true needs only to compare the expressions for gamma-ray intensity versus distance and shock strength versus distance. Because of the above, MIKE shot presents the best opportunity to date for using the densitometer technique, and excellent results are expected. The smaller yield of KING shot will make a less desirable environment - not sufficiently less, however, to preclude its inclusion in the experimental program.

COPIED/DOE
LANL RG

[redacted]

[redacted]

Object of the Experiment:

To determine the free air pressure as a function of time using manned aircraft to position the measuring instruments in space, at altitudes significant to delivery aircraft. In addition, data on the dynamic structural response of aircraft will be obtained. The latter will be used as a basis for establishing structural design criteria, and for immediate use in planning delivery techniques for very high yield weapons.

Method and Procedure:

A. One B-36D and one B-47B aircraft will be instrumented for measurement of overpressures, induced loads (such as increased lift and structural strains in the wings and tail group), and the dynamic response of the complete airplane to the blast wave. Since the yield of MIKE shot may fall within broad limits, it will be necessary to instrument the aircraft with two distinct sets of pressure gauges to cover a pressure range of 0 to 10 psi. Strain gauges will be employed to determine deflections of individual aircraft components.

The data will be recorded on consolidated oscillographs with a total of seventy-two sensing channels. These data will be returned to the ZI for reduction and analysis. It is hoped that the final results will be useful for the establishment of criteria for tactical employment of currently available (or future) aircraft as delivery devices for high yield bombs.

B. The instrumented aircraft will orbit the zero point at a safe distance until just prior to the detonation, at which time they will turn so as to be flying directly away from ground zero at the time of detonation. These aircraft will be based at Hickam AFB, T. H., with the B-47B being phased in and out of Kwajalein.

The aircraft used, and results obtained, will be coordinated with those of Project 6.11. This project is also closely associated with Project 8.5, in that the thermal attenuation measurements are being made in the same aircraft. In addition, the B-36D will carry radar scope cameras for Project 9.4.

Remarks:

1. This project is a continuation of the previous work on the effects of blast upon aircraft, which has been conducted by the

COPIED/DOE
LANL RC

1846

[redacted]

Massachusetts Institute of Technology under Air Force contract. Valuable data were obtained during Operation GREENHOUSE, and such results are reflected in the refined pressure-time and pressure-distance curves which are currently being used by the USAF for tactical planning. The positioning of all aircraft for IVY is being influenced by these curves.

(Manned Aircraft)

COPIED/DOE
LANL RC

COPIED/DOE
LANL RC

Object of the Experiment:

This project is designed to measure the free-air over-pressure versus time, at a number of different known altitudes and distances from an atomic bomb explosion. Data on the attenuation of a shock wave in a non-homogeneous atmosphere will be obtained to aid in the determination of safe (to flight crew personnel) procedures for aircraft delivery of high yield atomic weapons, and to verify (or deny) presently available theoretical approximation methods. In addition, free space thermal measurements will be obtained, under the conditions of severe reflection or absorption (due to cloud coverage) which may exist at shot time.

The effect of the ambient pressure and temperature gradients on a passing shock wave is almost completely unknown. Theoretical discussions of the effect exist, but there are no reliable experimental observations to test the resultant approximate theories. Such experimental data as do exist suggest that present theories are inadequate. The effects may be significant in determination of the optimum height of burst,* particularly for bombs of very large energy release. There is also an obvious application in the determination of minimum safe ranges and altitudes for dropping aircraft.

Method and Procedure:

A. For this project, the general plan of operation will be to obtain pressure and thermal measurements at twelve points along a radial line from the bomb - extending from the shortest range at which data can be obtained to approximately the operational range for manned aircraft. Twelve parachute-suspended canisters will be dropped on each shot, from two B-29 aircraft flying at approximately 32,000 feet. The altitude of the canisters at shock arrival time will vary from approximately 10,000 feet for the nearest to 30,000 feet for the most distant. The twelve instruments will be divided into two groups, one to give useful data in the event of a low yield and the other adjusted for documentation of a high yield. The two B-29's will each deploy six canisters, in such a way that a maximum of useful data will be obtained should either of the planes fail.

B. Each canister will contain a pressure sensitive element, a thermal sensing device, and a telemetering transmitter - it will be approximately 8 feet long, 14 inches in diameter, and will weigh 275 pounds.

* In the sense of maximizing the area subjected to a given peak pressure.

COPIED/DOE
LANL RC

The position of each canister is to be determined by an electronic system known as MOTS (Multiple Object Tracking System), which is being developed by the Glenn L. Martin Company of Baltimore, Maryland. There will be two such MOTS installations, one on the southern end of Eniwetok Island and one on Runit Island.

The airborne telemetering system was developed by the Bendix-Pacific Division of Bendix Aviation Corporation. Each canister utilizes three telemetering channels; one for an altimeter, one for a preselected pressure range, and one for thermal radiation data. A separate sub-carrier frequency will be frequency modulated by two additional signals - one from an ambient pressure transducer and one from a differential pressure measuring device. The sub-carrier frequencies are mixed and in turn frequency modulate the radio frequency carrier. The thermal radiation sensing device is a thermocouple (or an array of thermocouples) arranged such that a nearly hemispherical sensitivity pattern is achieved. The omnidirectional characteristic is essential as there is no control of canister aspect. The time constant of the thermal sensing element is to be as small as practical (considering the time available for development of the system) and will be of the order of .08 seconds. The output of the thermal sensing device is to be impressed upon the input of a saturable reactor modulation element of the Bendix telemetering system. The sensitivity of the various sensing elements will be adjusted to allow for the anticipated variation in radiation flux with distance.

The telemetering station consists of receivers, carrier discriminators, amplifiers, and recording instrumentation for each canister. It is planned to have this station on board a ship. Transmission range is 25 to 30 miles.

Remarks:

The system proposed for this project was proved during Operations BUSTER/JANGLE and TUMBLER/SNAPPER, and the instrumentation is almost fully developed. Detailed dropping procedures for the canisters are being established by AFCRC, WADC, and TG 132.4. For KING shot, particular emphasis is being placed on flight-coordination with the strike aircraft.

Object of the Experiment:

The thermal radiation emitted by an atomic bomb represents still another subject that must be thoroughly investigated. In the field of weapons effects, both personnel and materiel can be jeopardized by exposure to the tremendous flux of heat - especially under ambient conditions of low density and/or high visibility. The latter considerations, of course, being advantageous for the use of atomic weapons against aircraft - or disadvantageous if one happens to be using the aircraft as a weapon delivery device. In the fields of weapon design and diagnosis of weapon performance, on the other hand, detailed knowledge of every energy transport mechanism is essential to an understanding of how an atomic explosion actually develops - and thermal radiation acts as a highly efficient transport mechanism under certain conditions.

The experimental projects of Program 8 are devoted to a study of thermal radiation as a "field variable".* This project, in particular, is devoted to documenting the total (integral over time) thermal radiation received at various fixed distances from an exploding weapon. To further clarify the above statements, consider the equation:

$$Q = \frac{FY}{4\pi} \frac{T}{R^2} \qquad (8.1.1)$$

in which:

(1) Q is the total incident radiation, at a distance of R centimeters from the bomb, in calories per square centimeter.

(2) Y is the total energy release of the bomb in calories.

(3) F is the fraction of the bomb's total energy that is in the form of thermal radiation.

(4) R is the distance in centimeters from the bomb to the surface upon which the radiation is incident.

* See "preface".

COPIED/E
LANL RC

(5) T is that fraction of FY which reaches the surface under consideration - usually called the "transmission". A natural extension of this notation is the replacement of T by $e^{-R/\lambda}$ - where R is the same as above and λ is the mean free path* of the radiation for the particular medium (atmosphere) under consideration.

Equation 8.1.1 is not capable of theoretical justification as an exact description of the thermal radiation versus distance phenomenon. It does, however, appear to fit past data reasonably well - which is justification enough for its use in weapon effects planning. The knowledge of how thermal radiation affects things is sufficiently vague that an approximation device (such as the above equation) is quite adequate for the effects people.

The above equation is useful to the extent that we can determine F and T (or equivalently, λ) as functions of Y and the ambient atmospheric conditions respectively. This project is concerned with the determination of Q in equation 8.1.1, as a function of R, for both MIKE and KING shots.

Method and Procedure:

A. Two methods will be employed to measure total incident thermal radiation. The first of these is the conventional ballistic thermocouple technique. The output of an Epply thermopile is recorded by a GE photoelectronic galvanometer. The thermopile is essentially an electric current generator, the amount of current generated being proportional to the heat energy "seen" by the instrument - and a galvanometer is an electric current "sensing" device. Laboratory calibration of such a combination of devices allows the galvanometer reaction to be interpretable directly in terms of calories per square centimeter at the instrument.

The second method involves the use of so-called "black balls". For IVY, these will consist of black containers filled with some liquid - the color black being chosen to maximize heat absorption. The heat-induced expansion will move a diaphragm, and the motion of the latter will be recorded through a stylus linkage on a spring driven revolving drum. Laboratory calibration will again allow the peak expansion of the liquid to be interpreted as so many calories of heat per square centimeter falling on the instrument.

COPIED/DOE LANL RC

* Defined as the distance (in the same units as R) over which the radiation must travel in order to be attenuated by a factor of e. (e = 2.718···, the base of natural logarithms.)

COPIED/DOE LANL RC

B. For MIKE shot, six ballistic thermocouples will be operated - two from the Parry photo tower, two from station 801 on Engebi, and two from station 803 on Biijiri. In addition, "black ball" stations will be placed on Biijiri, Bogallua, Aitsu, Bokon, Kirinian, Engebi, and Bogon islands - and still another will be placed on a piling between Engebi and Bogon (at site Noah, a small artificial island).

For KING shot, six thermocouples will be used - two on the Parry photo tower, two in station 803 on Biijiri, and two mounted on a 12 x 12 foot platform (25 feet high) on Aniyaanii. In addition three "black ball" stations will be established near the north end of Runit. Each "black ball" station will consist of a pressure-tight case roughly two feet square and three feet high, to the top of which one or more balls (6" diam.) will be attached. The case will then be either buried (with the balls protruding above the surface of the ground, of course) or bolted to a concrete emplacement.

Remarks:

The tremendous amount of dust thrown up by a surface burst implies a strong variation of transmission with azimuth angle - and also the possibility of variations along a given radial line. As a result of this, one cannot be certain of adequate documentation of the total thermal radiation with a given number of measuring stations. In any event, the MIKE shot measurements will be characteristic of the weapon design, and of Eniwetok and the firing conditions - and hence may be of little use in predicting thermal effects from thermonuclear weapons in general.

The relatively dust-free light paths from an air burst are conducive to much more reliable documentation, hence the KING shot measurements may well be sufficiently complete and reliable to allow predictions to be made. The results of these measurements, when combined with past work on smaller yield bombs, will make air drop data available over the yield range of 1-500KT.

COPIED/DOE
LANL RC

223

COPIED/DOE

Object of the Experiment:

To the soldier who may be exposed to thermal radiation from an exploding atomic bomb, perhaps the most important single question to be answered is "Can I duck it? - Is it possible to escape a large portion of its harmful effects by jumping behind a tree or rock, etc.?" To obtain the answer to such a question, we must investigate the time dependence of total thermal radiation.

To the weapon diagnostician, the early time dependence of thermal radiation is closely related to the fireball opacity and to the blast propagation near reflecting surfaces. Also, of course, it is important to the understanding of thermal radiation itself as a field variable. As an illustration of the latter, it can be combined with the spectrum versus time data to aid in the documentation of transmission* as a function of energy and atmospheric conditions.

Method and Procedure:

A. At IVY, three methods of measuring total thermal radiation versus time will be used,as follows:

(1) High speed bolometers, having approximately 25 μs time resolution, will be used to cover the period of time from just before to several seconds after zero - when the thermal radiation flux has returned to background values. The bolometer consists essentially of a small piece of blackened platinum wire that is exposed to the thermal radiation source, by means of a rotating chopper wheel, several thousand times each second. As the temperature of the platinum wire changes, its resistance changes - hence it is capable of supplying a signal to an electronic recording circuit, the magnitude of the signal being proportional to the temperature it "sees".

The bolometer assembly for this project consists of two such bolometers connected in push-pull electronically. Connected in this fashion, they generate a 24000 cycle AC signal, the amplitude of which is proportional to the radiant flux incident on the equipment. This AC signal is recorded on magnetic tape, using techniques which allow a dynamic range of one thousand times background (with a linear portion for 600 times background).

(2) Liquid flow meters, having a time resolution of approximately 1 ms, will be used to cover the same period of time as the

* See the discussion of Project 8.1.

COPIED/
LANL RC

bolometer assemblies above. These meters have the advantage of being non-electronic (requiring no timing signals or power), and consist of a rigid chamber filled with an opaque liquid. A quartz window is placed in one wall of the chamber, through which the radiant flux may reach the liquid. This flux heats the liquid, with resultant expansion - and the rate of expansion is proportional to the rate of heating. In fact it can be shown that, to a fairly high degree of accuracy, the rate of flow (escape) of liquid from such a chamber is proportional to the rate at which radiant energy enters the quartz window. For this instrument, the rate of flow will be recorded on a revolving drum.

(3) For very early time coverage (0.1 μs to 100 μs), photocells will be used. These are nothing more than current generators having extremely good time resolution. The instantaneous current generated is a known function of the instantaneous radiant flux "seen" by the cell, and the known function is supplied by laboratory calibration. The current signals supplied by these instruments will be converted to voltage signals, attenuated if necessary, and recorded by oscillographs.

B. For MIKE shot, stations 800 on Engebi and 803 on Biijiri will each contain the following thermal radiation versus time measuring equipment:

(1) Two high speed bolometer assemblies.

(2) Two photocell recorders - one sensitive to the violet portion of the spectrum, and the other sensitive to the red portion.

(3) One or two of the above mentioned non-electronic instruments.

For KING shot, station 803 on Biijiri will be reactivated to take the same measurements as mentioned above for MIKE. In addition, these measurements will be duplicated from the 25 foot tower on Aniyaanii.

Remarks:

Contamination due to MIKE may make station 803 on Biijiri unavailable for KING shot thermal radiation measurements. If this should be the case, the Aniyaanii station will be depended upon for all time dependent total thermal measurements. Such a situation increases the probability of loss of data because of localized cloud cover.

Object of the Experiment:

A complete documentation of thermal radiation as a "field variable" associated with exploding atomic bombs must include studies of the radiation energy spectrum. To the theoretician interested in weapon diagnosis, such information may explain an early phenomenon in the explosion development - or it may explain a connection between thermal radiation and another field variable, such as pressure. To the weapon effects theoretician, knowledge of a bomb's expected thermal spectrum will be an aid in predicting the penetrating power of the radiation - both through air and into more solid substances, such as human flesh.

This project is part of a continuing series of experiments, the purpose of which is to obtain as much information as possible concerning the thermal radiation spectrum associated with various sizes and types of atomic bombs - detonated under a variety of conditions. Both integral (summation over all time) and time dependent spectra will be measured. The relatively high yields expected from the IVY devices should insure a considerable extension of these data with respect to energy release.

Method and Procedure:

A. The classical method for measuring the energy spectrum of a radiation beam involves the use of an instrument known as a spectrograph. This instrument passes the beam through a "spreading" device (prism or diffraction grating) and then directs it to a photographic emulsion. The spreading device deflects each component of the incident composite beam by an amount dependent upon its energy. Hence the beam after spreading consists of a "fan" of smaller beams - each of the latter being essentially monoenergetic. These beams cause "exposure" in the silver halide of the emulsion - hence a dark line on the developed negative is associated with a particular energy level of electromagnetic radiation. The spectrograph record produced by a beam containing many different energies consists of many dark lines separated by lighter areas - the latter being associated with energy levels not represented in the beam.

Calibration of the instrument with known monoenergetic sources allows the experimenter to identify a given line on the record as being indicative of a given energy.

The above outlined technique does not, in itself, allow for time resolution. The record simply gives the integrated spectrum for whatever length of time the composite beam is incident upon the instrument. One way of obtaining the spectrum versus time is to add

COPIED/DOE
LANL RC

230

[redacted]

a shutter and moving film - then operating the spectrograph like a "motion picture" camera. A member of discrete integral spectra will thus be obtained, each covering a short period of time. The time resolution of such a system is fixed by the shutter and film speeds. Another way is to move only the film using no shutters. This technique supplies a continuous strip of spectrum (rather than a series of discrete spectra), each line of which is more or less dense as its length is traversed - depending upon the time variation of that particular energy.

For either of the above methods, timing marks are created on the film as it moves - in order that a particular spectrum can be identified with a given elapsed time from the start of the record.

B. For MIKE shot, moving film spectrographs will be installed at stations 800 on Engebi and 802 on Biijiri. At each of these stations measurements will be taken with two film speeds - one to obtain a spectrum every 2 milliseconds, the other to obtain a spectrum every 2 microseconds. The above mentioned "motion picture" technique will be used for the 2 ms resolution, whereas the continuous strip technique will be used for the 2 μs resolution. Each film frame of the slow speed record will contain 5 spectra. The first four of these are identical in content but with differing exposure levels, ranging from 1 to .03 on a relative scale, produced by the use of three ND* filters. The fifth is that of either a standard intensity source or a standard wave length source - whichever is most useful for calibration under the circumstances. The high time resolution will be produced by forming a 20 micron high spectrum of the source on a film moving at the rate of 25 meters per second. In this fashion, high time resolution is gained by sacrificing the range of intensities that can be covered.

In addition a high resolution of energies will be obtained on a integral spectrum. The instrument for this measurement will be installed in a small room directly below the photo tower cab on Parry island. Approximately 0.1 Angstrom (A)** wave length resolution will be obtained by using a 21 foot focal length 15,000 line grating in a Wadsworth mounting. The spectrum between 3800 and 8000 A will be formed on a plate 30 inches long, and simultaneously (by means of filter separation) the spectrum between 1900 and 4000 A will be formed adjacent to it. This folding technique, of course, effects a great saving in space.

For KING shot, the above mentioned Biijiri and Parry install-

* See the footnotes on page 3.5.2

** 1 Angstrom = 10^{-8} cm.

COPIED/DOE
LANL RC

231

ations will be activated. The measurements taken from them will be identical to those taken for MIKE shot.

Remarks:

The relatively poor energy resolution obtainable in the high speed spectra makes analysis of them very difficult. As a result, the high energy resolution of the records obtained with the integrating spectrograph serves as an analysis aid. For instance, a group of lines on the high speed record may look like a single blur, yet the position of this blur will allow it to be identified on the integral spectrum record. The energy resolution of the latter is sufficiently great that we no longer have a blur, but a group of well defined and distinct lines.

Object of the Experiment:

In the discussion of Project 8.1, we considered an equation (equation 8.1.1) of great potential usefulness for the prediction of incident thermal radiation versus distance. The use of this equation for making predictions implies that one must know F as a function of yield and T (or λ) as a function of the atmospheric conditions. To obtain the latter functional relationships experimentally, we measure Q as a function of distance (see Project 8.1) and mathematically determine the values of F and T which allow the best "fit" of equation 8.1.1 to the observed data. The value of F thus obtained can be related to the measured yield of the weapon, to obtain another point on the F versus W curve. The documentation of T, however, is much more complicated, since the range of electromagnetic radiation in any medium is dependent upon the energy (wavelength) of the radiation as well as the characteristics of the medium. We therefore must obtain information as to:

(a) The energy distribution (spectrum) of the radiation emanating from an atomic weapon.

(b) The effective range of electromagnetic radiation in the atmosphere, as a function of energy and the atmosphere's ambient conditions.

The primary purpose of this project is to add to the already existent fund of knowledge for (b) above. The secondary purpose is to satisfy an operational requirement - this will be discussed under "Remarks" below.

Method and Procedure:

A. The observation of a known monochromatic light source enables one to obtain data as to the transmission of a particular wavelength in the electromagnetic spectrum over the path from the source to the receiver. Laboratory calibration of the source allows us to determine the actual wavelength and total energy being radiated. Similarly, laboratory calibration allows us to interpret the detector reaction as so much radiation energy received.

A typical known light source for field use consists of a parabolic reflector with a tungsten lamp mounted at its focus. The light from the projector is modulated at 60 cycles per second by a shutter mechanism to make it easier for the detector to distinguish between the primary light signal and "noise" created by scattered light from other sources. A typical receiver (detector) consists of a

LANL RC

parabolic mirror with a photocell mounted at its focus. The current generated by the photocell is proportional to the intensity of light seen, and this current signal is used (usually after amplification) to actuate various types of recording devices.

B. Transmissometer (source, detector, and recorder) assemblies will be operated over several light paths at Eniwetok atoll for IVY.

For MIKE shot, one light source will consist of two 60 inch searchlights with 4000 watt tungsten lamps at their foci. One light will be used, and the other will be on automatic standby (the failure of the first will automatically turn on the second). The 60 cycle modulation will be produced by rotating a sector disc between the bulb and the mirror - 100% modulation being obtained. The searchlights will be mounted approximately 100 feet above sea level on the Parry photo tower, and the associated receiver will be on Elugelab - the latter consisting of a vacuum phototube mounted at the focus of a 60 inch (focal length) parabolic mirror, and its associated recording equipment. A similar set-up will be used between Bogon and Bogallua, with a smaller searchlight (18") source on Bogon. This pair of transmissometer assemblies will monitor the air attenuation along their lines of sight at all times prior to the shot, and they will be made a part of the "go-no-go" system in the firing circuit.

For KING shot, an attempt will be made to measure air attenuation between bomb zero and the thermal stations on Parry (photo tower), Aniyaanii, and Biijiri (station 803), until some few hours prior to the shot. A helicopter will be used, if possible, to hold the light source at the proper position.

Remarks:

For MIKE shot the success of Programs 2 and 3 is dependent upon good air transmission of light at shot time. This is considered to be sufficiently important to warrant a postponement of the shot if localized rain conditions cause the transmission to drop below prescribed values ($\sim 20\%$). Such a postponement, if necessary, will be made automatic by the following circuitry: When the current signal generated by the detector phototube (at either Elugelab or Bogallua) falls below the prescribed value, and stays below for 20 seconds, a relay will be opened. When it rises above the prescribed value, and stays above for 20 seconds, the relay will be opened again. The firing circuit is such that this relay must be open for the bomb to be detonated. The twenty second delay period is included so that a highly transient disturbance to the light path (such as a bird flying in front of the detector) will not actuate the relay.

COPIED/DOE
LANL RG

241

[redacted]

Object of the Experiment:

This project is designed to determine, in free air at altitudes significant to delivery aircraft, the thermal radiation intensity as a function of time, and the maximum associated radiation-induced aircraft skin temperature. Such information is essential to studies of safe aircraft delivery procedures.

Method and Procedure:

The maximum skin temperature of the B-36D and B-47B aircraft of Project 6.10 will be determined with skin patches - located on the inside surface of the skin. Thermocouples, properly located for representative measurements, will also be used. The temperature as a function of time will be correlated directly with the thermal radiation intensity measurements made with a directed phototube.

Attenuation measurements will be made over a two week pre-shot period, using similar equipment in a B-29, to determine the air transmission properties under conditions as nearly similar to those existing at shot time as possible. A strong mercury-arc light source will be operated on or near Elugelab island three weeks prior to MIKE shot and attenuation measurements will be made on a number of days, at about the same hour of the day as proposed shot time. Such measurements will also be made immediately prior to the shot. It is also planned to have a similar light source on Runit island, and as many pre-shot attenuation measurements as possible will be made during the time interval between re-entry into the atoll subsequent to MIKE shot and KING shot.

At shot time the light source will be destroyed, but prior to this it will serve as a point for alignment of the phototube mentioned above.

Remarks:

The attenuation data obtained in Project 8.4 will be of great value in final analysis of the data obtained herein.

243

CONFIDENTIAL

Object of the Experiment:

We have seen in other project discussions that electromagnetic radiation acts as an important energy transport mechanism for atomic explosions. Those projects, however, have been concerned with short wave length portions of the electromagnetic spectrum - heat, light, gamma radiation, etc. It also has been well established that a longer wave length component of the spectrum is radiated, but very little is known about the details of the phenomenon.

Past experimental results indicate that a broad-band radio signal of very high intensity is emanated by exploding fission bombs. The frequency range of the band extends from very low audio (one or two cycles per second) to moderately high radio (~100 megacycle) frequencies, and the total duration of the signal is approximately two seconds.

Naturally, one hopes to take advantage of such a phenomenon in some way. Perhaps it can be used in the field of long range detection, helping us to penetrate the atomic energy security mantle of another nation. Perhaps it can be used to supplant more cumbersome methods of diagnostic experimentation in our own weapon test programs. This experiment is part of a continuing effort to understand how, why, and where this radio signal is generated.

Method and Procedure:

A. The ordinary radio is designed to receive a very narrow band of frequencies at a given time - in order that the user may separate a desired signal from the host of those not desired. Such a "selectivity" is achieved by tuning the antenna system to resonate at a given frequency. Conversely, an untuned antenna (one with no resonant frequencies) is capable of detecting a wide range of radio frequencies simultaneously.

This experiment makes use of such an untuned antenna as its detector, and proceeds to amplify the signal in the normal "radio" fashion. The purpose here is not to drive a transducer, however, but to deflect the sweep of a cathode-ray tube. The amplified signal is fed simultaneously to the vertical deflection plates of several such tubes, each having a different elapsed time horizontal sweep (covering the range of 2 μs to 2 sec., approximately). A number of oscillographs are thus obtained (by photographing the tube faces for permanent records) of the induced signal, each accentuating a different detail.

B. Recording equipment will be operated at Parry island and at Los Alamos, for both MIKE and KING shots.

Object of the Experiment:

This project is designed to determine the effect of an atomic explosion on the ionosphere, with respect to the propagation of radio waves.

Method and Procedure:

A. The effects of atomic explosions on oblique incidence radio signals reflected from the ionosphere and the attenuation caused by the ionosphere layers will, if practicable, be observed. A vertical incidence ionosphere height recorder will be located as near to ground zero as practicable to observe near effects. Other recorders will be located at suitable distances to observe the undisturbed ionosphere for control purposes.

Radio signals from various widely separated transmission paths will be recorded in an effort to determine unusual disturbances which may be correlated with previous projects and experiments. The effect of atomic explosion-induced ionospheric disturbances upon the scattering of radio waves will be observed. Serious disturbances of the ionosphere, with consequent interruption of routine radio communications, have been observed at past tests. This project is devoted to improving our understanding of the phenomena.

B. Several HF sky-wave circuits will be keyed preceding, during, and following the shot. Observations will be made relatively close-in (50-200 miles) to determine the effect of the explosion on the circuits monitored.

Vertical incidence CRPL Type C-3 automatic ionospheric-height recorders will be operated at Parry and Bikini islands. Special recordings will be made on C-3 recorders at existing Army Signal Corps and Department of Commerce ionosphere observation stations. Back-scratcher ionosphere equipment will be operated to sweep the ionosphere azimuth-wise. Field intensity measurements will be made at Guam of WWVH transmissions from Maui, T.H., prior to and during the test.

A simulated practical communications system will be operated as follows:

(a) Transmit on about 3 megacycles at Eniwetok using an antenna with maximum radiation in an upward direction. The transmission will use radio teletype keying and will be on test tape. It will be observed, on a con-

uous basis, at Bikini and other mobile stations in the shot area.

(b) Transmissions will be made in the high frequency band from aircraft 250 miles west of Eniwetok, diametrically opposite Bikini. These will be observed at Bikini and other designated stations.

Observations will be made on long wavelength radio communication circuits originating at Guam, Honolulu, and other locations.

Remarks:

This project will be closely coordinated with Projects 7.1 and 9.3.

Object of the Experiment:

This project will attempt further quantitative investigations of the electromagnetic pulse caused by atomic explosions, recording sufficient data, over a wide band of search frequencies, to support a theoretical study of the phenomenon.

Method and Procedure:

A. Special close-in measurements of the radiated pulse spectrum will be made. In addition, radio receivers and recording apparatus will be employed at various distances to record evidence of the phenomenon, to determine field strength and establish the frequency distribution. Current investigations have been initiated to determine the validity of the phenomenon on theoretical grounds.

B. A spectrum analysis of the radiated pulse will be made on Runit and Parry islands. Observations will be made at Hawaii and Belmar, New Jersey, on 10 kilocycles (using sferics receivers). Observations will also be made at such stations as Adak, Okinawa, Bikini, Kwajalein, Guam, Japan, and Belmar, New Jersey, guarding optimum propagation frequencies.

Remarks:

This project will be coordinated with Projects 7.1 and 9.2. The data obtained herein will be complimentary to that obtained from the radar scope photography in Project 9.4, and each will aid in the analysis and interpretation of the other as techniques for indirect high yield weapon detection.

Officer	1	M-30	K+5
Enlisted	5	M-30	K+5
Civilian	2	M-30	K+5

Support Required:

(1) Utilization of Project 6.10 aircraft, as well as any other aircraft within sufficient range and with adequate airborne radar equipment.

(2) Four Bhangmeters - to be supplied by EG&G.

DECLASSIFIED/DOE
RC

Object of the Experiment:

It is planned herein to evaluate components of the IEDA which is installed in aircraft scheduled to participate in Projects 6.10 and 8.5.

Method and Procedure:

A. Photographs of radar scopes will be made during the atomic explosions, and a detailed analysis will be made of the value of this technique as a measure of bombing accuracy, bomb damage, and weapon yield.

B. The basic radar equipment of the B-36D, the B-47B, and any available B-50's and B-29's will be utilized. These equipments are either complete AN/APQ-24 radar systems or APS-23 radar sets, the former incorporating the latter as part of the system. The response of the radar sets to each detonation will be observed and photographed on 35 mm film using standard O-15A camers (~15 frames/sec).

Indications of actual burst height and circular bombing error are to be obtained from the PPI presentations. In order that yield estimates can be obtained shortly after detonation (for correlation purposes), four Bhangmeters will be carried - two in each aircraft. The latter are described under Project 3.6.

Remarks:

1. Any radar sets and cameras equivalent to the above mentioned types that are airborne and within 50 to 75 miles from Eniwetok should be turned on and film should be made available to and later collected from each.

2. This project is a continuation of similar test projects conducted at GREENHOUSE, BUSTER-JANGLE, and TUMBLER-SNAPPER. Radar scope data is also available from CROSSROADS, SANDSTONE, AND RANGER. It is proposed that all these data be compiled and be the basis for a continuing Air Force study of this indirect bomb damage assessment method.

[redacted]

CONFIDENTIAL

Object of the Experiment:

This project is responsible for supplying all timing signals required by the IVY experimental program, and for supplying the firing pulse to the detonators of the MIKE shot weapon. Having such responsibilities, its most serious problem is that of maximizing the reliability of its equipment - a most perplexing problem indeed when one considers that Eniwetok atoll must be completely devoid of personnel for MIKE shot.

The importance of reliable timing signals for a complex experimental program of this type seems obvious. In fact, no exaggeration is involved in the statement that the success or failure of many experimental projects is heavily dependent upon their receipt of accurate and dependable pre-shot timing signals. Most measuring devices need to "get ready" just before they take a measurement - and many such devices need stopping before they try to measure too much. Timing signals are used to solve such problems.

Method and Procedure:

A. Consider an imaginary experiment station, S, which contains an assembly of experimental equipment, E. E is to be used for some measurement during an atomic explosion, and its proper operation depends upon the following sequence of events:

(a) 30 minutes prior to zero time an electric motor must be started.

(b) 5 minutes prior to zero time a voltage must be applied to the plates of a condenser.

(c) 1 minute prior to zero time the protective cover of a lens must be raised.

(d) 1 second prior to zero a shutter must be opened.

(e) At zero time the condenser must be discharged.

(f) 1 second after zero the shutter must be closed, the protective cover lowered, the voltage removed from the condenser plates, and the motor stopped.

The experimenter builds E in such a way that the closing of a switch is sufficient to cause each of the above to take place. He

[redacted]

COPIED/DOE
LANL RC

...then supplied with five relays (by those responsible for timing) ...h can be installed in S. The relays furnish the above mentioned ...ches for E, a separate relay being used for each circuit which re... its switch to be closed at a different time. Signal wires ex... from each relay to the nearest distribution station of the timing ...tem - which serves a number of experimental stations in addition ...S.

Each distribution station contains one relay for each time ...al available in the system - the closing of which actuates every ...perimental station relay intended to be closed at that time. Signal ...es extend from each distribution station relay to a corresponding ...tch in the central timing station. The latter is arranged to be ...rated either by hand or by a mechanically driven cam.

As an example, then, the sequence of events at 1 second prior ...zero is:

(a) The 1 second switch in the central timing station is closed - by a motor driven cam in this instance. This allows a signal to pass along the 1 second "line" to all distribution stations, where

(b) All 1 second distribution station relays close. This allows current to flow in the 1 second lines leading to experimental stations, where

(c) All 1 second experimental station relays close. This is the final desired result, and, in the case of E above, the shutter will open.

The above outline is perhaps over-simplified, but it will ...rve to identify the components in the IVY description which follows.

B. The timing signals which past experience has shown will meet ...e requirements of most experimenters are as follows:

Two of the master switches are actuated by manual push buttons, and the remainder by an automatic sequence timer. The automatic sequence timer (or cam sequence timer) is a precision device driven by a synchronous motor. The timing cams operate mercury master switches in the proper sequence. For a tower shot, a sequence-start button (manually operated) places the cam timer in operation, and the timer shuts itself off after opening all the signal circuits after zero. For an air drop, a radio tone signal is interrupted at the time of bomb release, and controls the actual start of the cam timer.

nly

relays

Power to actuate all relays is supplied by batteries. In every case, the batteries are located in the station from which the signal comes - that is, the power to actuate the experimental station relays is provided by batteries located in the associated distribution station, etc.

All relays are type DN-11 railroad relays, which can operate on as low as 7.5 or as high as 100 volts. The operating time is essentially constant for voltages across the coil in excess of 25 volts. Four double-throw switches are available on each relay for the experimenters use. Two of these switches are rated at 10 amperes, and the remaining two are rated at 4 amperes.

Each relay circuit contains a monitoring milliammeter, in order that faulty operation of the circuit may be diagnosed. The criteria for meter location are identical with those mentioned above for battery location.

The fundamental limitation on the total number of basic time signals is the availability of lines from the control station. Since it is not feasible to string several miles of line for one additional time, the practice is for an experimenter to receive a standard signal and construct a delay line which will adapt it to his individual needs.

COPIED/DOE
LANL RC

For an air drop, uncertainties in the release time and time-of-fall force all signals to be given with respect to predicted zero - and actual zero may vary from predicted zero by as much as 1.5 seconds either way. Thus no signal can be expected to exhibit an accuracy with respect to actual zero of better than ± 1.5 seconds. Signals given prior to release time (for example, a -15 minute signal) must obviously be given without knowledge of what the actual precise release time will be. It is quite possible for conditions on the ground or in the plane to delay, or cause an abort of, the planned bomb run. Approximately 25 minutes are required for the plane to make another run - hence such an eventuality will delay zero time by that amount. The practical significance of this is that batteries (for instance, a filament supply) that are turned on prior to expected release time should be capable of supplying current for the time necessary to make one or two extra bomb runs.

For pre-shot test purposes in the field, a practice (or "dry") timing signal run is made twice each day - with zero times at 1000 and 1500 hours local time. An experimenter receives any or all of these "dry run" signals, by his request only. Reliability considerations, of course, dictate his use of a maximum number of dry run signals.

C. In addition to the above system, "Blue Boxes" are available to those experimenters requiring them. The Blue Box is a device which responds to a very fast-rising (in intensity) light signal - and hence to the initial bomb light but not to extraneous sources. Its response consists of suppling either or both of two signals. The first of these is a voltage pulse rising to ~200 volts within 100 μs after zero, and holding at ~100 volts until manually reset. The second is a relay closure which is completed within 2 ms after zero. The relay includes one double throw switch, the contacts of which are rated at 2 amperes. The Blue Box is self-contained and weather proof. Models are available for both standard (110 volt) AC power line and battery operation.

D. Everything we have said thus far applies to timing systems in general, and only one restriction has been implied - the existence of a man at the central timing (control) station to actuate the manually operated switches. For MIKE shot, this restriction cannot be satisfied since the atoll will be completely evacuated - hence an additional link will be required in the system. The link will be supplied by radio control, and television monitoring, of the Elugelab central timing station from the "Estes" in the evacuation fleet. For details of the radio link operation, the reader is referred to the Project Officer.

COPIED/DOE
LANL RC

E. The possibility always exists that experimental conditions will be such that a shot must be stopped and delayed. For air drops, radio contact is maintained between the control station and the dropping aircraft - and a verbal order to the bombardier can prevent release of the bomb if given early enough. For surface shots, a master disconnect switch is included in the system to allow manual stoppage after the sequence timer is actuated.

In addition, for surface shots, one wishes to allow for the necessity of a shot stoppage that can not (or need not) be subjected to the vicissitudes of human reaction. Two examples suggest themselves:

(a) If something untoward happens less than a second before zero, it may well be too late for a human to find out about it - or to decide what to do if he does find out - or pull the switch if he decides.

(b) Certain eventualities are so serious that their occurrence does not require a last-minute decision. If they do occur, the shot must be stopped.

One solution to the problem implied by these examples is the inclusion of one or more automatic master disconnect switches in the firing circuit. Such a system bears the name "go-no go", and will be included for MIKE shot. The discussion of Project 8.4 describes one of the go-no go installations. Another will be supplied by the cryogenics system.

F. Firing signals originate in the control station in the same manner as the cam timing signals, a separate "zero" cam being used. The master disconnect switch, and the remainder of the firing circuit, is isolated from the timing system for safety's sake.

COPIED/DOE
LANL RC

[redacted]

Object of the Experiment:

In the discussion of Project 10.1, we mentioned the use of a cam-driven sequence timer to actuate the majority of the timing signal master switches. We also mentioned that, for an air drop, the sequence timer is triggered (started) by the interruption of a radio tone signal when the bomb is released. This project is responsible for furnishing the starting signal to E.G.&G.'s sequence timer - in order that the complex timing-signal system described previously may be put into operation. Reliability is the most important boundary condition (to the design and operating techniques used herein) implied by such a responsibility.

Method and Procedure:

A. Knowledge of the objective to be achieved by this experimental project makes the basic method of achievement obvious. Prior to the release of the bomb, a radio tone signal is transmitted from the dropping aircraft. When the bomb leaves its shackle, this signal is interrupted. The line which supplies power to the sequence timer contains a relay-actuated switch, the relay coil being connected to a radio receiver which is tuned to detect the tone signal. As long as the tone signal is being transmitted, the switch is held open; the interruption of the tone, however, allows the switch to close. The latter starts the sequence timer and "the die is cast". The equipment duplication techniques, used to augment this basic method (see below), are indicative of the striving for reliability.

B. Two transmitters (transmitting on different frequencies) will be operated in the dropping aircraft, a normally-closed switch being located in the "ground" line of each (S_1 and S_2). These switches are opened (by remote control, utilizing sealed micro-switches) when the bomb is released. Two relay-actuated normally-open switches (in series) are located in the sequence timer power line (S_3 and S_4), - each relay coil being connected to an associated receiver. Each receiver is tuned to the frequency of one airborne transmitter.

The opening of S_1 and S_2 interrupts both tone transmissions. This in turn causes the receivers to pulse their respective relay coils, closing S_3 and S_4 - which allows current to flow to the sequence timer. The series connection of S_3 and S_4 implies that both tone signals must be interrupted before the sequence timer can start - hence the failure of one transmitter or one receiver cannot cause the timer to be actuated prematurely.

The above is a highly simplified representation of the equip-

(3) Minor use of laboratory and shop facilities ashore.

COPIED/DOE
LANL RC

COPIED/DOE
LANL RC

[redacted]

Object of the Experiment:

Although many water depth soundings have been made in Eniwetok lagoon and in the deep ocean water outside the island ring, the configuration of the close-in oceanside profile of the reef is unknown. Because of the expected magnitude of MIKE shot, there is some possibility that the reef may be shattered and breached in the vicinity of the shot island. It is therefore important that the reef configuration be determined before the shot. Such soundings will also provide information necessary for possible model studies of the atoll, to aid in the interpretation of shot-time measurements.

Method and Procedure:

The Navy Hydrographic Office has agreed to make the necessary soundings. The method employed will be a modified acoustic sounding system, whereby a vertical "fan" of acoustic pulses will be directed against the ocean side of the reef, the echoes being recorded by photography of oscillograph traces. The work will be done from the COCOPA (ATF-101), supported by a 42-foot boat for close-in measurements. Detailed sounding profiles, to a depth of several hundred fathoms, will be taken at 500-yard intervals for a distance of five miles either way from Elugelab and at intervals of about one mile for the remainder of the reef perimeter. This work will be accomplished during June, 1952.

(2) Logistic support within the atoll.

(3) Occasional use of heavy equipment such as tractors, bulldozers, trailers.

(4) Support from Task Group 132.2 consisting of 15-man team (to handle high explosives) and approximately 10 radio operators.

COPIED/DOE LANL RC

COPIED LANL RC

Object of the Experiment:

Predictions as to the ground shock at any given distance from an explosion may be based on scaling laws, which have in turn been based either on theoretical assumptions or on actual measurements for a series of shots of different yields. For a particular geological setting measurements in situ must be made. It was therefore decided to make a series of ground shock measurements at Eniwetok. Such measurements can serve as a check on predicted scaling laws and also as a measure of ground shock attenuation under the particular sub-surface conditions at the atoll.

Method and Procedure:

A series of scaled shots for ground shock measurement were made at Eniwetok during March and April, 1952. The high explosive charges for these consisted of a combination of Composition C-2 and Tetrytol. Five shots were fired, these being the equivalent of 1, 5, 10, 15 and 20 tons of TNT.

The shots were arranged in a "beehive" configuration, the base of which was placed at the saturated sand level on the shoreline of Elugelab near proposed MIKE zero point. Motion pictures of each shot were taken, for a study of wave action.

Seismic recordings for ground shock measurements were made at five stations around the atoll, with seismographs provided by the U. S. Coast and Geodetic Survey. These stations were at San Ildefonso (1200 yards), Engebi (6000 yards), Runit (25,100 yards), Rigili (27,800 yards), and Eniwetok (41,700 yards).

The records of both the seismic and photographic measurements are being analyzed at the present time.

(2) Support by 14-man Seabee team to build drilling platform of Navy T-6 pontoons on Site Mack. Heavy equipment support and some labor help for this team from Holmes and Narver.

(3) Military aid for handling and firing explosives to prepare Site Mack.

COPIED DOE
TAM RC

[redacted]

Object of the Experiment:

Although coral atolls have been studied in one way or another for many years, much is still unknown about their structure. From various indirect evidence it is assumed that the rings of coral islands are built on eroded flat-topped platforms of volcanic origin and basaltic composition. The validity of this assumption has never been checked by drilling through the coral to the basement structure beneath.

Drill holes at selected locations on the atoll will give direct information on the geologic column which cannot be obtained in any other way. Deep drilling will give a direct measure of the depth of coral as well as determining the proportion of sand and rock layers. It will provide information necessary in the interpretation of the seismic refraction survey (Project 11.4) and will give an opportunity for determining vertical seismic profiles by velocity shooting.

Method and Procedure:

A deep-well rotary drill rig of the type used for oil wells will be used to drill two holes, each to an estimated depth of 5000 feet - or into the unaltered basement rock. Continuous samples of the drill cuttings will be taken, and at intervals cores of the rock will be cut for study.

The first drill hole will be near the shot point on Elugelab in order to determine subsurface conditions there before the disturbance created by the shot. The second hole will be drilled from a Navy steel pontoon platform on the shallow coral head (Site Mack) in the lagoon west of Runit. This second hole will provide information on subsurface conditions near the middle of the atoll structure and will be especially valuable in the interpretation of the seismic refraction survey.

It is expected that the drilling will be completed by early July, 1952.

PROGRAM 11

PRELIMINARY GEOPHYSICAL SURVEY OF THE TEST AREA

Project No: 11.4 Project Title: Seismic Refraction Survey.

Shot Participation: Pre-Shot

Sponsor: DOD (AFSWP & ONR)

Project Officer:

Name: J. W. Smith
Address: Office of Naval Research
Washington 25, D. C.

Phone: Liberty 5-6700
EXT. 6-4476

Conducting Agency: Scripps Institution of Oceanography
La Jolla, California

Personnel Requirements in the Forward Area:

	Approximate Number	From	To
Officer	8	M-30	M-1
Enlisted	120	M-30	M-1
Civilian	25	M-30	M-1

Support Required: Erection of high targets for positioning ships up to 20 miles offshore.

COPIED/DOE
LANL RC

271

[redacted]

Object of the Experiment:

In order properly to interpret seismic measurement made in conjunction with high yield weapon tests, the seismic characteristics of the substructure in the region around the shot should be known. Measurements of these characteristics can be made by conducting a seismic refraction survey, of the same type as is used so widely in exploration for oil. In such a survey high explosive charges are fired at one point and the resulting refracted elastic wave is detected by a recorder at a second point. By varying the spacing between shots and recorder, the results can be interpreted in terms of the elastic constants and structure of the underlying rock layers.

Such a survey was recently completed at Bikini by an expedition from the Scripps Institution of Oceanography, and yielded much information indicating a rather complex structure under the atoll. The proposed survey at Eniwetok should yield more significant information because of the additional control provided by the deep-drill holes and experience gained during the Bikini survey.

Method and Procedure:

The refraction survey will be based on the technique worked out at Bikini, and the same group which conducted the Bikini survey will work at Eniwetok.

Two ships will be used, one for firing explosive charges, the second to act as recording point for the seismic waves. Detection of the waves will be by means of a hydrophone trailed behind the recording ship. In such a technique the water is considered as one layer of a multi-layer problem. Furthermore, the known seismic velocity for sea water is used to measure the separation of the two ships.

Measurements will be made along traverses criss-crossing the lagoon, and these will be interpreted in terms of the configuration of the subsurface layers under the atoll. The two deep-drill holes will give positive control for the interpretation of measurements.

Field work for the seismic refraction survey will be completed during the month preceding MIKE shot.

FAMILY COMMITTEE
Minutes of Twelfth Meeting
June 1, 1950

A. Attendance.

The twelfth meeting of the Family Committee was held Thursday, June 1, 1950 at 1:15 in Room B-117. Since the items on the agenda were not finished during this session, the Committee appointed a substantial subcommittee to continue in session throughout Friday, June 2 and Saturday morning, June 3. The entire Committee reassembled on Saturday, June 3 at 1:15 P.M. in Room B-117. The report rendered below is a composite of these sessions without regard to chronological order. Those present during the sessions were:

H. M. Agnew	J. M. Keller
H. V. Argo	E. Konopinski
N. E. Bradbury	D. P. MacDougall
H. Bradner	J. C. Mark
J. C. Clark	W. E. Ogle
F. de Hoffmann	F. Reines
D. K. Froman	L. B. Seely
R. W. Goranson	B. R. Suydam
A. C. Graves	R. F. Taschek
E. F. Hammel	E. Teller, Chairman
M. G. Holloway	J. A. Wheeler
E. R. Jette	H. F. York

B. Minutes of the Eleventh Meeting.

The Committee unanimously adopted the minutes of the Eleventh Meeting reported in ADWD-141, with the following corrections:

(1) On page 4, the third line from the bottom, the new sentence should start: "A time $\tau/2$....."

(2) On page 6, line 11, change the figure 60' to read 60".

C. General Problems Concerning X-ray Experiments.

Graves opened the discussion by presenting the Committee with a series of questions which had to be answered in the near future in order to proceed with the planning of the X-ray experiment. These questions were the following:

1. What spots are to be measured.

2. What quantities are to be measured and with what precision.
   (a) Is the radiation black body? i.e., what frequencies must we measure?
   (b) Time and temperature range for each spot.

RESTRICTED DATA
This document contains restricted data as defined in the Atomic Energy Act of 1946

3. Interpretation of data.

(a) Is there a pip in x-rays?

(b) [redacted]

(c) [redacted]

Bearing these typical questions in mind, the group proceeded to a discussion of separate items involved in the X-ray experiment. In the course of these, the above questions were answered in Sections D through F below; except for question 3(b).

[redacted] Rather, any results will be more in the nature of supporting arguments in answering such a question.

DOE b(3)

[redacted]

DOE b(3)

[redacted]

(γ) Deviations of the temperature distribution from a black body spectrum.

(δ) Information concerning the high-energy x-rays emanating from the DT mixture when it goes.

D.

DOE b(3)

The problem that was considered was the radiation distribution in a slab of thickness S where the temperature at the inner surface is denoted by T_o and the temperature at the outer surface is denoted by T_s.

DOE b(3)

The other curve on Figure 1 shows the results of an equilibrium calculation.

DOE b(3)

It will be noted that this curve does not differ radically from the one for the first radiation breakthrough.

DOE b(3)

It should be noted that all the above calculations and formulas 1 and 2 are based on analytical fittings for the opacity data. These formulas have less accuracy than one can eventually hope for in these relations if one uses numerical integrations from the actual calculated opacity points that are now known.

[redacted]

It would, however, be desirable to have a "transparent spot" somewhere in the wall. Such a spot, which would be more transparent than the wall itself, would have the advantage that radiation would break through at an earlier stage. Thus, one could observe phenomena at an earlier time and moreover the original temperature distribution is not likely to be so distorted as that which comes through the main part of the wall at a slower rate. We shall return at a later time to a further discussion of one or more transparent spots.

[redacted]

It was agreed to refer this problem to a committee consisting of Konopinski, MacDougall and Taub, and to request them to report to the Family Committee what solution they have adopted.

[redacted]

DII. Number, Type and Location of Spots.

Teller reminded the Committee of the dual function of the X-ray experiment, to serve as

a. A diagnostic experiment.

[redacted]

b. An engineering experiment.

[redacted]

Point of view b should not be sold short. Taschek remarked that, on the other hand, point of view a would gain added weight if the experiment should turn out to be a failure and the DT would not go. As a matter of

[redacted]

Hence a second scope has been added so that there is some possibility of detecting this distortion.

[redacted]

Because of the experimental difficulties involved, no detecting method chosen is likely to be fool-proof. Thus it would be advisable to have two parallel detecting methods employed (the particular ones favored at present are described in Section F below). Hence in order to buy this amount of insurance we must essentially double the number of detectors and scopes. Thus the total number of detectors is 10 and the total number of scopes 16. To this we must add three scopes for intercalibration of timing and one scope for a timing tie-in with other experiments such as DINEX. In addition, it would be valuable to run a blank detector and ~~blank scope so that we finally end up with the following numbers:~~ [redacted]

2. Transparent spot looking at DT. Such a transparent spot would yield diagnostic information directly. Super engineering information could be derived from it. [redacted]

Such high energy radiation will have a comparatively long mean free path and some of it could pass directly from the DT through the transparent spot--which is the reason for aiming the spot at the DT. [redacted]

unwieldy. Wheeler raised a word of caution and pointed out that there could very well be some important reason for adding scopes beyond this figure which may show up in the theoretical considerations now being pursued.

In connection with the physical arrangements of looking at the two spots, York pointed out that a one-centimeter radius would seem to be the very minimum so that the x-ray equipment has a sufficiently large area to look at. In fact, the experimentalists would hope that the spots could be arranged to be of considerably larger radius. As will become apparent in Section F below, it will be useful to have the evacuated pipes leading to the spots of as large a diameter as possib

DoE
b(3)

DIII. Time Scale and Shape of Scope Traces.

Do

The question arises of how late a time after this first signal any x-ray record would still be of interest

DOE
b(3

We are indeed interested, however, in times which occur after the DT mixture has burned because of engineering reasons.

DOE
b(3

At the present time it is very difficult to make any predictions about the shape of the scope traces to be expected, but just in order to get some very qualitative feeling a given set of possibilities was sketched.

DOE
b(3

This is a crude guess. It is not certain that the initial rise and the rise due to the thermonuclear reaction will be separated.

E. [redacted]

EI. Number, Type and Location of Spots.

The Committee reaffirmed the decision that the two spots specified in Section F of the 10th minutes of the Committee were to be chosen for the X-ray experiment. [redacted] It is evident that the major use for the measurement of the mockup spot is from the point of view of a diagnostic experiment. [redacted] thus one might try to arrange this mockup spot in further designs in such a manner that it has as little of a covering surface as possible. However, this point is subject to further calculations and is not settled.

[redacted]

EII. Time Scale of Scope Traces.

[redacted]

F. Detecting Schemes for X-rays and Experimental Problems.

Bradner and York reported that about 12 detecting schemes had been under active consideration in Berkeley. Of these, there are two which are currently favored, which are discussed below.

1. "Fluorescence" detecting scheme. Figure 2 shows a schematic view. It is seen that the incident x-rays fall on a given fluorescing target. Secondary x-rays are emitted and counted by phototube detectors. It has not yet been decided whether these detectors will be cathodes with no covering, thus measuring the secondary x-rays directly, or whether they will be covered with a fluorescer in order to increase their efficiency. In view of results obtained by the Stanford group showing that terphenyl has a response time as short as 2 or 3 x 10^{-9} seconds, it is likely that a fluorescer will be used because the smearing of the time signal will not be very worrisome.

2. "Thick K edge filter" detecting scheme. Figure 3 shows a schematic view. The incident beam goes through a thick K edge filter, thus eliminating a certain portion of the spectrum. The spectrum is then narrowed down even further by passing the beam emerging from the K filter through a low pass filter. This low pass filter consists of a series of parallel plates at a very small angle to the beam (or the order of 1:600). X-rays which strike

one of the plates are totally reflected and if they are of the right energy will be reflected another time from the adjoining plate so that they fall upon the detectors. Recent experimental information from Kirkpatrick at Stanford shows that it is experimentally feasible to manufacture such low pass filters.

Clark expressed a preference for methods on which more experimental information is already available. According to his view, a differential method with measurements behind several consecutive K edge filters might be preferable. While this method suffers from the fact that it relies on small differences of large intensities, it has the advantage of tying in closely with older laboratory methods. York and Bradner reported that this method had been considered and that their method number 2 is actually a modification of this idea.

[redacted]

[redacted] It was agreed that some adaptation of the scheme described in Figure 2 of the Tenth Meeting such that the x-ray pipe would be considerably wider would be acceptable. Figure 4 shows such a modified layout where the x-ray pipe is as wide as the spot to be examined.

[redacted] Rather accurate corrections for the radiation leakage can be applied as long as the gap is so small.

[redacted] It was agreed that this would be preferable from the point

of view of heat conduction and no objection was raised to it from the point of view of x-ray transmission. This question will be discussed on June 22. Figure 4 shows one pipe for the DT spot and a corresponding pipe to be provided for the mockup spot. This scheme could of course be modified to permit one very large pipe to cover both spots and to have it branch into two pipes several meters below the spots.

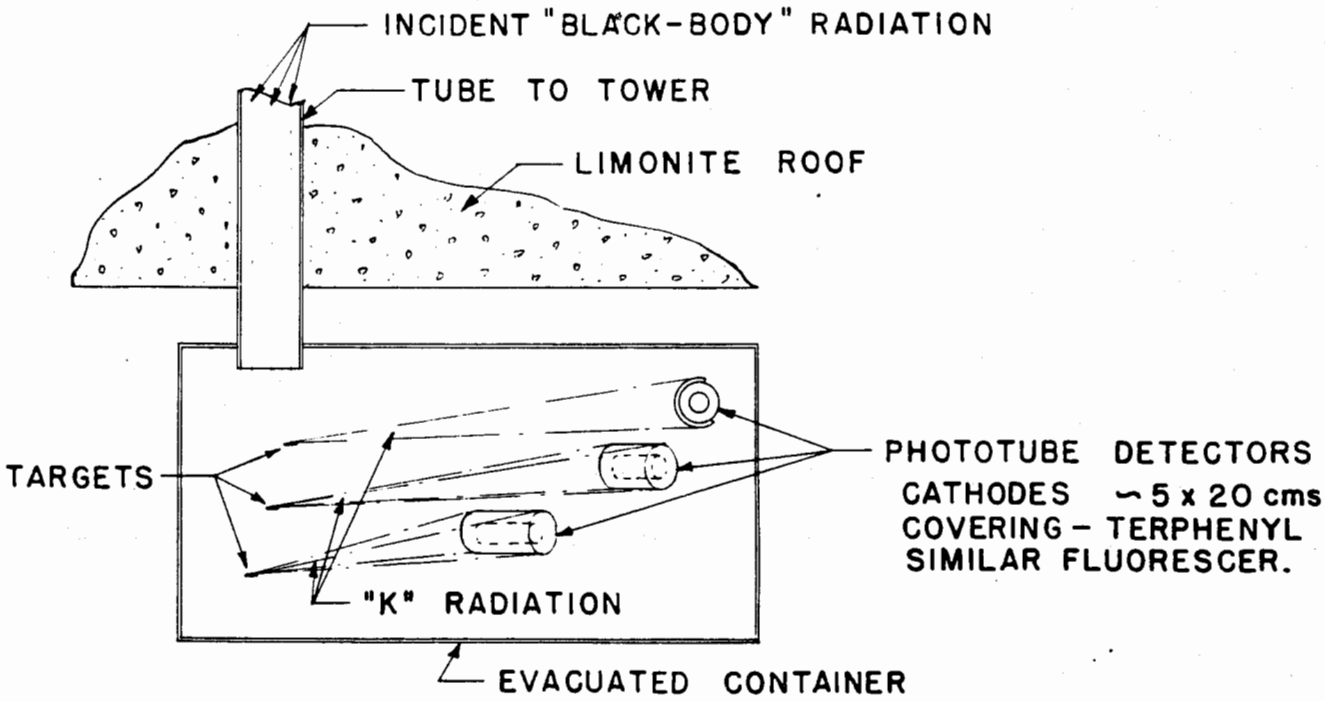
DOE b(3)

However, to date no experiments have been provided for to give information about such an incipient reaction.

DOE b(3)

Such a step would of course be investigated in the tests following those of the Spring '51.

DOE b(3)



G. Next Meeting.

The next meeting which is to take place on Thursday, June 8, will examine the Argo-Agnew report on neutron experiments. Agnew, Argo, Hall, King, Ogle, and Reines are to be invited to this meeting. A report on the Hippo calculations will be given.

D. B. Hall	E. Teller, Chairman
M. B. Holloway	

B. Minutes of the Twelfth Meeting.

The Committee unanimously adopted the minutes of the Twelfth Meeting reported in ADWD-146, with the following additions and corrections:

(1)

DOE
(3)

(2)

C. TENEX.

Agnew gave a summary of the conclusions which had led him and Argo to report favorably on the possibility of performing TENEX for the Spring '51 tests. (These arguments are outlined in detail in ADWD-142.) It was estimated that about two scopes would be required at both stations with possibly some more scopes as a timing tie-in. The scope figures are here reported in order to give an indication of the order of magnitude involved. The distant station is needed to measure the energy spread due to temperature in the 14 mev neutrons. The close station establishes the fact that the actual DT reaction occurred in a time short compared to the time signal in the distant station. The low number of scopes, in spite of the large ranges to be covered, is due to the fact that soft scopes, that is scopes driven at low voltage, will suffice for the time resolution required in this experiment.

It was reported that most likely the detecting chambers in the TENEX experiment would be of the hydrogen recoil type rather than fission chambers since in the former case one can get many more atoms per cm^2 so that the

reiterated a statement he had made in previous meetings that at the present time all information concerning crystal response could only be put into the class of "guesswork" because the experiments concerning these crystals were still in progress at various laboratories throughout the country and the results still seem to differ by large factors. Moreover, Taschek remarked that such crystal response would have to be studied under large current drawing conditions.

It was agreed that if the fall time were larger than one shake, then the advantages with respect to timing of FLUNEX over TENEX would be nil. However, if the effective fall time is less than or about a shake, then FLUNEX will give information about the crucial induction time in the case of a fizzle, whereas TENEX would not have sufficient time resolution.

Discussion took place concerning the way one would establish a fiducial timing mark for the FLUNEX experiment. Two possibilities present themselves:

(1) Observation of the point at which the curve breaks away from the constant alpha region and comparison with the theoretical time at which this should take place.

(2) An absolute calibration of the number of neutrons falling on the fluorescer by means of comparison with such experiments as ANEX or PHONEX.

It was noted that in the experiment as proposed by Teller, some cables and some shielding of these cables would be necessary, which is a deviation from the originally proposed experiment--not now deemed advisable because of the scattering in air. Reines pointed out that if one only wanted to obtain information in the DINEX experiment concerning the shape of the 14 mev neutrons, without much regard to absolute values, one might be able to eliminate a considerable amount of the shielding required for DINEX. It was noted, however, that in the case only a very small fraction of the DT burned, elimination of such shielding may give rise to difficulties in DINEX, due to swamping of the 14 mev neutrons by neutrons of lower energy, such as 5 mev. In the case of FLUNEX one would have the advantage that the distance at which the crystal is placed automatically insures some time of flight separation between the 14 mev and 5 mev neutrons.

The group then proceeded to try to examine whether in view of the above discussion it should recommend that the FLUNEX experiment was very worth while performing in addition to the other experiments now planned for the Spring of '51. Teller stated that he felt that insurance for the DINEX experiment was definitely needed and suggested that the Family Committee request appropriate people to make more detailed studies in the immediate future to determine the experimental feasibility of incorporating FLUNEX in the Spring '51 tests. He felt that the loss of data which would result in the case of a complete DINEX fizzle would be very serious and that the FLUNEX effort would definitely be warranted unless it proved to be an experimental monster.

Taschek, Froman, the experimentalists present and others felt that the insurance obtained from FLUNEX is not likely to counterbalance the detracting effect that the FLUNEX experiment would produce. In particular, they believe that such an experiment is of considerable magnitude because the experimental data on which it is to be based do not yet exist, and that there is no certainty that they can be obtained in time--at least without disrupting efforts which must proceed on DINEX and other larger experiments now scheduled for the Spring of '51. Graves reported that J-Division would have to know within the order of two or three months whether FLUNEX would be incorporated or not in order to make experimental arrangements at Eniwetok. (The outside time limit would assume that certain construction items on the testing tower and at the bottom of it would be irreversibly frozen and the FLUNEX experiment would have to adjust itself to the given physical conditions.)

The Committee found it impossible to resolve the conflict concerning what scale of possible effort (ranging between a nil and a full-fledged effort) would be recommended with respect to FLUNEX. In view of this, the Committee requested that Graves examine the situation further and, keeping in mind the commitments made at this meeting, make a decision concerning the scope and type of effort which should be expended on FLUNEX. It was requested that Graves report his conclusions to the Family Committee.

UNCLASSIFIED

INTER-OFFICE MEMORANDUM

APPENDIX A

Date 7 June 1950

TO: - The Family Committee

FROM: Emil Konopinski and Roy Goranson

SUBJECT:

DOE b(3)

REF: ADND-3-3

PART I. THEORETICAL CONSIDERATIONS

Presented herewith are the results of discussions in which the following have participated: Teller, Goranson, Mark, Wheeler, Smith, Taylor, Hammer and Konopinski.

DOE b(3)

The types of advantage considered as possible are:

1. The increased H.E. dimensions will result in a greater compression of core and tamper if their mass is unchanged or if their mass is not scaled up fully together with the H.E. dimensions. The greater compression will produce higher central temperatures. This is partially offset, as far as the yield of radiation is concerned, by the greater density of core material which the radiation must penetrate on its way out.

2. The tamper may be thickened.

DOE b(3)

3.

For a more quantitative comparison of the above advantages, Wheeler proposed as a criterion that the quantity

E

should be maximized. Here φ is the undepleted efficiency, which primarily determines the temperature.

DOE b(3)

The second column of the table gives the mass of 25 in kilograms. The third column gives the radius R of the compressed 25 in cm.

DOE b(3)

ρ/ρ_0 is the core compression. φ and φ' are undepleted and depleted efficiencies, respectively. The column headed Y gives the expected final yields in kilotons. The final column lists the values for Wheeler's criterion.

The next two lines deal with models obtained by scaling up all radial dimensions from the first line, so as to keep the same compression.

DOE b(3)

The models of lines 5 and 6 keep the same mass of tamper as obtained in line 3.

DOE b(3)

Calculations at present indicate that this yield will be needed to assure adequate radiation temperatures.

The tamper mass in the line 6 model is the same as in lines 3 and 5

DOE b(3)

The latter model has the added advantage that it

makes the early energy evolution more secure against interruption by the tamper rarefaction. It is the model of line 6, therefore, which is recommended as the result of these discussions.

One qualification upon this recommendation was pressed by Teller.

DOE b(3)

This may constitute a hazard for the observers of the test, for the observation records of the test, or for the sites of subsequent tests. The main argument for the existence of this small chance of an excessive yield is the following: The Hippo calculations lead to much higher yields than were actually observed at Trinity.

DOE b(3)

PART II - DESIGN CHARACTERISTICS

DOE b(3)

The figures are drawn to scale as presently conceived. However, dimensions have been omitted where there exists a possibility that later minor modifications may be found to be advisable.

DOE b(3)

In Table II

DOE b(3)

These figures are compared with the three earlier preliminary design considerations listed in columns 1 to 3 inclusive.

I.B.M. calculations have been made on F-4 and F-5.

DOE b(3)

The implosion of F-4 on 0.7 scale and of F-6 on 0.6 scale have also been studied photographically and by the pin technique. Compressions given in the third and fourth columns are estimated from those calculated for the first two columns.

DOE b(3)

DOE
b(3)

There exists a small but finite probability (perhaps 5%) that the calculated efficiency may be underestimated by a factor of 50% (or perhaps even by 75%).

DOE
b(3)

). It should be pointed out, however, that the pre-detonation probability (a fizzle) is expected to be greater than the probability of an excessive yield.

B. Minutes of the Twentieth Meeting.

The Committee unanimously adopted the minutes of the Twentieth Meeting reported in ADWD-176 with the following correction: DOE b(3)

[redacted]

C. DINEX vs. GANEX.

Dave Hall reported that a meeting on the subject had been held with the NRL group all of Friday, August 25th. These discussions led to the feeling that basically DINEX and GANEX had the same chance of yielding information on the time dependence [redacted] DOE b(3)

There seemed to be weight given to two points in favor of GANEX. The first one of these concerned itself with the fact that the DINEX shield, as previously noted in these minutes, gives rise to interference with experiments such as ball of fire, TENEX, PHONEX and ANEX (up to recently no alternative to DINEX was available so that this interference had to be tolerated; now one is in a position of minimizing this interference in replacing DINEX by GANEX). The second point concerned itself with the feeling that the radio-chemistry would suffer appreciably due to the great amount of lead present in the DINEX shield (this point was cleared up during the course of the present meeting and is discussed further on in these minutes).

RESTRICTED DATA
This document contains Restricted Data as defined in the Atomic Energy Act of 1954. Transmittal and disclosure subject to Administrative and Criminal Sanctions.

In view of the Friday meeting, Hall submitted a possible program for discussion:

1. DINEX effort continued but is cut back to the extent that parts dealing with insuring energy level measurement such as absorber-scatterer measurements are eliminated.

2. GANEX be engineered.

3. At the earliest possible time but not later than January 1, 1951, decide on either GANEX or DINEX but decide at once that no combination of the two should be used.

Considerable discussion ensued concerning this proposal. Krause raised the point that one of the difficulties in successfully planning any program was that connected with the uncertainty of what kind of gadget would be shot.

[redacted]

DOE b(3

Rod Spence was asked to join the group at this point to evaluate the difficulties the DINEX shield would present with respect to the radiochemical program. He was able to report that the difficulties would not be as great as anticipated. In particular, it has now been established that the filter papers would not be clogged--rather the difficulty would arise from the amount of tungsten and uranium contained as impurities in the approximately 500 tons of lead required for DINEX. Spence hopes that it will be possible without too much difficulty to analyze representative samples of the lead used for uranium and tungsten and make appropriate corrections. While this will lower slightly the accuracy of the radiochemical method, it is not believed that this would be a sufficiently strong argument against the use of DINEX.

Krause suggested that it may be advisable to carry on a program which would result in a shot with a cut back DINEX and GANEX (where GANEX also would be kept to its essentials, that is for instance, one would not indulge in the luxury of measuring fission neutrons by GANEX). In this case, the logistic effort would be planned such that DINEX and GANEX jointly would not exceed the logistic effort of the full scale DINEX alone. Clark reported that from the point of view of J Division, it would be acceptable to plan for either DINEX alone, GANEX alone or a combination in the manner just indicated.

J Division could hold up on the decision to build a limonite column for DINEX as late as November 1, 1950. On the other hand, arrangements for the 200 ton tower should probably be made immediately.

Wheeler emphasized that the NRL group should be given as much freedom of decision as possible in view of the fact that they are the group that will actually have to take the experimental responsibility for the success of the experiment. The group strongly supported this view. Fermi expressed the view that possibly the instrumentation of both DINEX and GANEX might lead to too much effort being put into these experiments but agreed that this depended to a large extent on how much NRL itself felt it could carry. Holloway dissented strongly from the majority view and thought that it was too late to introduce a new experiment such as GANEX into the schedule and that one would have to have strong reasons forcing one to include GANEX. He would think it preferable if DINEX were to be instrumented to completion now and the schedule adhered to.

[redacted] DOE 6(2)

Probably the ball of fire would be most strongly affected and TENEX least. In view of the possibility of replacing DINEX by GANEX, it was thus recommended that J Division re-examine the extent of interference of the DINEX shield, particularly because PHONEX and ANEX were currently thought of as rather valuable and simple experiments.

In view of this situation, the following summary was agreed upon:

1. The NRL group should have as much influence as possible in deciding questions of DINEX and GANEX.

2. Re-evaluation should be undertaken immediately concerning the interference of the DINEX shield with the ball of fire, ANEX, PHONEX and TENEX.

3. If this re-evaluation shows that the interference is very considerable, then it is believed NRL may want to concentrate on GANEX and carry along DINEX only as insurance if GANEX should show up flaws.

4. If this re-evaluation shows that the interference is either tolerable or can be circumvented by calibration methods and other experiments then the NRL group would try to reach a decision whether or not to carry on DINEX only, GANEX only, or a combination of the two requiring no more than the original logistic effort envisaged for DINEX.

A. Attendance.

The twenty-seventh meeting of the Family Committee was held Wednesday, November 15, 1950 at 1:15 PM in Room B-117. Those present were:

N. E. Bradbury	M. G. Holloway
J. C. Clark	E. R. Jette
F. de Hoffmann	D. P. MacDougall
D. K. Froman	J. C. Mark
R. W. Goranson	E. Teller, Chairman

B. Minutes of the Twenty-sixth Meeting.

The Committee unanimously adopted the minutes of the twenty-sixth meeting as reported in ADWD-206 with the following corrections:

On page 2, in the sixth line of the first paragraph of Item D, the word "radium" should read "radius".

On page 4, 5.11.2, substitute 3/8" instead of 3.8".

C. [redacted] DOE 5(3)

The Committee discussed memorandum CMR-9-261 from Ed Hammel to de Hoffmann, which is attached to these minutes as Appendix A. [redacted] DOE b(3)

D. Scope of Committee Work.

In line with the discussions reported under Item E of the twenty-sixth minutes, the Director presented his views concerning the scope of the work which the Committee should undertake. Bradbury reiterated that basically his original directive envisaged the Committee to be one that would deal with all the thermonuclear phases of the laboratory program.

UNCLASSIFIED

~~SECRET~~

RESTRICTED DATA
This document contains Restricted Data as defined in the Atomic Energy Act of 1954. Unauthorized disclosure subject to Administrative and Criminal Sanctions.

He recognized that in line with the current laboratory program Greenhouse had taken up almost the entire time of the Committee. It is hoped, however, that from now on the Committee will be able to turn its attention in an increasing manner to those phases of the laboratory program on thermonuclear work that should be undertaken after Greenhouse and to long range questions of achieving any kind of thermonuclear weapon. It was agreed that the Committee should not restrict its attention solely to super-type weapons but that such items as the alarm clock, boosted weapons, etc., should also be examined.

As to the procedural way in which the Committee is to operate, the Director expressed the hope that the Committee would continue to be essentially a "line function" type structure so that the Director could look to it both for direction as well as action in the thermonuclear field.

E. Longer Range Problems.

Teller reported on the status of some current calculations and ideas and these are summarized below.

[redacted] DOE b(3) This has been necessitated by the fact that almost all theoretical manpower available has been needed to make detailed calculations for Greenhouse and because some of the work is, of necessity, shifting towards a more detailed examination of the inverse Compton effect as detailed below.

[redacted] DOE b(3) DOE b(2)

2. Boosted Weapons.

At the moment essentially no effort is being devoted towards the further exploration of boosted weapons. This has come about almost automatically since the lack of theoretical manpower (between that needed for

Greenhouse and that going into ignition and propagation considerations for the super) did not permit this work to be carried on. Since the boosting principle would be of greatest interest for small weapons, it was agreed that the lack of effort on this problem was reasonable until after such a time as small weapons were explored more completely at Greenhouse.

[redacted] DoE b(3)

3. Alarm Clock.

[redacted] DoE b(3)

It is recognized that the volume involved would be quite large since the final yield is determined

by the total volume. It should be emphasized strongly that these estimates of the initial conditions required are exceedingly uncertain.

[redacted]

DOE b(3)

In view of this the possibility of performing machine calculations is being explored. Such a machine calculation would tell one more definitely whether the alarm clock idea was worthwhile and if so in what direction it should be pursued.

3. Aluminum Plug.

[redacted] DOE (C)

In consequence, it would not be desirable to make the aluminum plug out of 24S aluminum. The Committee therefore requested that the aluminum plug be manufactured from 2S aluminum and also that a sample be saved for analysis of impurities.

[redacted] DOE b(3)

After this discussion the following position was arrived at. [redacted] DOE b(3)

A discussion of these items is reserved for January 4 and 11. There follows below a summary of the discussions concerning each item. Hall and Seely presented the status of each experiment.

1. DINEX

It is planned that the experiment cover an intensity range slightly greater than a factor 10^7. This will be done by having two channels record the proton recoils from the 14 Mev neutrons. One channel will only be sensitive to very high signals. Thus it is hoped that the peak from the DT burning can be recorded although its shape will not be known accurately. [redacted] DOE (C)

It will be recalled that the signal is fed from the tower to ground through shielded co-axial cables and NRL is confident that sufficient shielding has been provided. [redacted] DOE b(3)

It would seem that anything greater than 1% burning of the DT should be detected successfully by DINEX. It was estimated that the chance of DINEX performing as expected was rather better than even.

2. GANEX (Note: neutrons were converted into gamma signals by the use of iron GANEX "converters" in Ivy-MIKE shot of1952 according to the film, "Operation Ivy")

It will be recalled that GANEX used natural uranium as a gamma converter. Experiments during the summer indicated that iron would result in a higher gamma conversion. In consequence, NRL presently plans to use 3 cm of iron for the gamma converter. Taschek expressed some doubts concerning the reality of the iron results and it was agreed that it might be useful to consider backing up the iron by uranium or perhaps to replace the last centimeter of iron by uranium.

It was noted that GANEX would not yield an absolute value of the 14 Mev neutrons and that the uranium scheme would therefore not introduce any calibration difficulties.

It is expected that GANEX would successfully record the burning of more than a few percent DT.

3. PHONEX

If fogging of plates by gamma rays can be prevented, PHONEX is likely to give the most reliable single number for the quantity of DT that has burned. Probably this number should be good to ± 15%. This is likely to compare favorably with the results from the n,2n experiment which is not reported upon at this meeting.

4. ANEX

Some trouble has been encountered with ANEX. Activation functions of such elements as sulfur seem to vary sharply over the region of interest (i.e., within a few Mev). This throws some doubt on the interpretation of results that might be obtained.

5. TENEX

There are two stations for TENEX, one at 200 yards, to determine burning time, and one at 1000 yards to determine temperature. It is estimated that TENEX has a better than even chance of giving usable results.

6. X-RAY

Brahner, in cooperation with Jacot, has furnished two figures concerning how the present setup looks. These are attached.

At present each spot provides for two sets of independent measurements. In each case detectors have been so arranged that the difficult effect of lines in the spectrum can be subtracted off in evaluating the results. Theoretical work has proceeded on the interpretation of the iron and combination spot at Berkeley.

Attention has been given to the question of closing up of diaphragms but there is still some danger from this phenomenon.

It should be noted that the experiment can not be "tested" with a dry run.

While it is dubious whether all aspects of the X-RAY experiment will work simultaneously, it is believed that the chance that the X-RAY experiment will give useful information is quite high. For instance, the experiment has now been so designed that even if intensities and temperatures are not recorded properly, quite a bit of information can be obtained from breakthrough times through the iron and combination spot.

F. Next Meetings.

The next meetings of the Committee are to take place on Thursday, January 4, 1951 and Thursday, January 11, 1951.

5. [redacted] The results obtained, which still contain uncertainties due to imperfect statistics with only 1016 neutron samples, agree with the earlier estimates to within about 10%. [redacted]

6. [redacted]

8. Preliminary Planning for an Alarm Clock Test. Mark reported on current thinking in the Laboratory Director's Office on the scheduling and philosophy of an eventual alarm clock test. [redacted]

1) It was erroneously reported in the 15th Minutes that a disintegration cross section of .1 barn was included in these Rand calculations. Actually, a calculation including disintegration of the deuterium has not yet been carried out.

DOE
b(3)

[redacted] The objective should be to test the design of a weapon giving the largest yield consistent with delivery from an existing aircraft or one that will be available at a predictable date.

9. Airplane Characteristics. Some pertinent information on the types of military aircraft that should be considered for delivery of a thermonuclear bomb such as the alarm clock was presented by Agnew and is summarized in the accompanying table.

As a guide to military planning and delivery of a thermonuclear bomb, the following specifications on weight and size have been tentatively proposed: Weight 50,000 lbs; length 20'; diameter 6'. The "compatibility" in the last column of the table is with respect to these specifications.

There are expected to be about 200 B-36 D planes available in 1953-54. The YB 60 and XB 52 will become operational during 1954, with 10 of each in operation. The B-47B is operational at present, though the modifications necessary to carry the 50,000 lb. bomb load are not yet incorporated.

DOE b(3)

DOE b(3)

An expression similar to that used for AC calculations to account for the temperature dependence of opacity:

[redacted]

DOE b(3)

20th Meeting of the Theoretical megaton Group, 1952: radiation flow and heat capacity as function of temp.

Varying the temperature does not help matters because at low temperatures radiation flow and heat capacity each vary about as T^3 so that the time required for heat flow, which depends on their ratio, will be unchanged. At higher temperatures radiation flow varies as T^2 and heat capacity as T^3, with consequent loss.

Bethe, Broyles, and Freeman will prepare a problem for either CPC or SEAC operation which is expected to give a good treatment of propagation along the channel.

7. Experiments planned for Snapper.

J-Division's primary interest is to investigate experimental techniques proposed for the Ivy test.

Zero time would be obtained from an external phosphor.

The streak cameras have, in principle, a 2 shake resolution time but the over-all time uncertainty was expected to be perhaps 10 shakes. Framing cameras with 1/3 μsec resolution will obtain over-all pictures of the gadget.

The uncertainties discussed in the above sections have enhanced the interest of TMG in this experiment. In consequence, during a discussion following the regular meeting, certain modifications of the original design were requested.

Certain other kinds of observations and other observational positions were discussed but no final decisions on these were reached at this meeting. It was first stated that 8 to 10 observational spots was a maximum; it appeared later that by avoiding some duplication this number could be extended if desirable.

Goranson reported on some of the results obtained.

Sweeping Image Cameras

The sweeping image cameras were trained, via mirrors, on the spots indicated as A through J in Figure 2. (2-K is Teller light.) The pipe shields for D and I were evacuated and the others were filled with helium. (It will be observed from the two streak pictures that the luminescence in D and I is quenched by outward expansion of the surface whereas the other spots continue bright from the shocked gas.)

Onset of the Teller light is taken as zero time. This is difficult to determine on some of the streaks. The method used, therefore, was to determine this time where possible and adjust according to the survey data, then use the mean of these values as zero time. The survey assumes the spot to be centered in the 6" diameter mirror and thus there exists a large uncertainty which could amount to 10 shakes. Correction for variation in light path length is not more than 1.5 shakes.

It should be noted therefore that the inferences drawn from these observations are also subject to considerable uncertainty.

32nd Meeting of the Theoretical Megaton Group, June 1952: Hans A. Bethe's treatment of of rise of "Taylor instability" as a mechanism for fuel mixing, when the high pressure gas or fluid from x-ray ablation of the surface of a pusher accelerates/compresses a higher-density solid.

This is in essential agreement with the results obtained at LASL (see 30th Minutes).

6. Investigation of Mixing

If a system is accelerated by a series of sharp pulses, does mixing occur? If this were averaged, one would obtain mixing according to the usual formula. Under what conditions would this be justifiable?

Matterhorn has been investigating this problem and finds that recurrent shocks are capable of giving rise to Taylor instability.

Now

$$A = A_0 e^{\alpha t}$$

where A_0 is initial amplitude and

$$\alpha = \frac{1}{\Delta t} \text{ arc cosh } \left[1 + \frac{g}{2\lambda} (\Delta t)^2\right]$$

where Δt is the time interval between pulses.

If the shocks are close together and λ is large the irregularities in the acceleration are not resolved so that one gets the ordinary expression

$$\alpha = \sqrt{g/\lambda} \ .$$

If the shocks are not closely spaced, then

$$\alpha = \frac{1}{\Delta t} \ln \left[g(\Delta t)^2/\lambda\right]$$

so that

$$A = A_0 \left[g(\Delta t)^2/\lambda\right]^n$$

where $n = t/\Delta t$ = number of shocks in time t.

7. Report on Alarm Clock Design

Nordheim reported on a preliminary design study of an alarm clock now being carried out by ACF. This tentative design of a deliverable bomb will come within the present Air Force limitations of

weight	< 50,000 lbs.
outside diameter	< 62.5"
length	< 20'

[redacted]

DOE b(3)

8. Calculations Required for Alarm Clock Design

The theoretical problems and calculations for final alarm clock design were outlined and discussed by Bethe.

[redacted]

DOE b(3)

A problem which has been investigated by Bethe is that of growth of small amplitude waves for variable density (as behind the radiation front). Long waves are unaffected; for short waves k in the expression

$$e^{\sqrt{gk}\cdot t}$$

DOE b(3)

However, the last figure should be tied down by more study of the effect.

6. Alarm Clock Implosion Calculations

34th Meeting of the Theoretical Megaton Group, July 1952: planned testing of GANEX and TANEX diagnostics at a1953 Nevada based Upshot-Knothole tests, prior to Operation Castle (planned for 1954).

DOE b(3)

The density distribution in this case was obtained from mocking-up SEAC runs.

Relative Effectiveness of a Shallow Earth-Penetrating Nuclear Weapon (U)

Archie V. Farnsworth, Jr.

Computational Physics and Mechanics Division II
Sandia National Laboratories

RESTRICTED DATA

This document contains Restricted Data as defined in the Atomic Energy Act of 1954. Unauthorized disclosure subject to Administrative and Criminal Sanctions

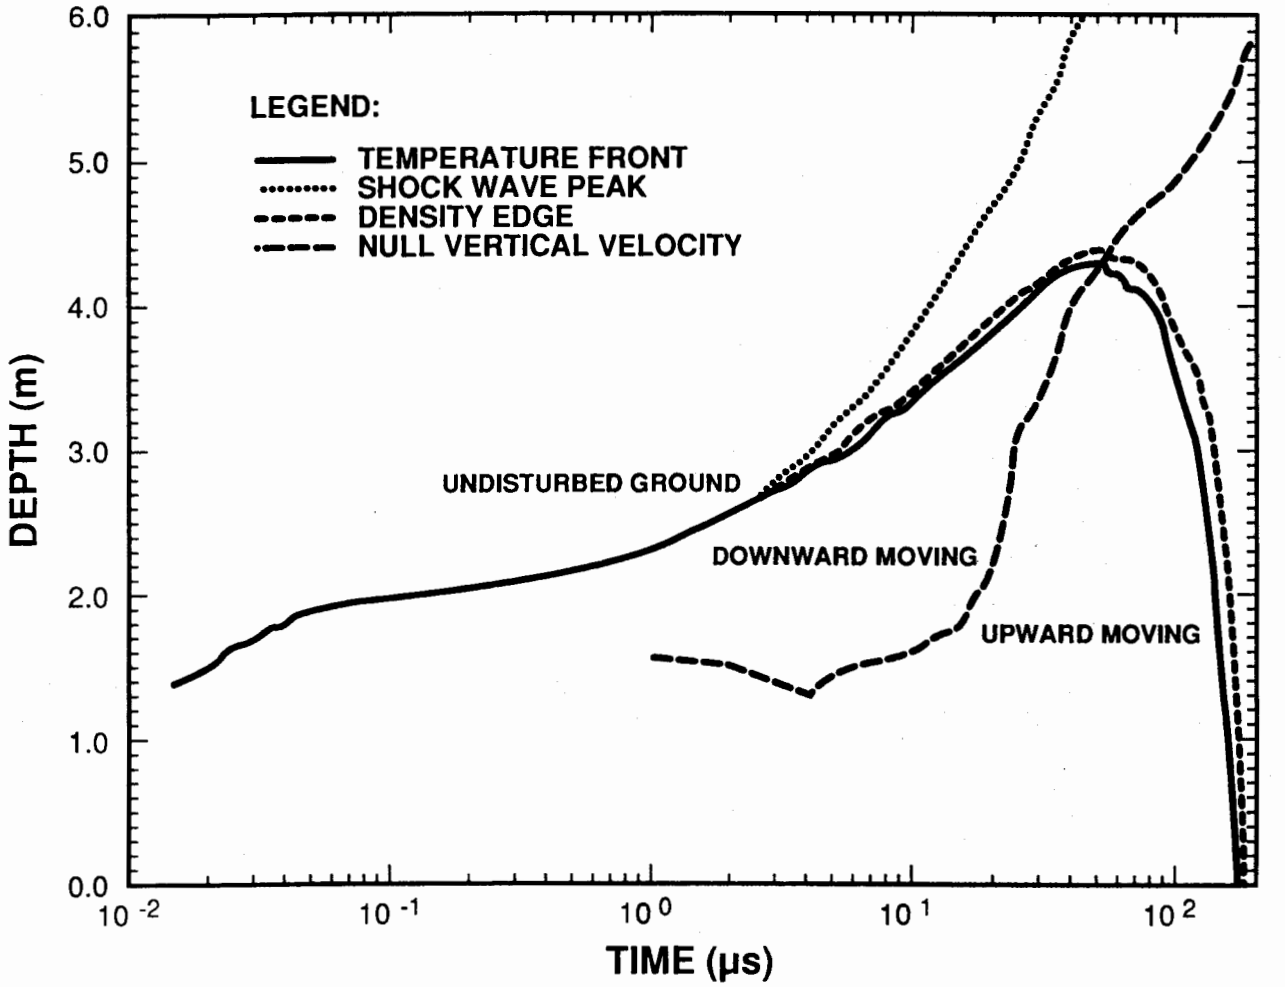

Figure 17: Depth vs. time diagram for phenomenologic features down axis.

[redacted] During this same time interval, the air shock continues to expand under the influence of the warm ejected tuff. The pressure (left) and temperature (right) contours as well as the material interfaces of Figures 19 and 20 show the structure of the above surface phenomena.

[redacted]

In Figure 24, the airblast peak pressure attenuation with range, at several heights, is compared with a reference airblast attenuation curve for a slightly above surface (contact) burst of 250 kT, due to Brode[12]. The lack of smoothness seen in the curves for this calculation results from the late time ejection of higher density, lower temperature, aggregations of tuff, that pass through regions of the grid out of pressure equilibrium

with the surrounding air. The overall comparison with the Brode reference curve, however, is rather good, and suggests that this shallow burst provides essentially half of its energy in airblast effects. It must be remembered, however, that the Brode curve describes an airblast that is driven by the prompt deposition of energy, almost entirely delivered by radiation, at very early time, whereas in the present calculation the energy reaches the atmosphere over a very much longer period of time, largely through the work done by the expansion of heated tuff.

Contours of maximum vertical stress in the ground for this calculation are shown in Figure 25. These contours represent the regions within which all points were subjected to at least the levels of vertical stress noted. The contour quantities are time independent, although they are displayed against the background of a dot density plot of mass density at 0.2 seconds, the concluding time of the calculation. Peak horizontal stresses, peak vertical velocities and peak horizontal velocities are similarly displayed in Figures 26-28, respectively.

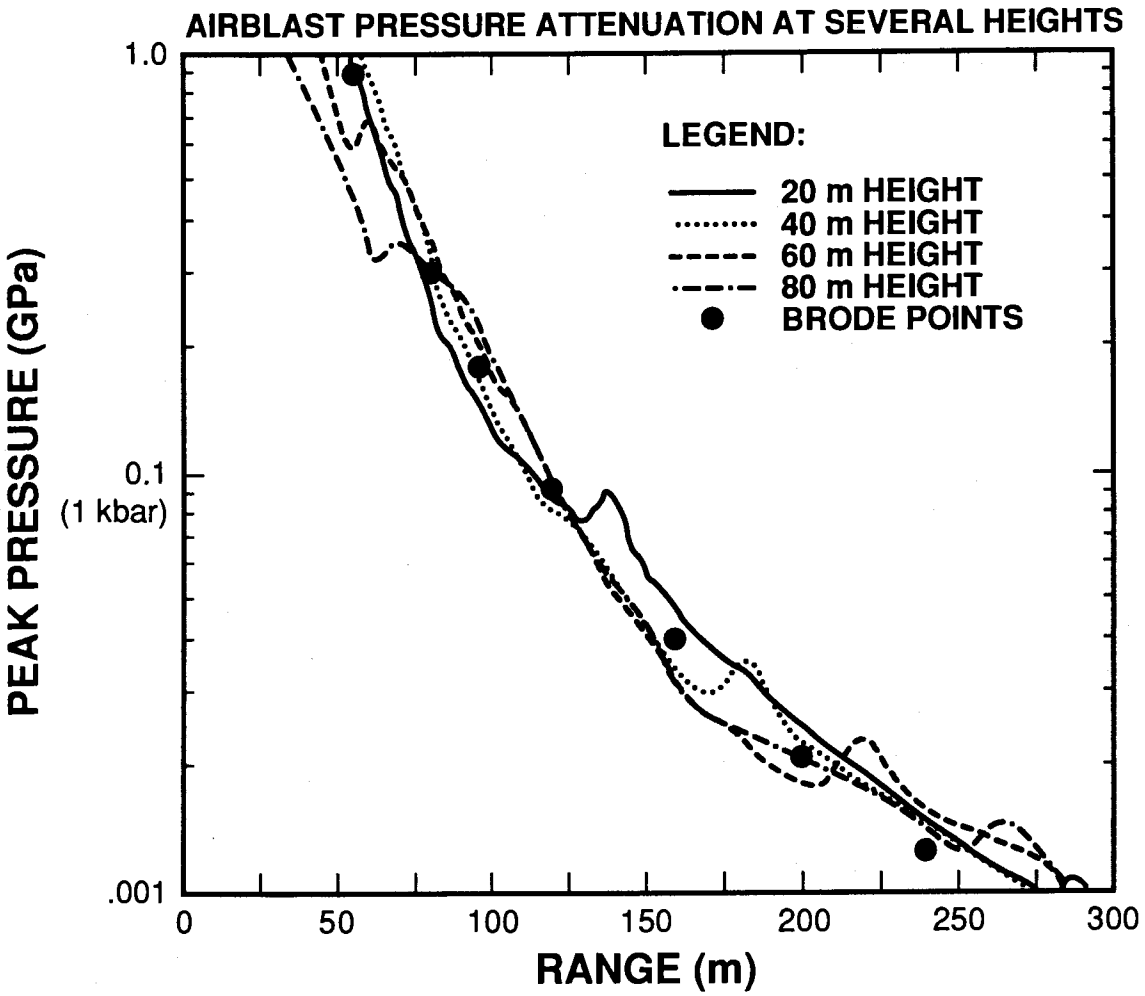

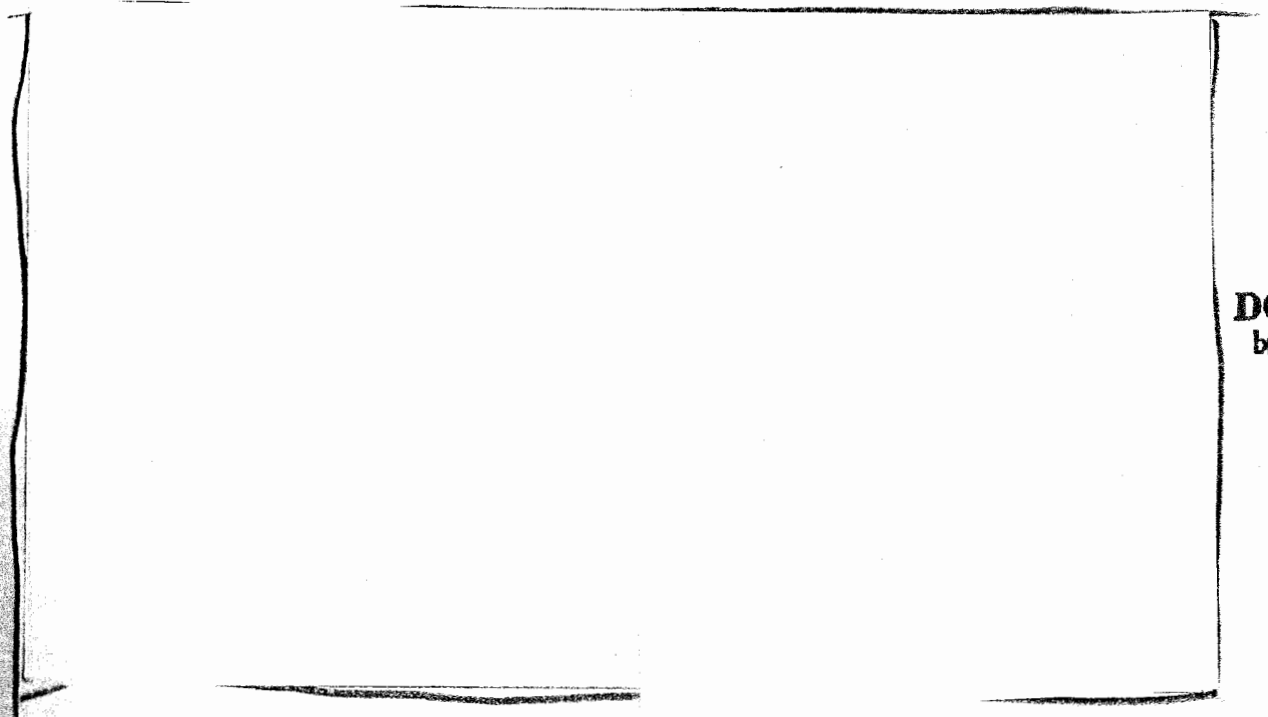

Figure 24: Airblast pressure attenuation with range, at several heights, compared with the Brode airblast results for a 250 kT burst slightly above the surface.

7 Energy Coupling: Discussion and Comparisons

In comparing weapon effects calculations, there is frequently a need to reduce the comparison to a simple, single parameter that can be used as a figure of merit, spanning a wide variety of possible conditions. One such parameter is that expressed by the frequently used concept of "equivalent yield"[15], by which is usually meant the yield at which a chosen reference explosion and environment produces a result that is, in some sense, the same as that for the subject explosion and environment. Obviously, such a simple concept for comparisons will not be satisfactory for every need, but its utility for some purposes makes it quite compelling. Associated with this concept is that of the "yield factor", which can be defined as the ratio of two equivalent yields. We consider here some of the possible yield factors obtainable from the series of calculations recently completed at Sandia National Laboratories, to quantify the effect of height or depth of burst on ground shock. In doing so, we shall utilize the well known scaling rules[16] for explosion effects in which distance and time are scaled by the cube root of the input energy, and other parameters are scaled according to their units, taking energy, time, and length units as fundamental.

DOE
b(3)

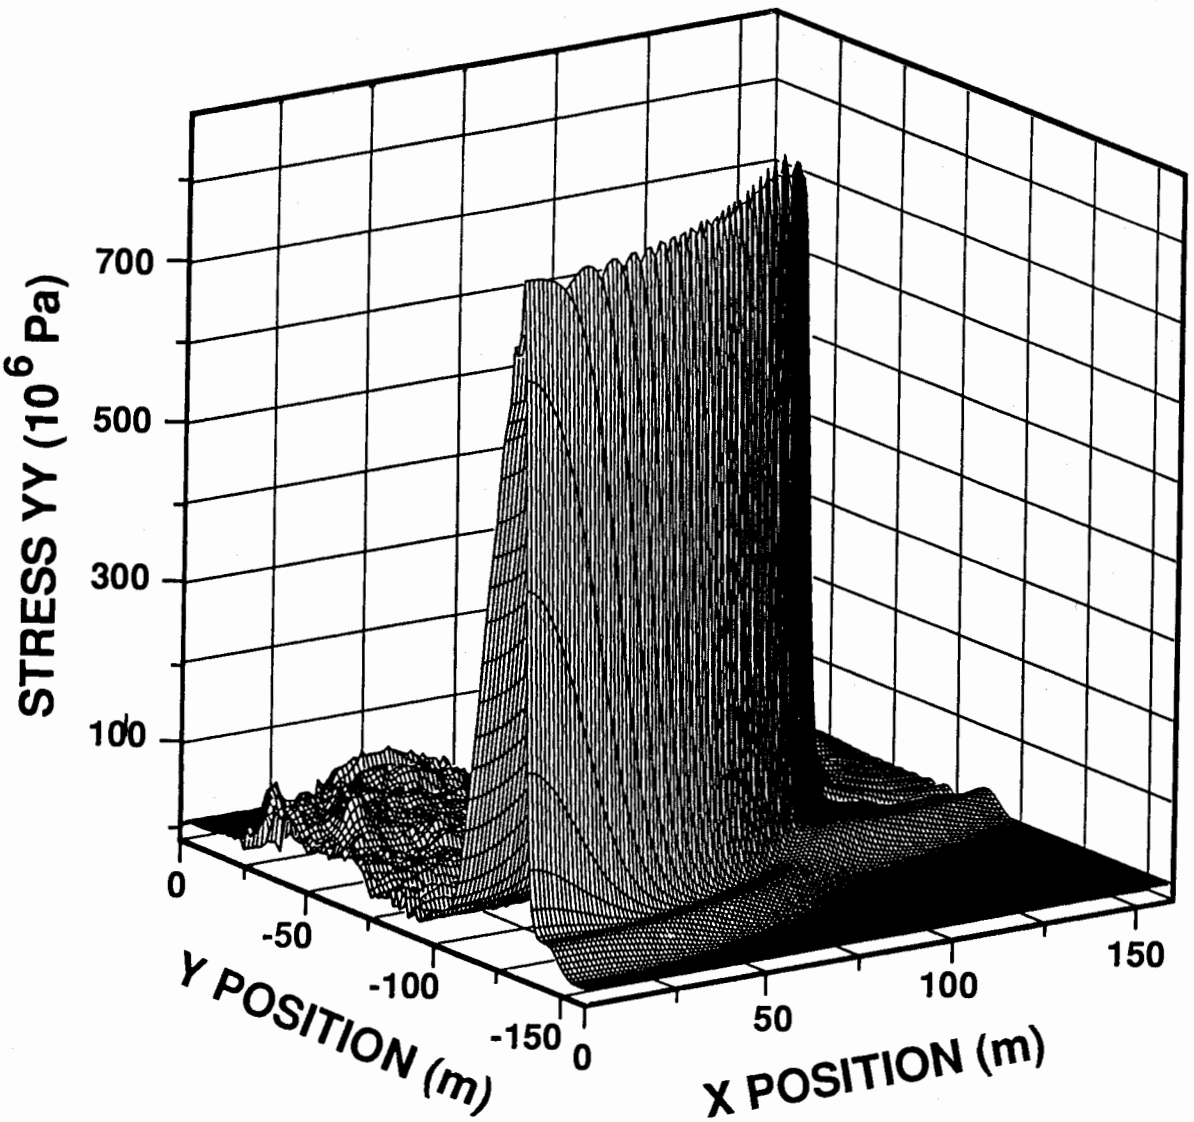

Figure 48: Pressure profile of the shallow burst calculation at 40 ms. The pulse representing the elastic precursor is seen slightly below the main shock wave. Slightly to the right, the airblast wave can be seen.

APPENDIX 1. Sensitivities to Modeling Assumptions

In connection with the shallow burst study discussed in the text, a number of calculations were performed to test early time sensitivities to changes in the initial conditions assumed. The computing times for running LASNEX using the implicit Monte-Carlo radiation transport method were long ($\approx$ 50 - 100 cpu hours), so most of these sensitivity checks were performed using the much faster diffusion options, especially the three temperature single group diffusion model. The interest here was primarily in determining the effect of different assumptions on the prompt radiative energy loss to the atmosphere. In every case tested, the diffusion treatments of radiation in the ground and debris in the hole led to larger estimates of radiation energy loss than the IMC treatment gave, which does not seem surprising, when one considers the limits inherent in the diffusion treatment.

The parameters varied in these calculations were, primarily, (a) the radiation transport approximation employed, (b) the density and opacity of the debris filling the hole, (c) the diameter of the hole, (d) the depth of the hole, and various combinations of these that the writer deemed interesting. The goal of these calculations was to investigate radiative energy loss sensitivities, rather than to provide a systematic study of the effects of parameter variation; however, the work hopefully provides some modest insights in that direction.

DOE b(3) 5 5(1)

APPENDIX 3. Input to the CSQGEN and CSQ Codes

The CSQ calculation was performed in ten runs, each having two input sets, the first to the CSQGEN program, the second to CSQ. The following are the input for those runs. The versions of those programs were: CSQGEN version 3.0, dated 9 Nov. 1986, and CSQ version 3.0, dated 9 Nov. 1986. The modifications to CSQ used for this work are discussed in References 1 and 2.

Input for CSQGEN, run 1.

DOE
b(1)

APPENDIX 4. Additional Information and Plots

A few figures not included in the text are presented here, for the use of those interested in additional detail on the evolution of the ground shock with time or some other features of the calculation. The first two figures, A1 and A2, provide early time density, temperature, and velocity profiles as a function of horizontal range, starting from the center of the burst (1.13m below the ground surface). The next seven figures provide density, temperature and pressure profiles vs. depth on axis, at each decade in time from 10^{-7}s to 10^{-1}s. The next four figures provide time histories of the maximum principles stress off axis, at a range of 400m, and depths at 100m intervals. Finally, Figure A14 provides a log-log version of the depth vs. time plot of Figure 17 of the text.

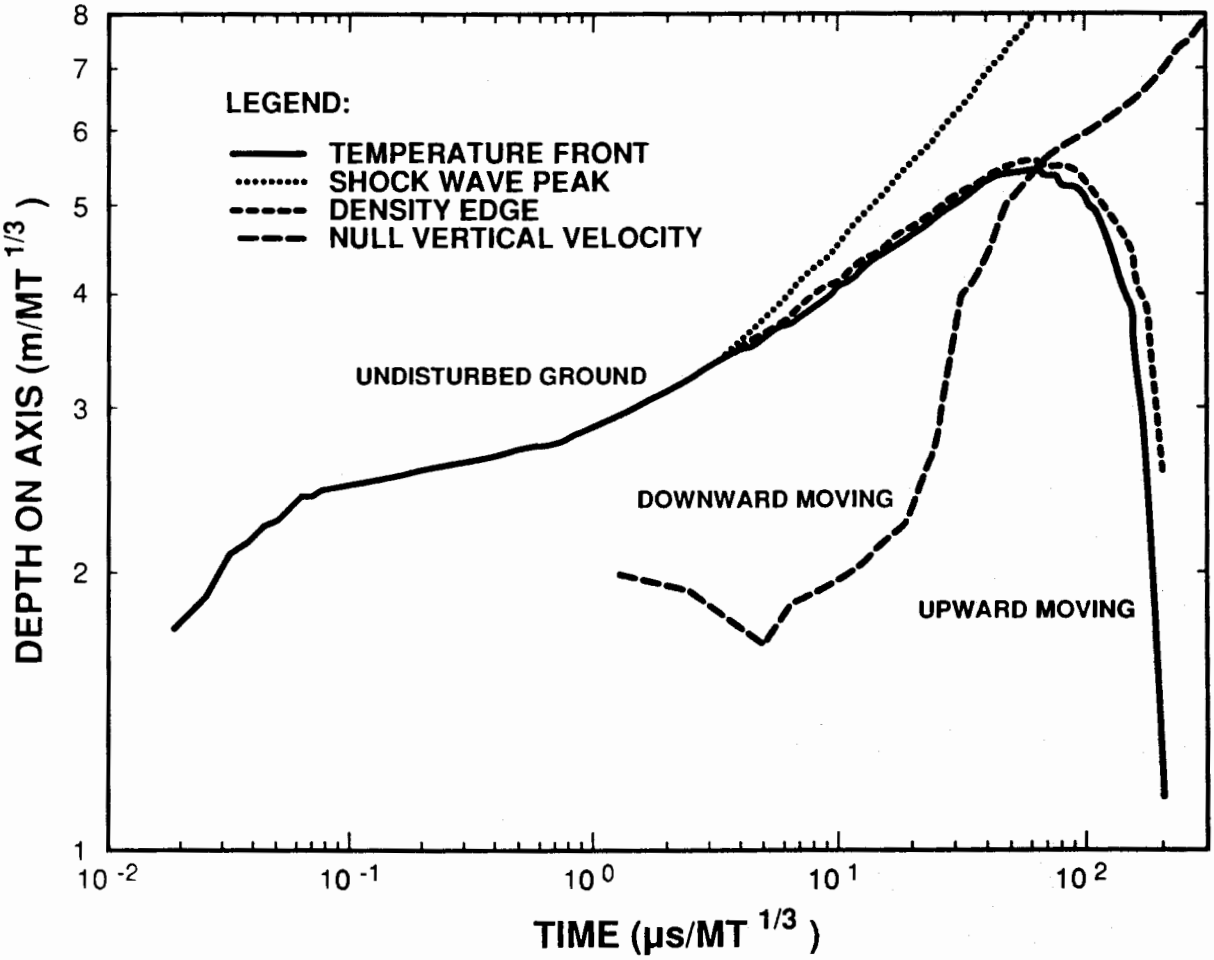

Figure A13. Plot of depth vs. time for some significant features down axis.

APPENDIX 5. Airblast: An Unsettled Issue

An intriguing feature of the airblast attenuation with range plot of Figure 14 of the text is that the rate of attenuation with range appears, on the average, to be somewhat less than that of the reduced-yield above-surface burst, as seen by the fact that at high pressures the present calculated curves lie slightly

below the Brode points while at low pressures they seem to lie slightly above the corresponding points. This feature appears to have its origin in the previously noted phenomenological difference with the above surface burst airblast: the large quantity of ground ejecta driving the airblast, in the shallow buried case.

An above-surface burst exhibits an impulsive delivery of most of the airblast energy by radiation, which forms the familiar fireball from which a shock wave subsequently emerges. In the present case, most of the energy is delivered over a much longer time interval, by the $\int pdv$ work performed on the atmosphere by the expanding column of ground ejecta. This quasi-cylindrical push against the atmosphere may result in a less rapidly attenuating shock front. The airblast from the Baker event (relatively shallow burial in ocean water) has been reported[1] to have produced a reduced attenuation rate at low pressures. Goertner[2] has suggested that the origin of the reported reduced attenuation rate might be the 2-D aspect of the air shock wave, as it develops, quasi-cylindrically, under the influence of an expanding column of water. This phenomenon could take on considerable significance in the context of aircraft delivered systems, for aircraft safety. The issue can not, at this time, be said to be resolved on the basis of either theoretical understanding, which does not clearly support the claim so far as this author has determined, or by the Baker data itself, which shows considerable scatter, and could be subject to alternative explanations.

Issue: Hard Target Defeat (U)

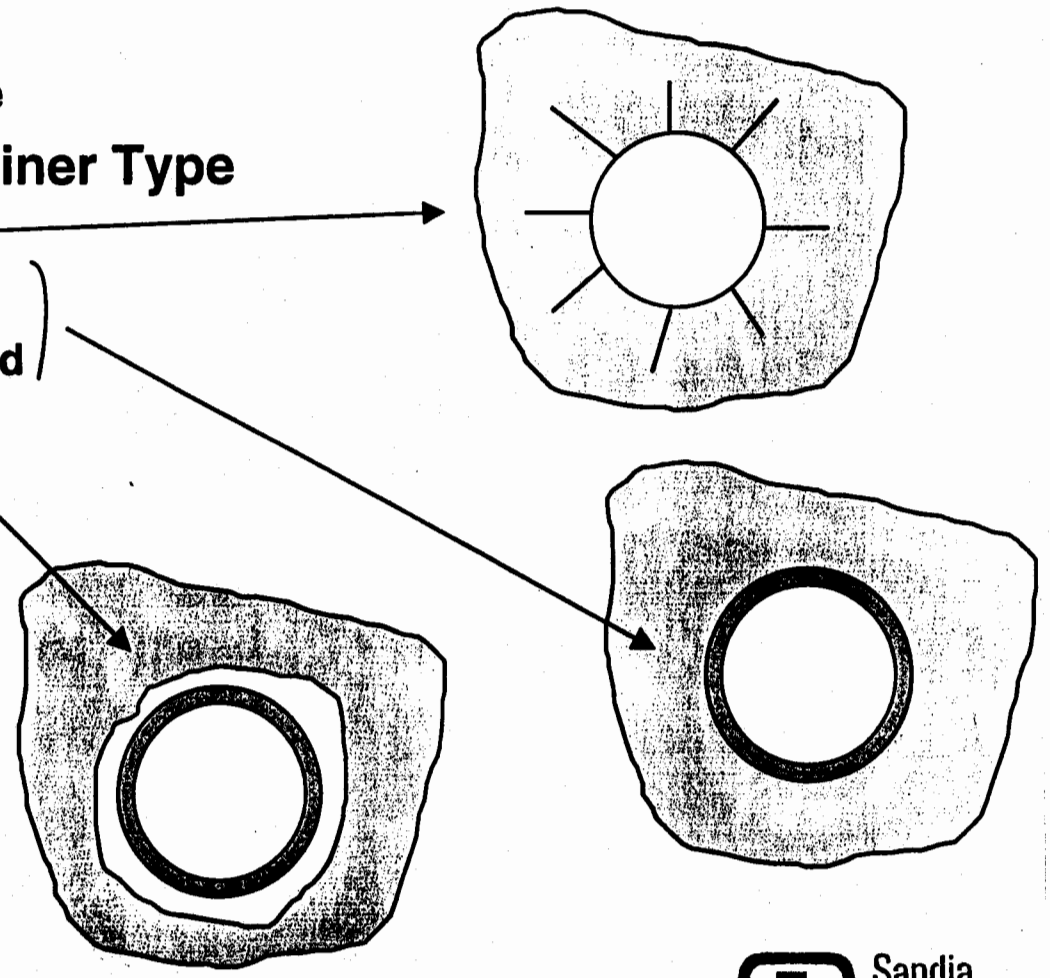
- **Briefing Outline**
  - Motivation
  - Previous Analyses
  - Example
  - Areas of Concern
  - Proposed Further Analyses

Why look at Tunnel Vulnerability? (U)

[redacted]

Sandia National Laboratories

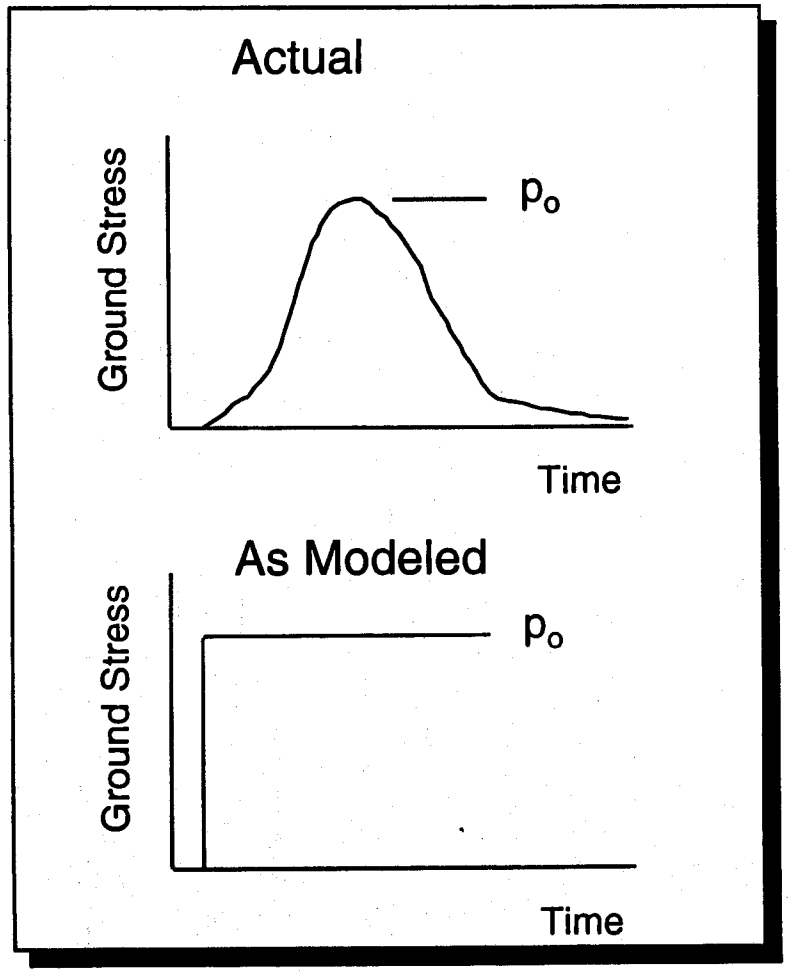
DOD (b)(1)



Attack Tunnels Using Nuclear Weapons (U)

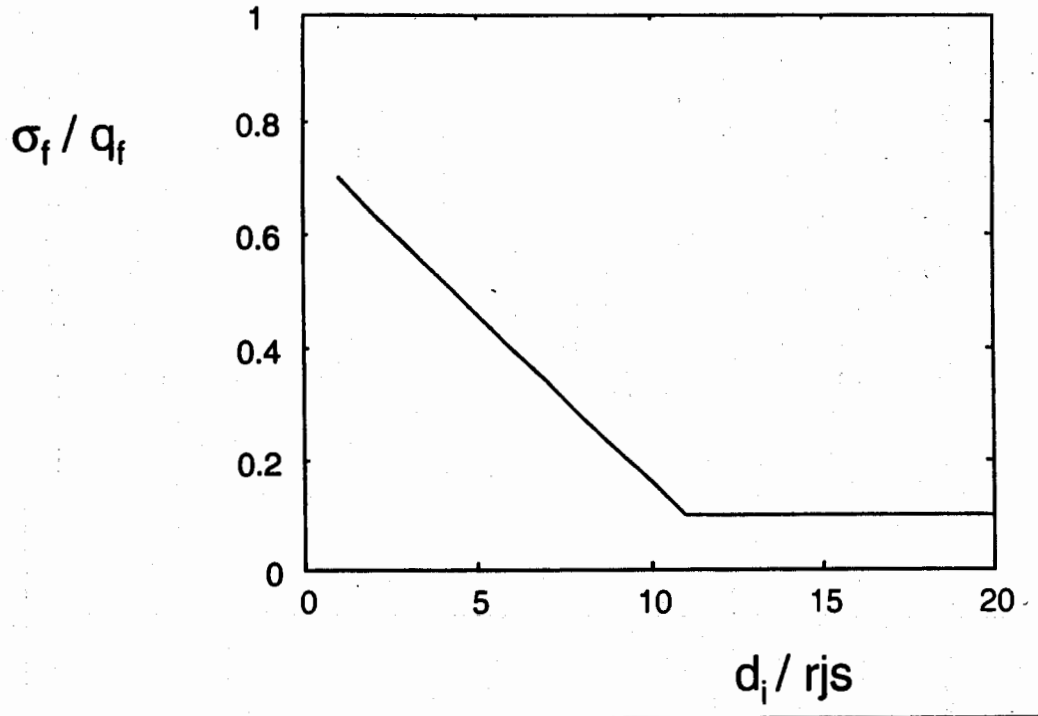
DOE
b (3)

Sandia National Laboratories



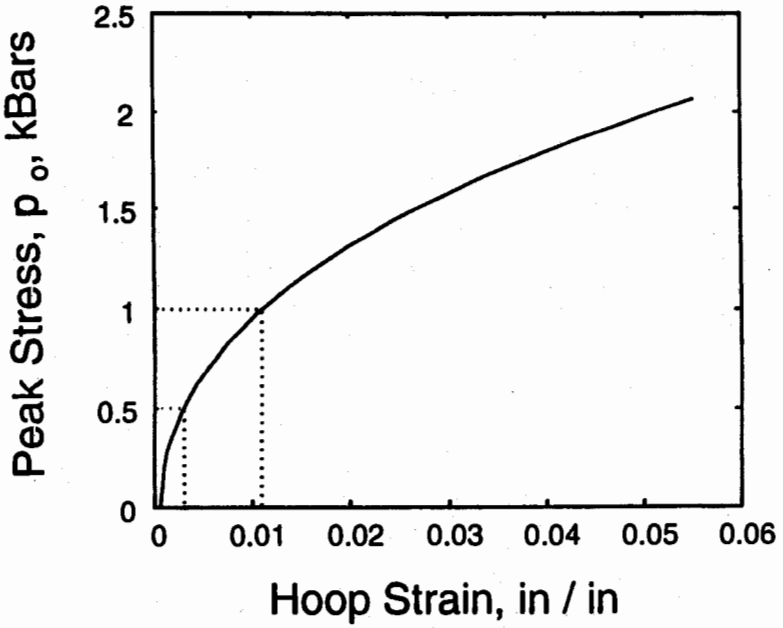
First Define the Tunnel (U)

- **Geology**
  - local to the site
- **Construction/Liner Type**
  - Rockbolted
  - Concrete lined
  - Composite lined
  - Backpacked



Hendron and Aiyer Analysis (U)

- **Published by Corps of Engineers in 1972**
  - Extension of work by Newmark (1969)
  - These are "Big Names" in Rock Mechanics
- **Assumes static loading**
  - Uniform external pressure, p_o
  - p_o is the maximum ground stress
  - Elastic/Plastic analysis with dilatency
  - Uses Coulomb-Navier failure criteria
- **Calculate Hoop Strain for a given external pressure**



Hendron and Aiyer Analysis - Cont'd (U)

Use a Rock Strength Reduction Factor (SRF)

σ_f = in-situ rock strength
q_f = unconfined laboratory rock strength
rjs = rock joint spacing
d_i = rock opening diameter

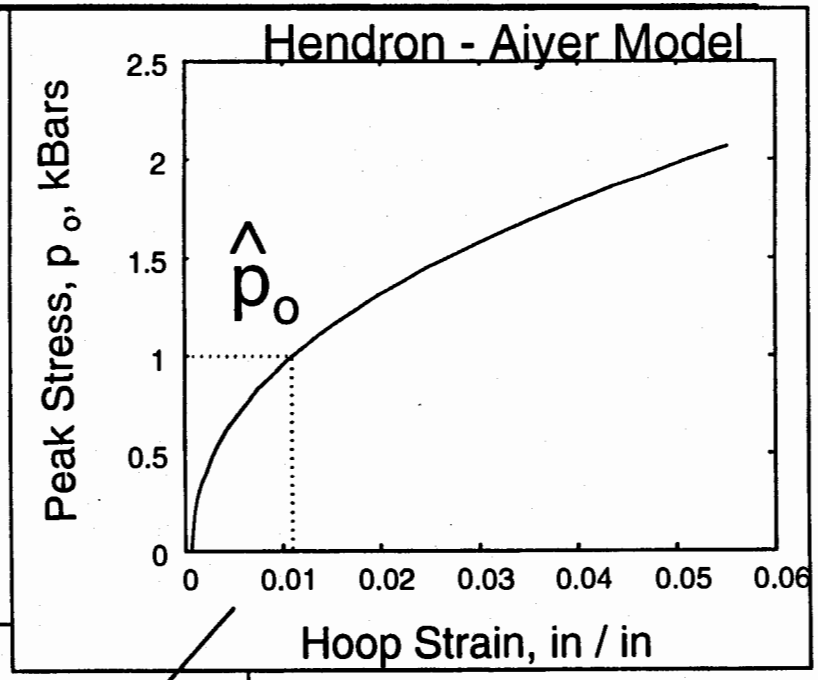
Hendron and Aiyer Analysis Results (U)

- Curve Depends on:
  - Liner
  - Rock Properties
  - Tunnel Size
- Similar / Identical sections in different locations have different peak stresses (p_o) but the same curve.
  - Different hoop strains
  - Identify failure/survival strain
- Many issues to consider

Issues to Consider (U)

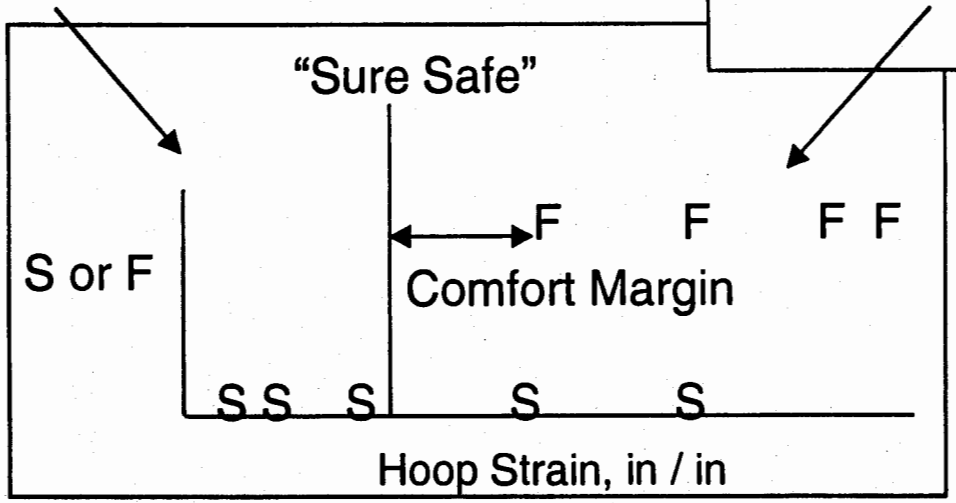
- **Dynamic loading effects**
  - Rock tends to be a lot stronger under dynamic loads than under static loads
  - Impulse versus peak load analysis
- **Liner/Rock interface not well modeled**
- **Test data come from 2 geologies**
  - Granite
  - Tuff
- **What are the inherent biases of the analysis?**

"Calibration" of Hendron and Aiyer Results (U)



- "Calibrated" for various construction types
  - Much of data from 3 UGTs
    - Piledriver and Hard Hat - tests in Granite
    - Mighty Epic - test in Tuff
  - Lots of tunnel sections and liner types, few large sections
    - Most sections 6 - 7 feet in diameter
    - Most sections loaded side-on
- Work was in support of Deep Basing (1983)
  - Goal was protection of U.S. assets
  - Focus was on "Sure Safe" design
    - Choose to err on the side of "defender conservative"

"Calibration" Continued (U)



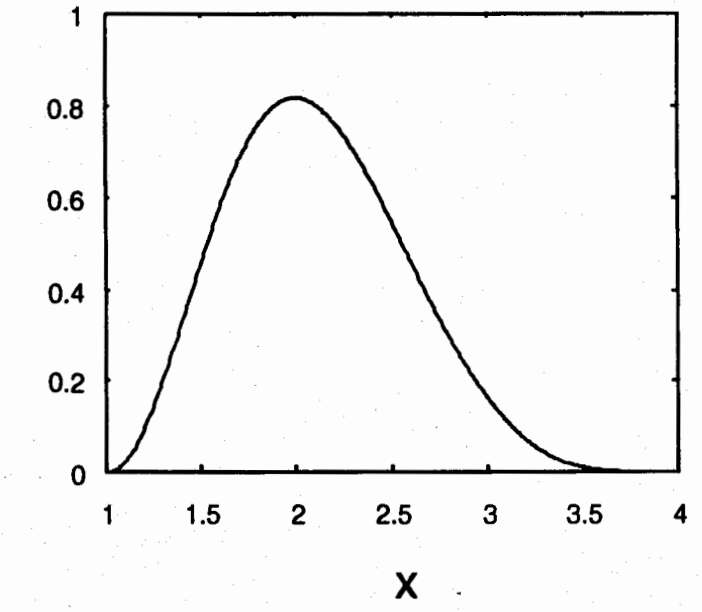
- The project officer made a post-test damage assessment
  - Severe Damage: Requires Remining
  - Moderate Damage: Major Repairs
  - Light Damage: Minor Repairs
  - Undamaged
- These categories were further reduced to
  - Survived
  - Failed

The "Calibration Trail" (U)

{Instrumentation} → $\hat{p}_o$ →

{Survive / Fail Assessment}

Sandia National Laboratories



Ground Shock Vulnerability Calculation (U)

- **1990 DIA Report Describes Method**
  - Uses Hendron and Aiyer Method for p_o - hoop strain relationship
  - Converts "Sure Safe" hoop strains to "Failure Strains"
  - Large Monte Carlo simulation representing uncertainty in target parameters
- **Results in a distribution of failure stresses, p_o**
  - Failure values for p_o are fit to a Beta-distribution
  - Published tables give min, max, mode, and t-value
  - These values are used for GVN determination
    - See later chart for more details
  - GVNs are used in PDCALC 6.2

What is the Beta distribution? (U)

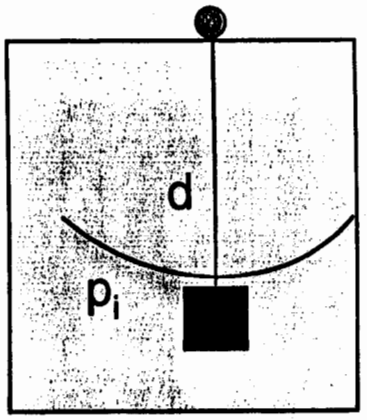
- **The Beta distribution has several convenient characteristics.**
  - **Bounded**
  - **Can take on almost any shape**
  - **Described by 4 parameters**
    - **minimum value**
    - **maximum value**
    - **mode**
    - **t - peakedness**
- **Uniform distribution**
  - **t = 2**

Beta distributed variable, x
min = 1, max = 4, mode = 2, t = 9

Calculating Tunnel Vulnerability (U)

- Select minimum and maximum values for all important parameters, for the target of interest
  - Geological characteristics
  - Liner characteristics
  - Size
  - "Sure Safe" strains (from earlier table)
- Select Beta distribution characteristics for each parameter
  - Peakedness, (t), and mode
- Run Monte Carlo simulation
  - Example has 10,000 draws from 13 distributions

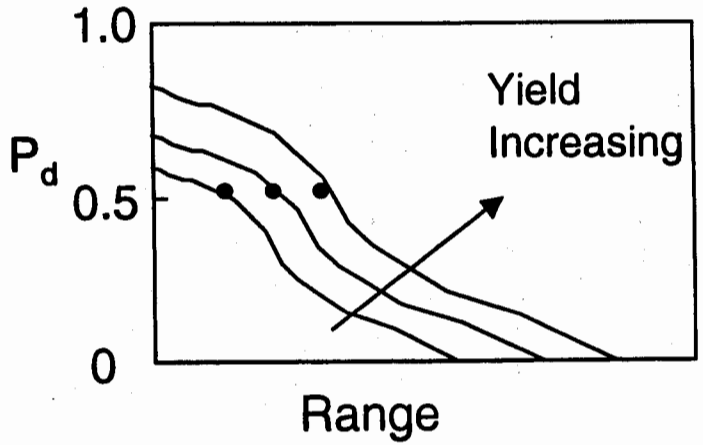
Observations and Issues (U)



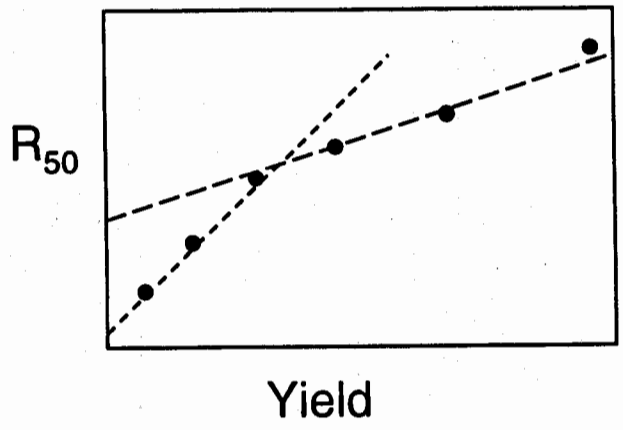
- The distributions represent uncertainty about the site parameters, not within site variability
  - E.g., Sure safe hoop strain
    - Assumed Beta Distribution ranges from:
      - 0.004 to 0.025 (Unreinforced concrete to very heavily reinforced)
      - The tunnel liner itself does not vary
- Choosing the resulting p_o mode is approximately the same as running a nominal case analysis - uncertainty is nearly irrelevant
- Uncertainty distributions have weak supporting rationale
  - Ranges, peakedness, independence

Hendron and Aiyer Analysis Issues (U)

- **Hendron and Aiyer Method assumes static loads**
  - Rock is much stronger under dynamic loads than static loads - strain rate effects
    - Tunnel is stronger than static load predicts
    - Conservative assumption for tunnel designer
  - Requires full engulfment of structure in ground shock wave
    - Probably OK for nuclear - not even close for conventional weapons effects
  - When failure occurs - loading or unloading - may be important but is not included in analysis



Where do GVNs come from? (2) (U)



- **Step 3: Pick many weapon yields**
  - Evenly spaced on log scale from min to max
  - HOB is 0.5 meters
- **Step 4: Monte Carlo simulation drawing from distributions on:**
  - Facility depth (assumes weapon directly above facility)
  - Geology parameters
  - Result: p_i, the peak ground stress at the facility
  - Compare to the chart in Step 2 to get P_d for that trial
  - Save P_d and depth for that trial associated with the yield.

Where do GVNs come from? (3) (U)

- **Step 5: Repeat the process for many yields**
  - Fit P_d vs. Range to lognormal for each yield
  - Select R_{50} for each yield from fitted curve

- **Step 6: Fit 2 straight lines to 50 % P_d values**
  - Determine GVN (parameters of curve fit)

Further Analyses of Tunnel Vulnerability (U)

- **Review tunnel vulnerability assessment methodology**
  - More sophisticated techniques are available
  - Include dynamic loading effects
- **Look again at failure models and test data**
  - Identify where conservatism exists and quantify
  - Reanalyze for "Sure Kill" levels
- **Consider other treatments of uncertainty**
  - Run selected cases
  - Evaluate parameter effects on p_o

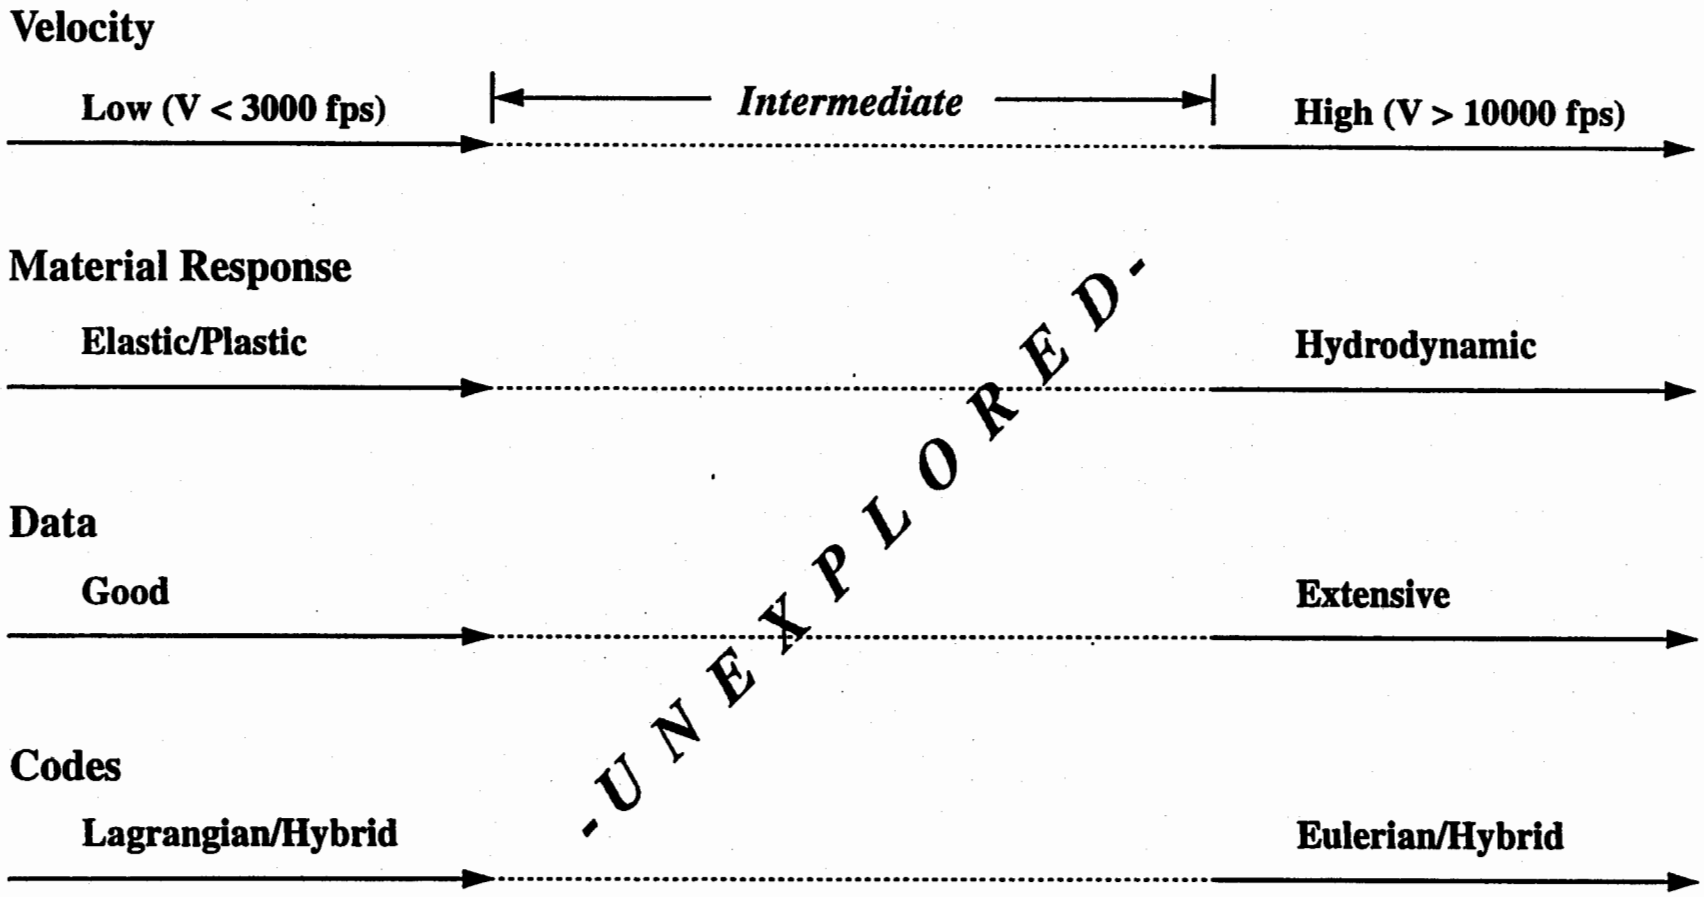
CINC Priorities for Counterproliferation Capabilities (U)

CINC Priority	CINC's Counterproliferation Capabilities
1	Detection/characterization of BW/CW Agents
2	Intercept cruise missiles
3	Defeat underground targets
4	Characterize and identify underground targets
5	Collect and analyze intelligence
6	Passive defense enabling operations
7	Support for operations in NBC environment
8	Biological vaccines
9	Planning and targeting for above ground infrastructure
10	BW/CW agent defeat
11	Detection and tracking of shipments
12	Prompt mobile target kill
13	Support for Special Operations Forces
14	Locate, detect, and disarm WMD in CONUS/OCONUS

LDRD Project: Unexplored Penetrator Regime Against Super-Hard Underground Facilities

Part 2: Review of Tech Base Activities

Technical goal



- Develop basic understanding computational models to predict unique features of earth penetration at high velocity:
  - Penetrator abrasion, plastic deformation, and failure

End product is a tool to predict:

- **Survivability:**
  - Predict loads, peak stresses on the penetrator case and warhead.
- **Lethality:**
  - Predict depth of penetration.

EPW LDRD

Modeling Regimes/Capabilities

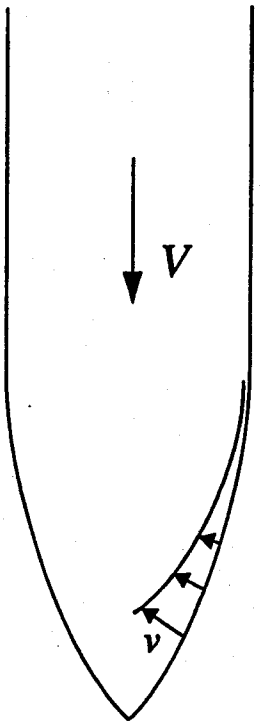
Technical challenges

- Overcome lack of understanding of physical processes.
  - Abrasion, friction, other interface phenomena.
  - Material failure: cracking, plastic flow.
- Overcome difficulty in modeling interface numerically
  - Allow gross changes in penetrator shape.
  - Develop ability to remove penetrator material from Lagrangian mesh.
  - Predict structural response while the above are occurring.
- Contribute to penetrator design process in this velocity regime.
  - Materials science basis.
  - Computational tools.

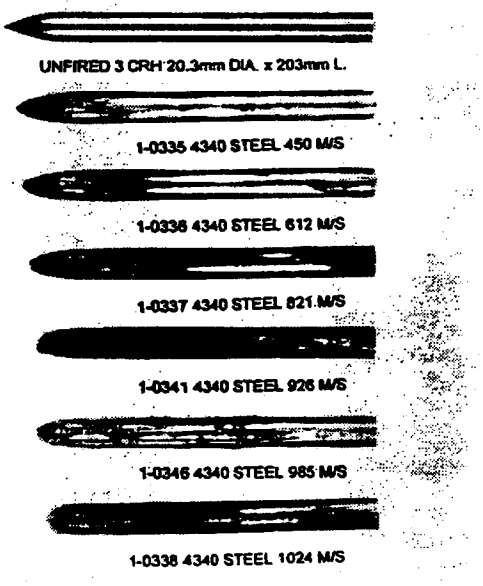
Major Technical R&D Activities

- **Physics model development**
  - Metal penetrator wear/erosion/abrasion
- **Micrographic analysis**
  - Investigate/discover erosion phenomenology
  - Guide model development
- **Ballistic testing**
  - Samples for micrographic analysis
  - Validation data for computational models
- **Production code implementation of penetrator erosion model**
  - Platform for validation of computational models
  - Model-based tool for routine EPW engineering design & analysis

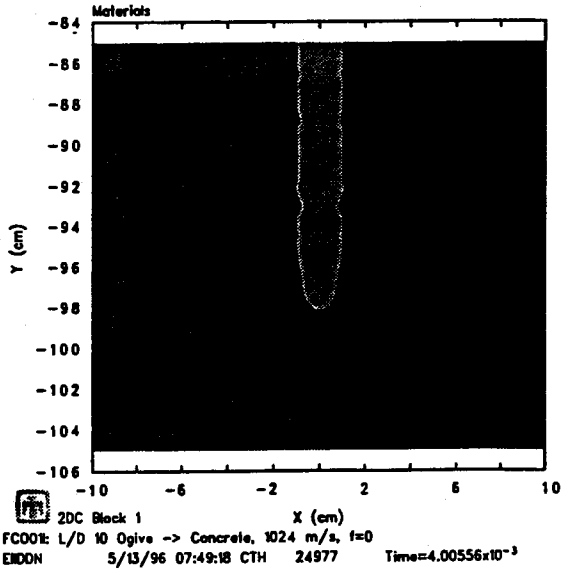
Technical accomplishments: Abrasion model



Sandia National Laboratories



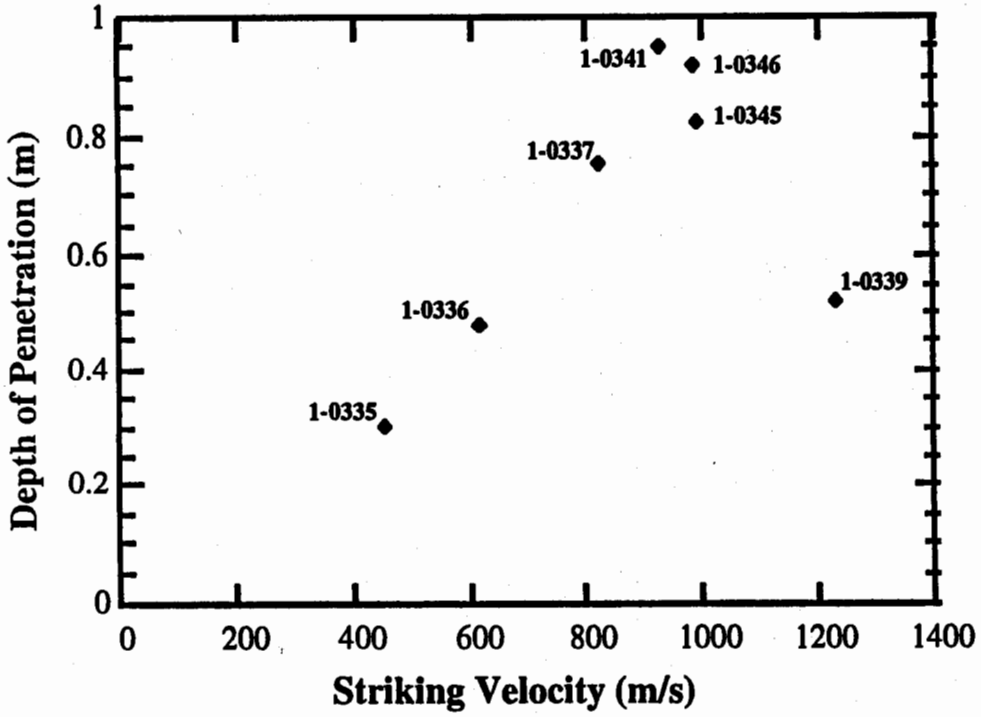
Computational Physics & Mechanics Department

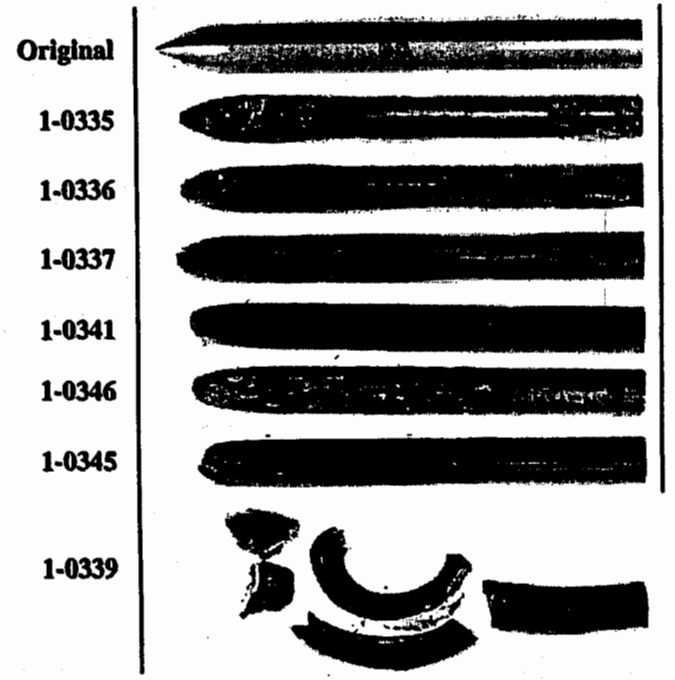


- CTH model removes mass from the surface according to local conditions.
- Data show mass lost is proportional to initial KE. This suggests model shown at right:
- Results agree well with experimental data by Forrestal on mass loss and penetration depth.

$$v = \frac{CVp}{\rho}$$

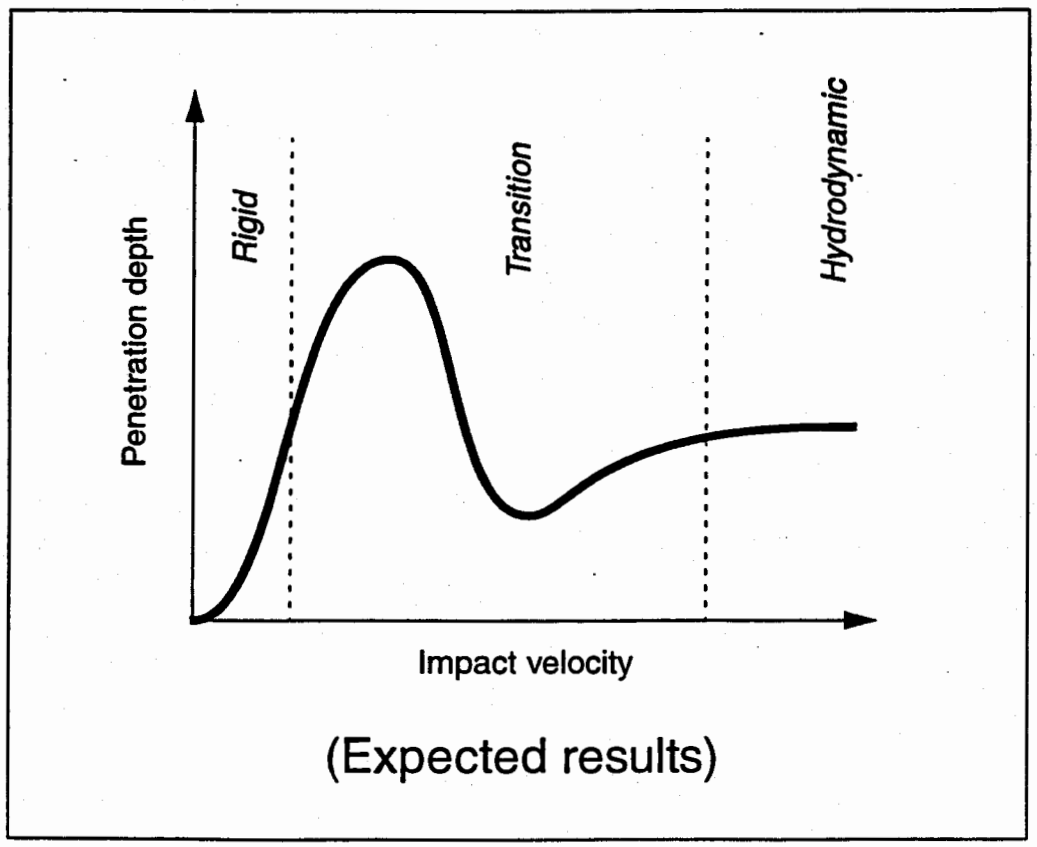
C=constant





EPW Technology

AISI E4340 SAQ Steel Projectiles into SAC-5 Concrete



Technical accomplishments: Experimental data up to 3 km/s

Sandia National Laboratories

Computational Physics & Mechanics Department

- Existing data on high velocity penetration is fragmentary.
- Obtain a consistent set of data over a wide range of velocity.
  - Steel rods into aluminum blocks, 1-3 km/s.
  - For use in model validation.
    - ♦ Can we predict the expected maximum and minimum in the penetration depth curve as a function of velocity?
  - To be completed in FY96.

(Expected results)

FY96-97 planned work

- Improve and validate penetrator-target coupling algorithm, implement in ALEGRA.
- Get data for and thoroughly understand penetrator depth curve in transition region (steel -> aluminum).
  - Reproduce computationally.
- Incorporate into models what is learned from micrographic analysis and penetration data.
  - Physical models can be incorporated into any applicable code.

Resource Utilization

FY96	*5400 (Rogers)*	*9200 (Yarrington)*	*2100 (Hansen)*
	186,354	*233,478*	*223,839*

Slant ranges for specified neutron doses for targets near the ground as a function of energy yield of air-burst thermonuclear weapons based on 0.9 sea-level air density (Reliability factor 0.25 to 1.5 for most thermonuclear weapons)

Slant ranges for specified gamma-ray doses for targets near the ground as a function of energy yield of air-burst thermonuclear weapons with 50 percent fission yield, based on 0.9 sea-level air density (Reliability factor from 0.25 to 1.5 for most thermonuclear weapons)

Characteristics of Expected Radiation Field

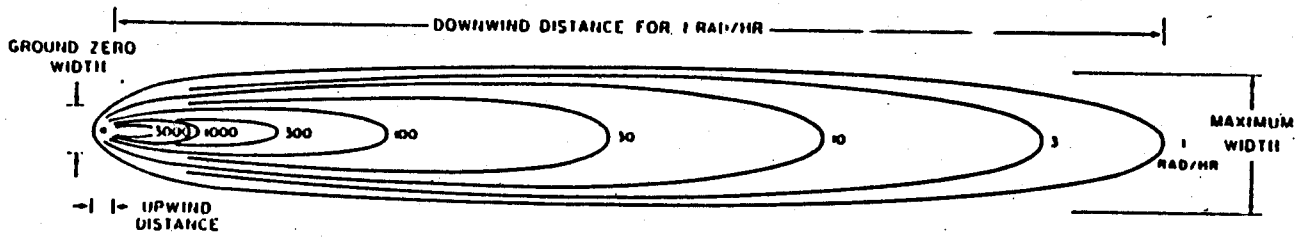

Illustration of idealized unit-time dose-rate pattern for early fallout from a surface burst (The contour dimensions are indicated for a dose rate of 1 rad/hr.)

SCALING RELATIONSHIPS FOR UNIT-TIME REFERENCE DOSE-RATE CONTOURS FOR A CONTACT SURFACE BURST WITH A YIELD OF *W* KILOTONS AND A 15 MPH WIND

Reference dose rate (rad/hr)	Downwind distance (statute miles)	Maximum width (statute miles)	Ground zero width (statute miles)
3,000	0.95 $W^{0.4}$	0.0076 $W^{0.4}$	0.026 $W^{0.4}$
1,000	1.8 $W^{0.4}$	0.036 $W^{0.4}$	0.060 $W^{0.4}$
300	4.5 $W^{0.4}$	0.13 $W^{0.4}$	0.20 $W^{0.4}$
100	8.9 $W^{0.4}$	0.38 $W^{0.4}$	0.39 $W^{0.4}$
30	16 $W^{0.4}$	0.76 $W^{0.4}$	0.53 $W^{0.4}$
10	24 $W^{0.4}$	1.4 $W^{0.4}$	0.68 $W^{0.4}$
3	30 $W^{0.4}$	2.2 $W^{0.4}$	0.89 $W^{0.4}$
1	40 $W^{0.4}$	3.1 $W^{0.4}$	1.5 $W^{0.4}$

Summary

- **On These Two Concepts Groups**
  - Design data are well developed, available
  - Weapon outputs, effects documented, modeled
    - Temperature history
    - Radiation outputs and spectra
    - Shock production
  - Major effort required is in area of
    - Estimating collateral damage/agent release
    - What is required for denial
    - What are consequences of agent release

FY 97 PROPOSED ACTIVITIES FOR AGENT DEFEAT WARHEAD STUDY (a)

DOE (b)(3)

[redacted] At this point we don't know which or how many of them will be selected for further development.

For the concepts selected, calculations of the performance and collateral effects of the nuclear candidates against the Agent Defeat Weapon target set will be required. A few of the nuclear concepts will also require additional weaponization effort. This would consist of preliminary concept layouts and packaging studies.

[redacted] What would be required for those proposals is presented in more detail on the next page.

PLYWD TYPE

Concept Description

- Low-yield nuclear weapon
- Precision guidance
- Standoff capability
- AB/SB/EPW capability

AGM-142-Like Concept

Technical Issues

- pit production/use
- nuclear material production
- warhead certification
- nuclear tests

Benefits

- Neutralization of Bio/Chem agents
- facility and weapon destruction
- Long-term denial
- can defeat area targets
- mitigates target/critical element location uncertainty
- potential collateral damage reduction
- high confidence BDA
- compatible with current and proposed AF weapon systems
- can engage weapons in all stages from manufacture to deployment on delivery platforms

1651 First Street SE, B-20360
Kirtland AFB NM 87117-5617

SUBJECT: Agent Defeat Weapon (ADW) Concepts Working Group (CWG) Action Items CWG-6 and CWG-7

1. CWG #6 was held at Eglin AFB, FL on 7 May 96. At this meeting Action Items CWG-6 and CWG-7 were generated. CWG-6 tasks the Mission Analysis Working Group (MAWG) to review the ADW concepts and provide specific questions. The MAWG reviewed the concepts during 17-20 Jun 96. The specific questions from this review are included in the attachment. Response is requested by 31 Jul 96. Although some of the concept questions are unclassified, many of the responses will be classified. Please classify response accordingly with the ADW Concept Exploration Security Classification Guide.

2. Action Item CWG-7 tasks the CWG and MAWG Chairs to schedule a joint meeting to discuss the results from the effort identified in paragraph 1. Concept providers will be required to brief their responses to the questions during this meeting. The joint meeting is scheduled for 6-7 Aug 96 with an ADW Program Review scheduled on 8 Aug 96. Details for these meetings are forthcoming.

3. If you have additional questions please contact Don Erdmann, (505) 846-4001 x206, DSN: 246-4001 x206, FAX: (505) 846-4618.

ADW CONCEPT QUESTIONS
CONCEPT 27
Existing Nuclear Stockpile Options.

1. (U) QUESTIONS REGARDING PHYSICAL CHARACTERISTICS:

   a. (U) What are the external dimensions?

   b. (U) What is the case thickness?

   c. (U) What are quantity & characteristics of ADW materials?

   d. (U) What is the toxicity of the by-products?

   e. (U) What are the mass moments of inertia?

   f. (U) How much HE, if any, and what type?

   g. (U) What type of propellant is used?

   h. (U) What is the overall weight?

2. (U) QUESTIONS REGARDING FUNCTIONAL CHARACTERISTICS:

   a. (U) What volume or area is effected by the weapon?

   b. (U) How will dust, debris and other contaminants effect the system?

   c. (U) What weapon outputs should be associated with each weapon and yield combination?

   d. (U) What are the CEP's for each weapon?

   e. (U) What are the available fuse settings for each weapon?

3. (U) QUESTIONS REGARDING LOGISTICAL CHARACTERISTICS:

   a. (U) What restrictions will different weather conditions pose upon the concept?

   b. (U) What intelligence dependencies does the concept need (agent type, target structure, BDA)?

   c. (U) Does the concept need any special handling?

ADW CONCEPT QUESTIONS
CONCEPT 27
Existing Nuclear Stockpile Options.

d. (U) What is the shelf life of the system?

e. (U) What is the time needed to prepare the concept for a launch?

f. (U) What are the VN and GVN numbers for the targets?

4. (U) QUESTIONS REGARDING COST:

a. (U) What is the life cycle cost?

b. (U) What is the average unit cost?

c. (U) What is the disposal cost?

5. (U) QUESTIONS REGARDING PROGRAM MANAGEMENT:

6. (U) GENERAL COMMENTS:

a. (U) What type of testing has been completed?

b. (U) What is the availability of defeat mechanism raw material?

c. (U) Is there any reference material available?

d. (U) What is the impact of missing the target on weapon function?

e. (U) What are the characteristics of the expected radiation field?

f. (U) What delivery accuracy will be required?

g. (U) For any system or subsystem performance specifics, justify or substantiate how these claims were arrived at. Was it due to a system level test, subsystem level test, or was it simulated or analysis performed (i.e. DARPA, contracted, in-house).

ADW CONCEPT QUESTIONS
CONCEPT 27
Existing Nuclear Stockpile Options.

i. (U) Please relate a concepts effectiveness to the ADW consolidated target list? For the ADW consolidated target list, how many sorts of a given concept are needed to defeat or deny access to that target?

j. (U) Can you provide energy spectra that should be used for transport calculations in bunkers with shielding? Or will you do the calculations or the threat scenarios? (radiation concepts only)

k. (U) Quantify collateral effects. Estimate effects - are containers vaporized, ruptured, thrown about, etc? Give some specific examples.

l. (U) We need more data to substantiate the kill mechanisms from these concepts. The radiation contours can be assessed in a straight forward manner - but thermal kill is a very difficult area. Provide the details that lead you to state the fireball will kill all agents. Since heat kill is a time and temperature criteria, how much dispersed agent is pushed out by the shock wave before the fireball temperature kills it. The lethality estimates call for about 2000 degrees for several milliseconds. Can you detail how the material is entrained and show that a conservative analysis kills most agent.

m. (U) Vaporization is certainly a kill criteria. But if you loft globs of spore the heat will kill spore on the outside but given the low thermal diffusivity of spore, the agent in the center may still be viable.

n. (U) Provide some sure-thermal-kill radius based on hydrocode calculations of the shock wave from weapon detonation and fireball temperature.

o. (U) Need to address agent in containers that may be ruptured outside of this sure-kill zone. Please estimate the probability of container rupture.

p. (U) Please provide detailed fallout data on this concept to use as a measure of collateral damage.

ADW CONCEPT ANSWERS
CONCEPT 27 (U)
Existing Nuclear Stockpile Options

J. F. Cuderman, Steve Schafer, Al Baker—Sandia National Laboratories

1. (U) PHYSICAL CHARACTERISTICS

   a. (U) External Dimensions:
   B61-7: 142"long, 13.3" OD; B83: 145"long, 18"OD;
   W80 CM Warhead: 31.5 "long, 12.75" OD.

   b. (U) Case Thickness:
   Not Applicable to non-penetrator systems

   c. (U) Quantity and characteristics of ADW materials:
   Nuclear Package

   d. (U) What is toxicity of the by-products:
   Radiation

   e. (U) What are moments of inertia:
   B61-7: Pitch and Yaw: 819 lb-in^2; Spin: 15,000 lb-in^2
   B83: See Fig. 1

   f. (U) How much HE, if any, and what type:
   Not applicable to nuclear systems since it is not significant part of the ADW material

(U) INTRODUCTION

(U) Desert Storm experience alerted U.S. theater commanders to the fact that major deficiencies exist in our ability to detect and locate critical mobile targets on the tactical battlefield. Possible ways to reduce these deficiencies include the use of sensors of various types to detect and identify SCUDs (or other missiles) with enough timeliness and precision to cue effective counter-attacks before the missiles are launched. Issues pertaining to sensor capabilities and deployment in this situation were analyzed in Reference 1. Another possible defense is to use sensors to detect missile launch and communicate launch time and location information to missile defense systems that can intercept and destroy the missile in-flight. The effectiveness of this defense will depend on sensor and interceptor performance and deployment parameters. The path from concept to a fielded, effective system is arduous, but a simulation analysis, such as is reported here, can provide ballpark figures that will be useful to system designers and operational planners.

(U) This report, as indicated, describes the results of a simulation analysis to evaluate a sensor-to-shooter architecture designed to detect and destroy tactical ballistic missiles (TBMs) during their boost phase. To perform the analysis, the previously-developed SENsor Evaluation Model (SENSEM) code[2], which was written to simulate the detection and identification of critical mobile targets, such as SCUD launchers in transit, was extended to simulate launch detection and boost-phase intercept.

DoD
b(1)

nterceptor ability was estimated as a function of the time delay from missile-launch to interceptor cue.

(U) SCENARIO DEVELOPMENT

DOD
b(1)

DOD b(1)

(U) SENSOR DEPLOYMENT STRATEGY

(U) Seismic sensors that have been used in the past to detect and locate Lance missile launches at White Sands Missile Range (WSMR) typically use accelerometers and geophones to measure the low frequency signature of the acoustically-coupled seismic energy associated with the first burn of the rocket motor. Although propagation times are a function of terrain type, detection ranges of 8-10 kilometers have been demonstrated[4]

DOD b(1)

in some of the tests conducted at WSMR. Based upon discussions with sensor hardware experts, a detection probability of 0.9 was assumed for launches within the maximum detection range of the sensor. Launches outside this range were given a detection probability of 0. A value of 10 km was used as the base case maximum detection range but was varied in subsequent cases in order to evaluate the sensitivity of sensor array performance to detection range.

though, that while coverage may be enhanced by closely spaced sensors, such spacing could degrade launch location estimation. This is an area for future study.

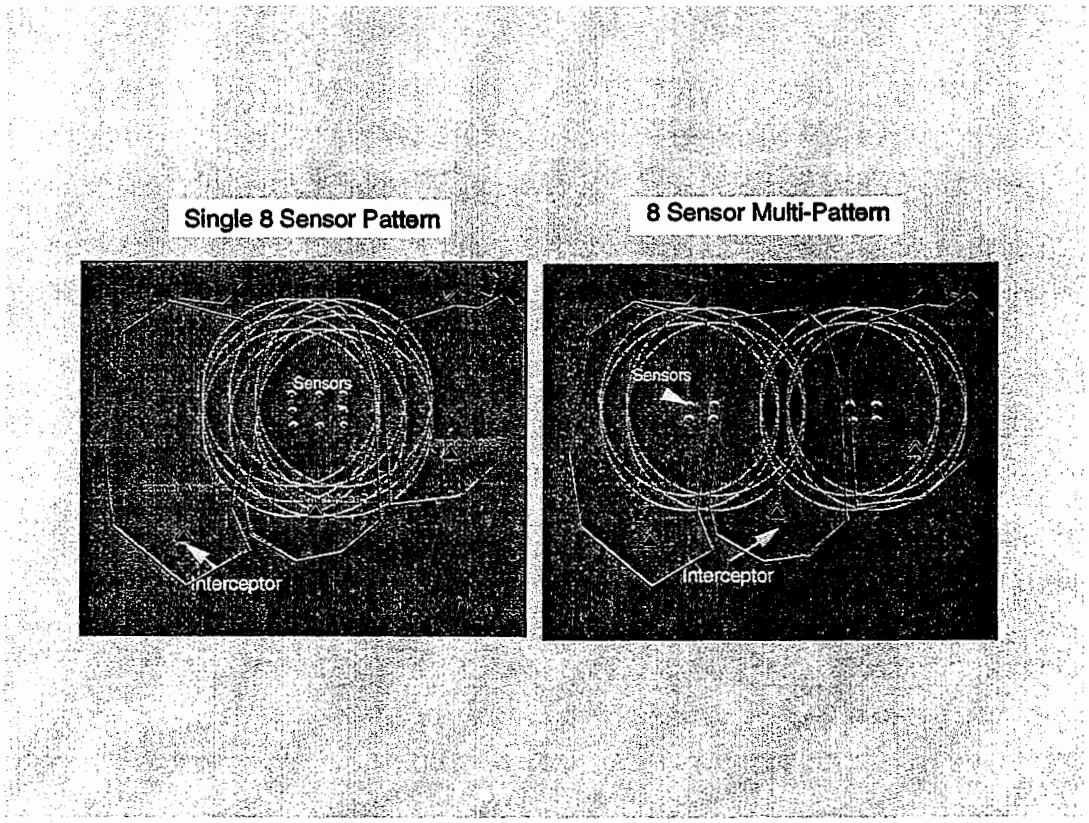

Figure 3. Deployment Patterns for 8 Sensor Array (U)

(U) SENSOR REQUIREMENTS FOR LAUNCH DETECTION AND LOCATION

(U) Sensor arrays were deployed across the three launch areas using the patterns discussed above and SCUD launcher tracks were generated using the SENSEM simulation. Multiple replications (50) were performed for a total of 200 launches and the percent of launches detected by 1,2,3,4,...., or 8 sensors was calculated. The base case results are shown in Figure 4 for a sensor maximum detection range of 10 km. No location solution is possible with less than 3 sensor detections, therefore the bar values for 0 (no detections) and 1 or 2 sensor reports represent detections only. The bars for 3,4,...., or 8 sensor reports represent the percent of launches for which detection and location estimates were made for the indicated array size. For example, for the 16 sensor array case, 19% percent of the launches were detected by only 2 sensors (no location solution) while 28% of the launches were detected by exactly 3 sensors and located after post-processing of the individual sensor data. The solid lines accompanying the bar charts sum the total percent of launches for which 3 or more and 4 or more sensors both detect and estimate launch location. As expected, the percent of launches for which position estimates are made increase as the number of sensors in the sensor array grows, e.g.

(U) Increasing the number of sensors in the array has the beneficial effect of improving the accuracy of the launch location estimate. In Figure 5, for all the cases where a location estimate was made, the conditional cumulative distribution of position errors is shown for the different size arrays. The results show, e.g., that the median estimation error is 400 m for 4 sensors, 100 m for 8 sensors, and about 30 m for 16 sensors and 24 sensors. It should be noted that large position errors can occur, e.g., in excess of 3000 meters. These situations almost always occurred when only three sensors detected the launch and the launch point estimation algorithm failed to find a local minimum (see Appendix).

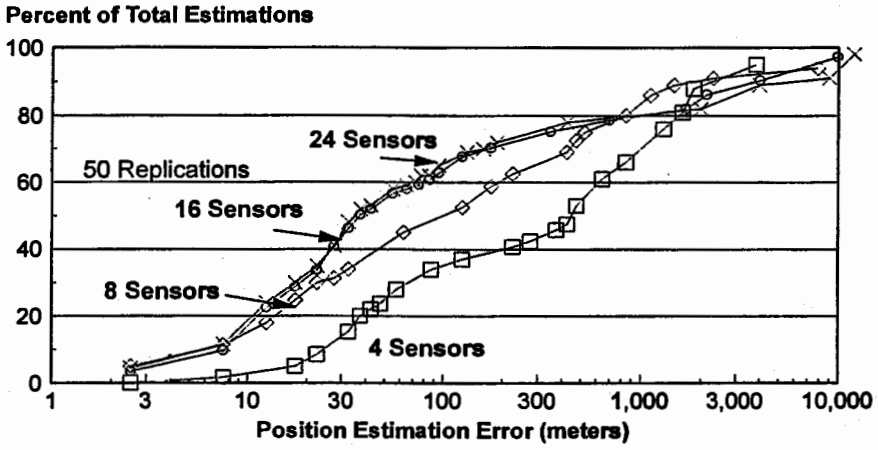

Figure 5. Distribution of Position Estimation Errors (U)

(U) SENSITIVITY OF SENSOR REQUIREMENTS TO DETECTION RANGE

(U) Additional calculations were made to assess the degradation in sensor array performance associated with smaller detection ranges. Although detection ranges of 8-10 km have been observed during test series, the base cases were rerun with a maximum detection range of only 5 km. The sensor deployment locations chosen for the base case (10 km detection range) were clearly not optimum for the 5 km case; therefore the off-line analysis was rerun for the latter case in order to determine more favorable sensor locations for use in the SENSEM model. The results of those calculations indicated that a deployment pattern similar to the base case was optimal for maximizing area covered by 3 or more sensors but modified by closer spacing between sensors.

(U) A comparison of sensor array effectiveness is shown in Figure 6 for both detection ranges. Sensor detection range is obviously a big driver in the performance of boost-phase sensor arrays. For example, with a detection range of 10 km, the 16 sensor array was able to detect and locate over 75% of the launches. However, when the sensor detection range was reduced to 5 km, only 20% of the launches were detected and located. Note that the area covered by a sensor is reduced by a factor of 4 when the detection range is halved, so, at least in the parameter region in which these calculations were done, there is a corresponding approximate factor of four decrease in the detect/locate probabilities.

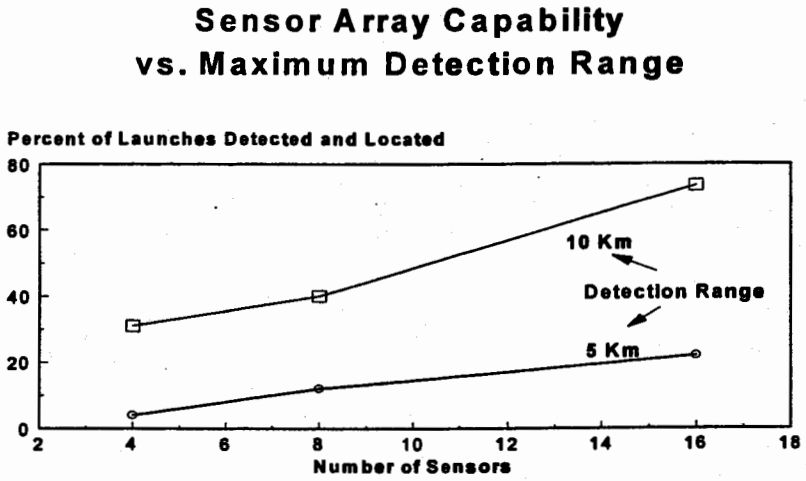

Figure 6. Maximum Detection Range Sensitivity (U)

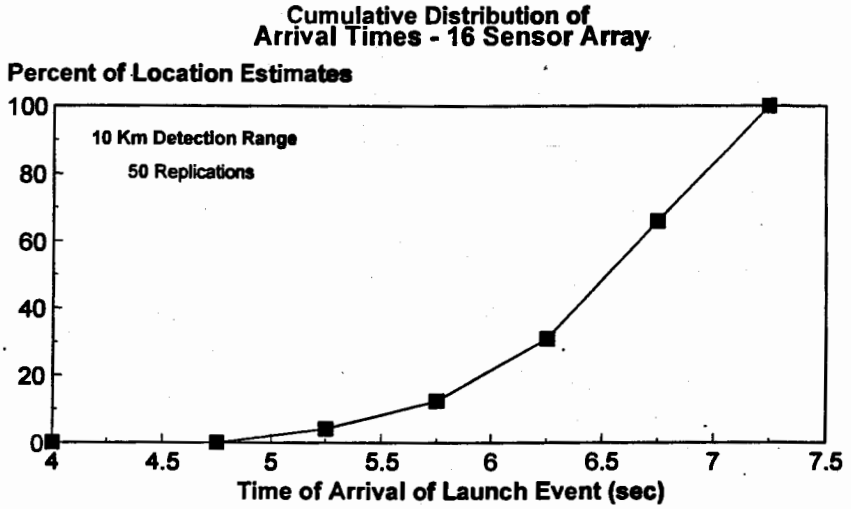

Figure 8. Maximum Arrival Times - 16 Sensor Array (U)

DoD
b(1)

(U) Detailed Command, Control and Communication (C3) architecture requirements for data transmission between sensors and interceptor platform were not considered in this study. Rather, it was assumed that a seismic sensor array could receive the launch signal

(U) CONCLUSIONS

(U) The results of this study indicate that a moderately small number of capable, reliable, well-placed seismic sensors could successfully detect and locate enemy TBM launches.

(U) The key assumptions underlying this conclusion area:

a. sensors can be suitably emplaced in the launch region and will be operational at the time of launch.
b. sensors will be able to identify TBM launches over the detection range and with the reliability modeled in the simulations.
c. the geology of the launch area is well-represented by the model used in estimating launch location.
d. there are no ambiguous signatures when near-simultaneous launches occur.

(U) In the baseline case, sensors with 10 km detection range and .9 reliability each covered about 25% of the launch area and a 16 sensor array was able to detect and locate ~75% of all launches. If the detection range is only 5 km, then only about 25% of the launches in the scenario studied can be detected and located. In general, launch detection

by four or more sensors is required to provide accurate location estimates, so the density and overlapping patterns of the sensors are important determinants of array performance. In this study, for 16 sensors the density is 16/(25*50)=1 sensor per 78 km^2, and this figure might be used to provide a rough estimate of sensor requirements in other launch scenarios. Neither the launches nor the sensors were uniformly distributed throughout the launch area in this study, so 'results may vary' in other applications.

(U) In summary, two components of this proposed boost-phase sensor-to-shooter architecture were analyzed. The detection and location phase seems promising although some risks are inherent, such as geology uncertainty, and a variety of issues pertaining to sensor emplacement, performance, and data processing would need to be resolved. On

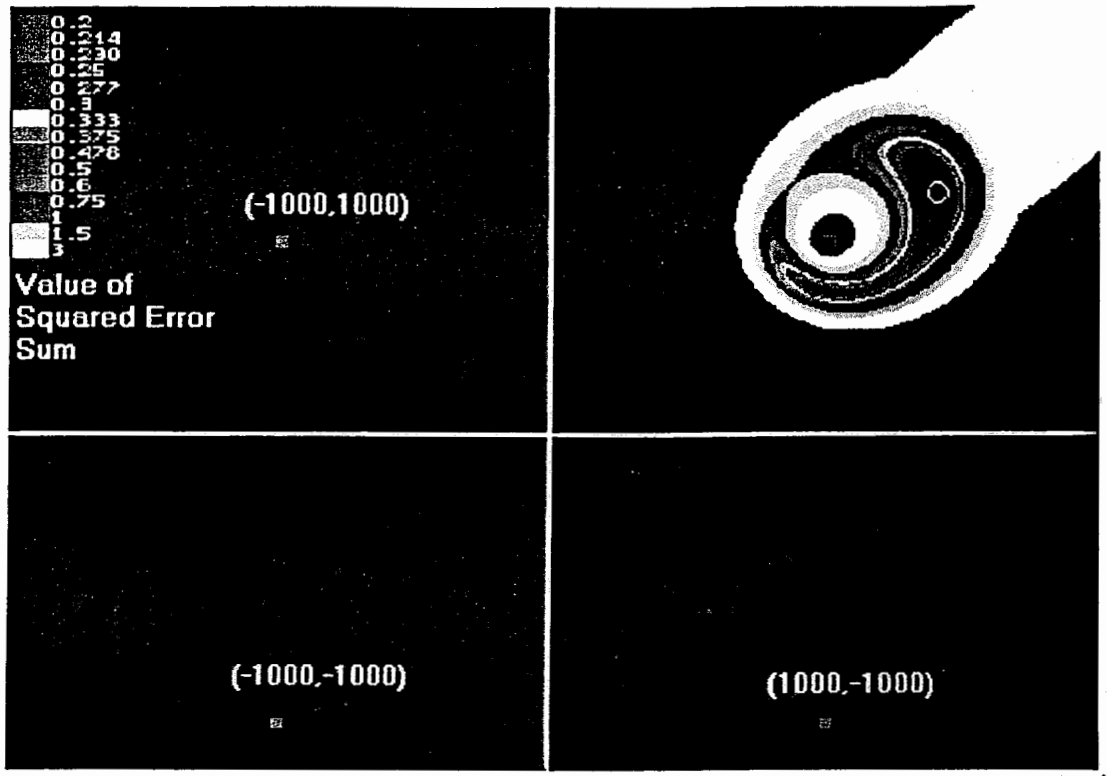

Figure A3. Multiple Minima on Cost Function

Launch Point Estimation for a Three Layer Model

Truth Model TOA:

The "actual" time of arrival (TOA) of the seismic signal at a sensor located a distance r from the source location is

$$\text{TOA} = t_{oa} = \frac{2d_1}{c_1 \cos\theta_1} + \frac{2d_2}{c_2 \cos\theta_2} + \frac{1}{c_3}\left[r - 2(d_1 \tan\theta_1 + d_2 \tan\theta_2)\right] \qquad (1)$$

where d is the thickness, c is the sound speed, and θ is the refraction angle at the respective layers.

Let θ_{1m} and θ_{2m} be the refraction angles in layers 1 and 2 which minimize t_{oa}. Then

$$\sin\theta_{1m} = \frac{c_1}{c_3}$$
$$\sin\theta_{2m} = \frac{c_2}{c_3} \qquad (2)$$

If c_1 or c_2 is greater than c_3, the minimum time path will never be through layer 3. Also,

acoustic time of arrival = r/c_0 (3)

surface wave time of arrival = r/c_1 (4)

1st refracted wave TOA = $$\frac{2d_1}{c_1 \cos\theta_{1m}} + \frac{1}{c_2}\left[r - 2d_1 \tan\theta_{1m}\right] \quad (5)$$

2nd refracted wave TOA =

$$t_{oa} = \frac{2d_1}{c_1 \cos\theta_{1m}} + \frac{2d_2}{c_2 \cos\theta_{2m}} + \frac{1}{c_3}\left[r - 2(d_1 \tan\theta_{1m} + d_2 \tan\theta_{2m})\right] \quad (6)$$

If more than three layers are included in the model,

nth refracted wave TOA =

$$t_{oa} = \sum_{i=1}^{n-1} \frac{2d_i}{c_i \cos\theta_{im}} + \frac{1}{c_n}\left[r - 2\sum_{j=1}^{n-1} d_j \tan\theta_{jm}\right] \quad (7)$$

The actual TOA will be the minimum of the above TOAs.

Measured TOA:

The "measured" TOA, t_{oam}, is obtained for each of the sensors by taking the corresponding t_{oa} and adding a random measurement error (standard deviation input by user) that represents the accuracy of the sensor. The smallest of the measured TOAs is taken to be a reference and a relative measured TOA, rt_{oam}, is obtained. Corresponding to these relative measured TOAs there are relative actual TOAs, rt_{oa}. The sum of the squared differences between these two values will be used to determine a launch point estimate.

Launch Point Estimate (LPE):

Let $rt_{oa}(x,y)$ be the actual relative TOA obtained when the source is located at (x,y). Then a two dimensional search is performed over a region determined by the maximum range of the sensors looking for the local minima of the function

$$L(x,y) = \sum_{k=1}^{n_s}\left[rt_{oak}(x,y) - rt_{oamk}\right]^2 \quad (8)$$

where n_S is the number of sensors within range of the source. An error is issued if n_S is less than three.

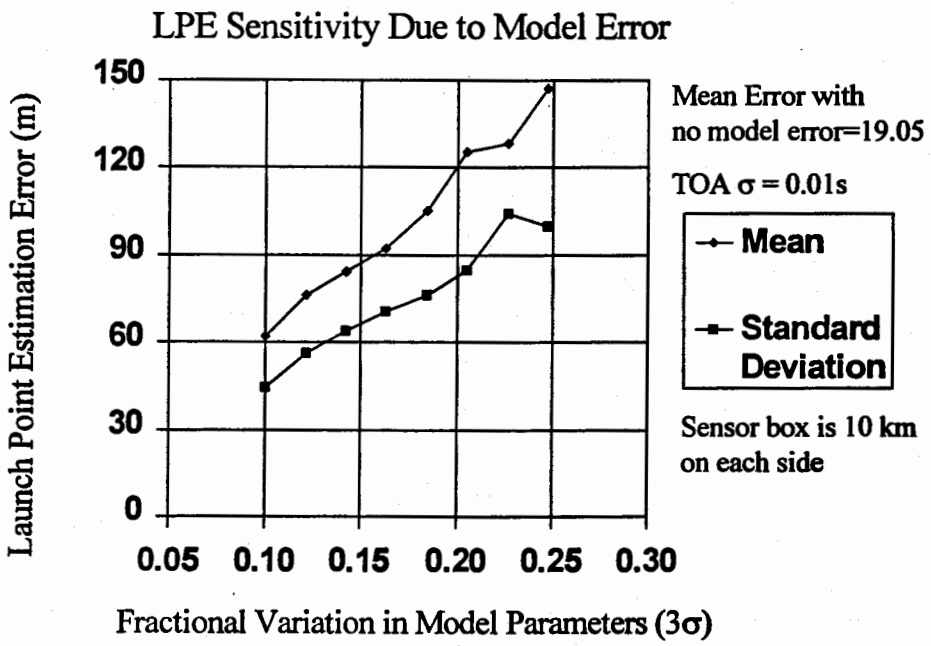

Figure A4. LPE Sensitivity - 10 km Case

A second case, with the sensors in a 2 km box, is provided in Figure A5 to illustrate the reduced sensitivity of the LPE when the sensors are more closely spaced.

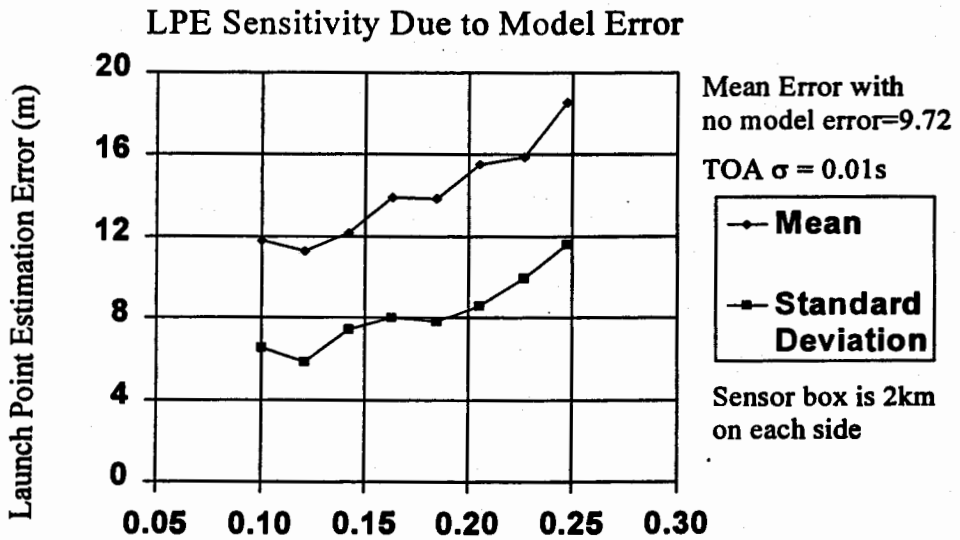

Figure A5. LPE Sensitivity - 2 km Case

1. What initiatives are currently underway?

A. Tactical Unattended Ground Sensors (TUGS)

The TUGS program objective is to develop seismic, acoustic, and magnetic sensors for monitoring and characterizing underground facilities. Specific TUGS tasks are indications and warnings (detection of activity), equipment identification and location within the facility, and battle damage assessment. Hand emplaced sensor units will be developed for the Counterproliferation Advanced Concept Technology Demonstration (ACTD) in FY98. An air delivery capability will be developed in late FY98 and FY99.

Sponsor: Defense Nuclear Agency

POC: Brad Parks, (505)844-6883

B. Sensor Evaluation Model (SENSEM)

Sandia's SENSEM computer simulation model provides a means to investigate several important aspects of underground facilities. [redacted] Users also deploy packages of various types of ground-based sensors to collect intelligence on vehicle movements.

Classified by: R. G. Easterling, Mgr., New Initiatives Dept. 5412, 4/10/96,
Derived from: [illegible]
Declassify on: [illegible]

Using SENSEM, users can represent operational activities of critical systems such as Multiple Rocket Launchers and tactical missiles as they move from underground hide sites to firing positions and return to hide sites. The utility of ground-based sensors can be evaluated in identifying and initiating the engagement of these targets during windows of vulnerability.

SENSEM can also be used to represent military and civilian traffic on the road network to include traffic patterns that might be characteristic of critical underground facilities. From these representations, investigations can be conducted of our ability to identify the location and operational status of important facilities through analysis of traffic patterns.

POC: Jim Crowther, (505)844-1206

C. Remote Induction of Signals into Power and Communication Lines

DOE-supported technology presently being developed addresses close-in survey to detect and characterize underground facilities. The present survey capability is very limited for covert operations. However, a closely associated capability has been demonstrated to be technically viable in the course of detecting and characterizing underground structures. This capability is remote signature coupling for two-way communication into and out of underground structures. The latter capability can support such intelligence needs as: (1) remote location of previously intercepted equipment acquired by a hostile operation and placed in service on the power grid at an unknown location; (2) covert transmission of operative messages or information from clandestinely installed sensors inside a facility; (3) intra-facility/sensor communication; (4) remote interrogation of a suspect power grid to estimate its linear extent to unknown termination points; and (5) (not yet demonstrated) remote imaging of the physical location and distribution of the power grid through induction of highly unique signals onto the suspect grid to facilitate remote tracking of segments of high interest.

POC: Dan Cress, (505)844-7182

D. Coherent Change Detection (CCD)

CCD is a technique that uses 2 complex radar images in a way that permits the detection of extremely subtle changes in the earth, e.g., vehicles traveling on dirt roads. This technique is currently being used to detect evidence of activity around sites such as chemical and biological facilities.

POC: Tom Prevender, (505)844-8768

E. Airborne Multisensor Pod System (AMPS)

AMPS consists of three pods carried on a P-3 Orion aircraft. AMPS Pod 1 contains a Synthetic Aperture Radar (SAR), AMPS Pod 2 contains a Multisensor Imaging system (MSI), and AMPS Pod 3 (in development) contains Effluent Species Identification (EFI) sensors. The data from the AMPS Pods can be used for Coherent Change Detection (CCD), or multisensor data fusion. The SAR Pod is being upgraded to an Interferometic SAR (IFSAR) using two antennas which will result in high-quality terrain elevation maps (3-D). AMPS has been used to observe underground facilities at the Nevada Test Site (NTS) through characterization of surface features such as ground subsidence, adit identification, and muck pile changes.

POC: Bob Huelskamp, (505)844-0496

F. Gravity Gradiometry

Variations in the local gravity field can be used as indicators of voids or structures underground. Measurement of the gravity field and its gradient can locate underground structures. Recent work has been directed toward both the improvement of the gravimeters used to measure the gravity field and the signal processing algorithms used to analyze the data.

POC: Bob Asher, (505)844-5900

Impact of CTBT

The Comprehensive Test Ban Treaty (CTBT) bans any nuclear weapon explosion or other nuclear explosions

- **Constrains the development of new-design weapons**
  - Will result in some loss of confidence in the nuclear weapons stockpile
- **The ability of the US to live with a ban on nuclear testing depends on having a vigorous Stockpile Stewardship Program (SSP).**
  - Guard against aging-related problems
- **The SSP is designed to:**
  - Provide the capability to survey and assess the stockpile for problems
  - Replace weapons components as needed
  - Certify the rebuilt weapons

(CTBT) has reduced our flexibility and options to meet future nuclear deterrent requirements

The CTBT prohibits nuclear explosions. In the past, the nation relied on full-scale integral nuclear testing to ensure the safety, reliability, and performance of our weapons. Furthermore, we relied on nuclear testing to ensure that our systems continued working as they aged.

The CTBT will constrain treaty-compliant nations from making significant advances in nuclear weapons.

Our ability to certify modifications, such as a life extension refurbishment of the enduring stockpile, depends on the success of the Stockpile Stewardship Program (SSP). The success of SSP, in turn, depends on a competent and motivated cadre of nuclear weapons experts, the accelerated strategic computing initiative (ASCI), new experimental facilities, infrastructure improvements, archiving, and funding.

- Stockpile Life Extension
- Safety and Use Control Policy
- Performance margin maintenance and improvements
- Manufacturing streamlining
- Specific stockpile issues

Nuclear Weapons Program

March 1999

UNCLASSIFIED

Los Alamos NATIONAL LABORATORY

11

The four major drivers for change are as follows:

1. National strategy and policy. The United States will adjust its security strategy and policy as the world changes. Treaties, such as START, will likely force changes in the deterrent structure. National nuclear policy will continue to evolve. There will likely be budget constraints on both DOE and DoD. In addition, laws and treaties, particularly in the environmental area, make components extremely expensive or impossible to replace as they were originally designed.

2. DoD initiatives. As many of the DoD delivery platforms reach the end of their lifetime, they will need to be replaced. This presents an opportunity to reevaluate the required military characteristics in light of the post – cold war era. The evolution of technology will probably lead to changes in the defined stockpile-to-target sequence (STS), thus placing new requirements on warhead designs. In addition, new mission needs statements could force changes in both the military characteristics (MCs) and STSs.

3. DOE initiatives. As existing warheads reach the end of design life, we will rebuild the warheads through the stockpile life extension programs (SLEPs). DOE must ensure the systems meet the MCs and STSs, but some of the components will be different. We have seen an evolution in surety standards in the past, and as the terrorist threat evolves, we should expect to see some further evolution in these requirements. DOE is responsible for the safety, surety, and performance of US nuclear weapons. Our confidence rests primarily on our nuclear test history. If we find reason to believe that we do not have enough performance margin in some systems, we may need to make a change. The manufacturing infrastructure is being sized and configured for a post–cold war era, but it will produce some components that are different from those originally manufactured; maintaining confidence will be a challenge. We may also find something in our surveillance program that could force change.

4. Technology. Sunset technologies, such as we have seen in the electronics industry, will force change. There are components and materials that are no longer available on the market; the W76 mount material and [redacted] are examples. The evolution in the nonnuclear technologies can affect delivery system capabilities. Improved advanced conventional weapons may replace nuclear weapons in some areas. Finally, changes in the defense systems may force changes in the US force posture.

Drivers

Secretary of Defense Richard B. Cheney, November 12, 1991 remarks to the San Diego Union editorial board

" Unfortunately, if you look at the historic record, we have never, ever gone through one of these periods and gotten it right. We've always screwed it up. Every single time when it's happened previously we've been so quick to cash in the peace dividend, to demobilize that force, that within a very short period of time we find that our weakness in and of itself becomes provocative and tempts others to do things they shouldn't attempt; that we always end up having, once again, to commit the force some place – we get in trouble in the world and have to send in troops; that we find ourselves with troops that are not well trained or well equipped, not prepared to go to war."

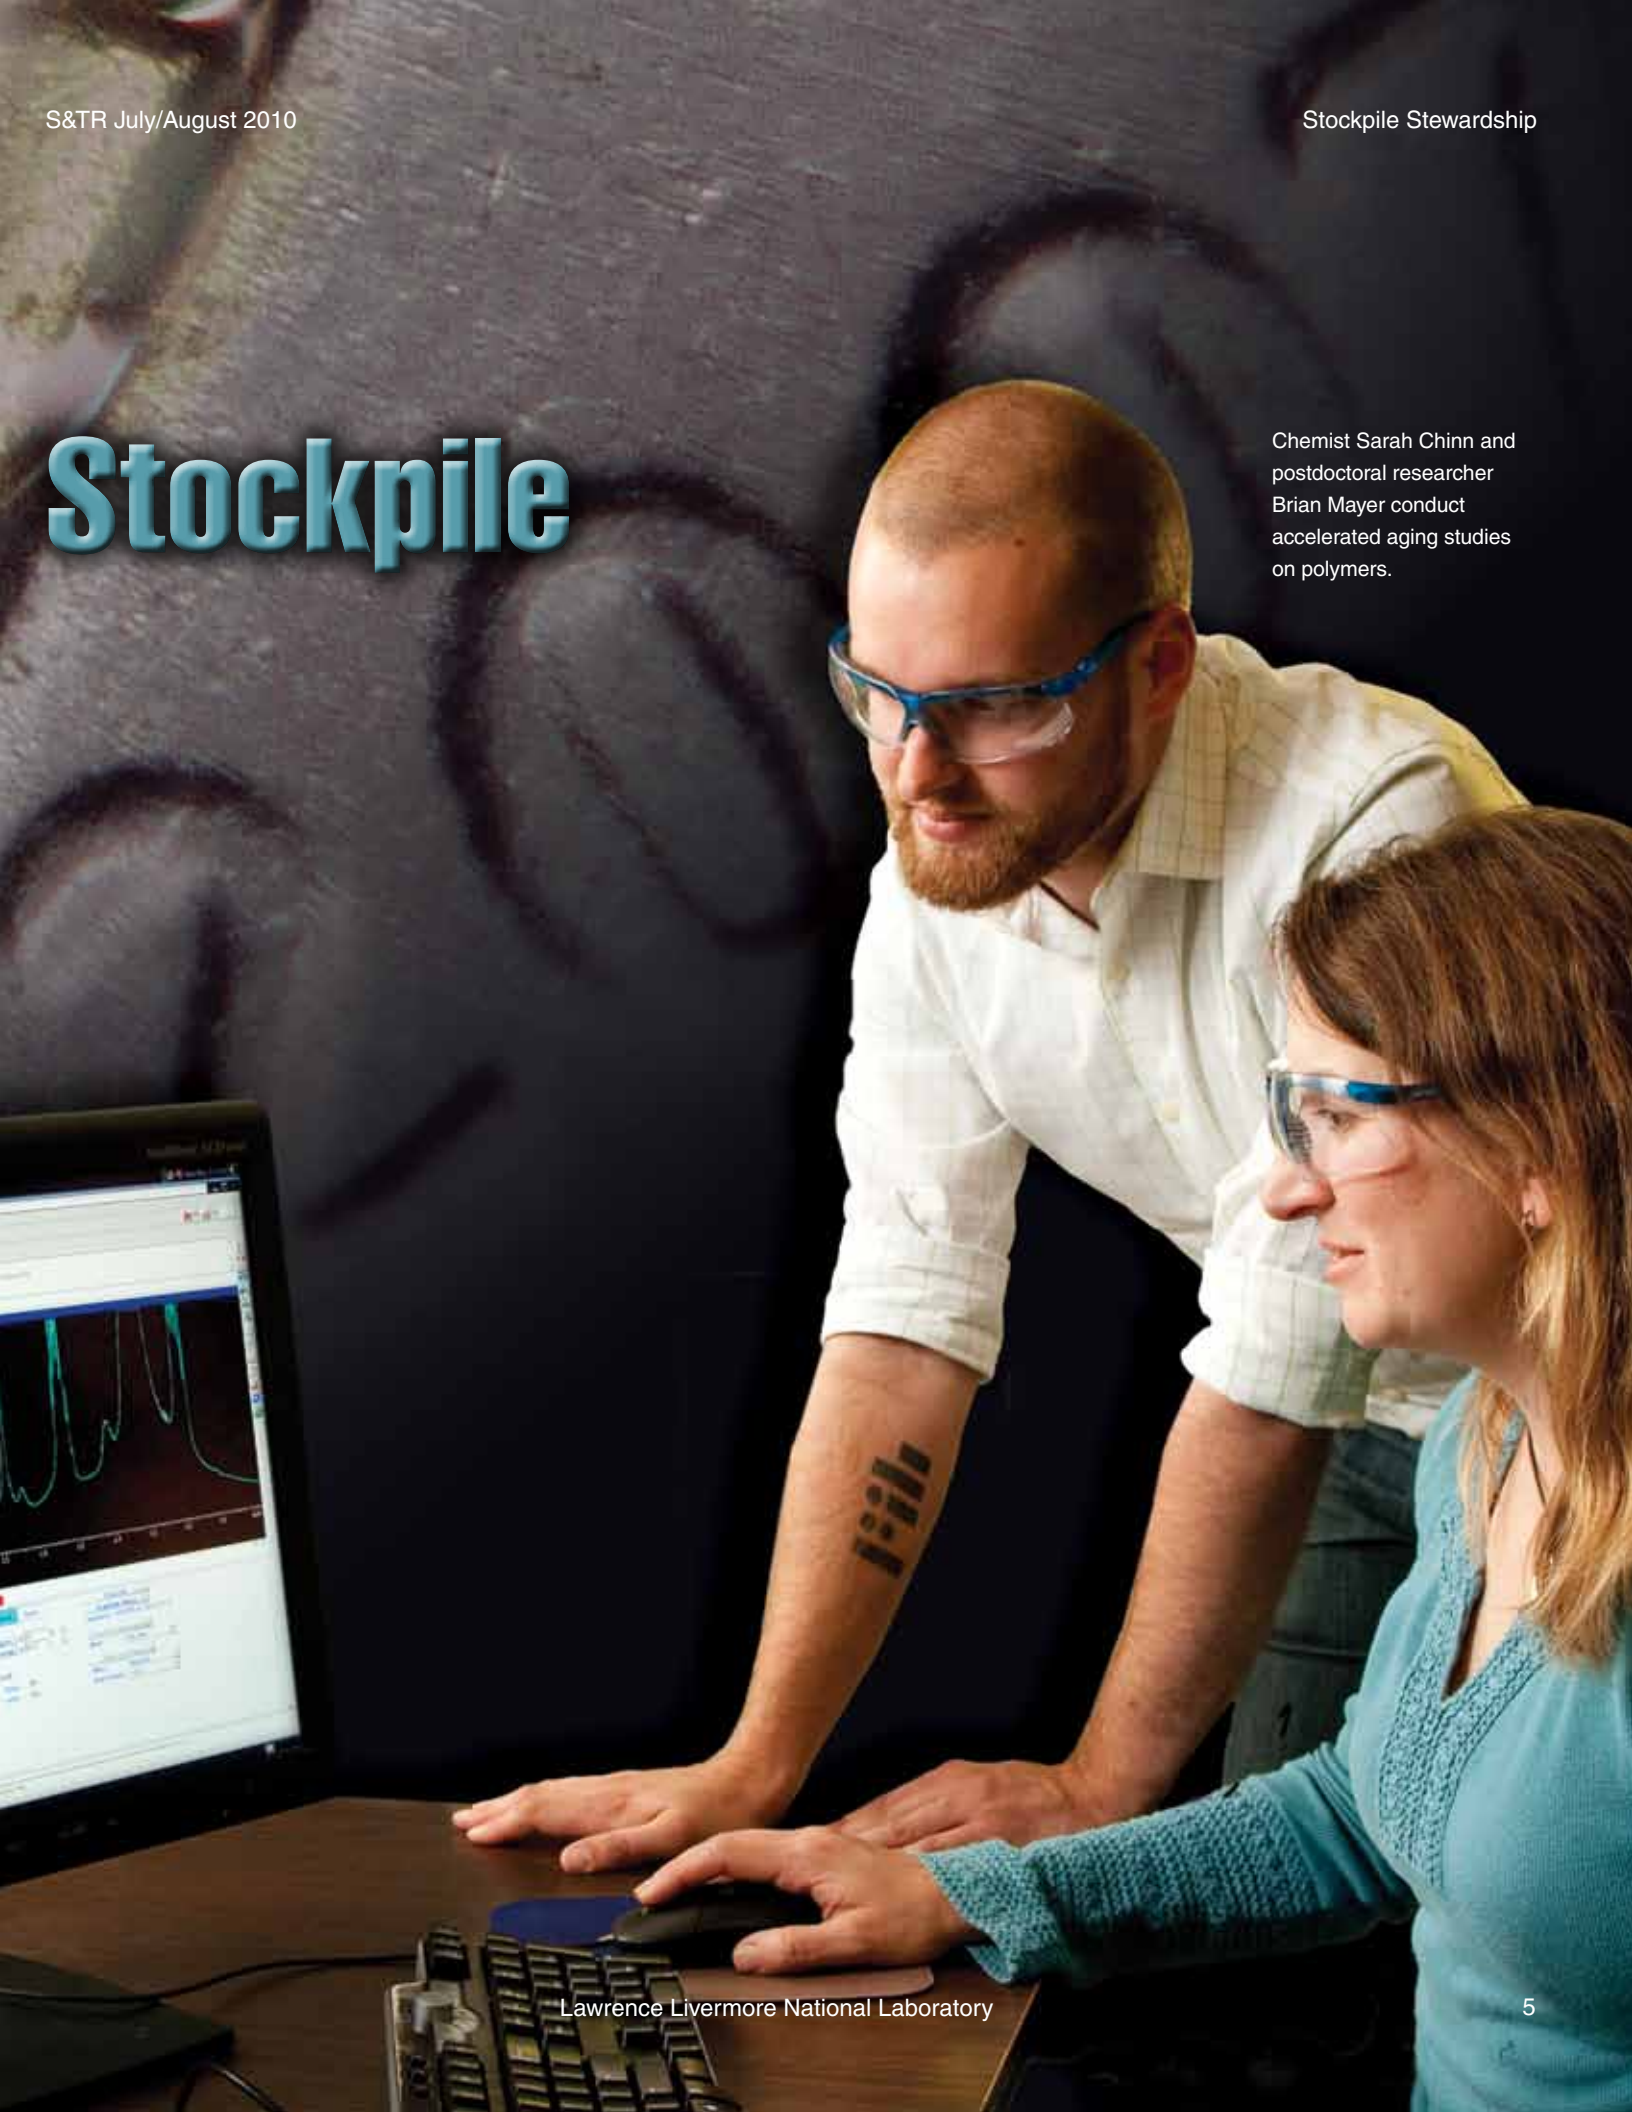
Enhancing Confidence in the Nation's Nuclear

Livermore researchers combine materials research, experiments, and advanced numerical models to anticipate any problems in America's aging nuclear weapons.



SOME experts compare the National Nuclear Security Administration's (NNSA's) mission to maintain and enhance the safety and security of America's nuclear stockpile with the National Aeronautics and Space Administration's mission to safely land a human on the moon. The comparison is often made because nuclear weapons are extremely complex devices, with thousands of components that must work together seamlessly to produce a nuclear detonation. What's more, since 1992, scientists can no longer check the performance of nuclear weapons by detonating them underground at the Nevada Test Site. (See the box on p. 6.)

Nuclear weapon components are made of various materials such as high explosives (HEs), steel, plutonium, uranium, and polymers (plastics). Scientists have found age-related changes in some of the components and materials in weapons removed from the stockpile and disassembled. These changes are occurring, in part, because many weapons have been in the stockpile longer than originally intended. Plastics can break down and give off potentially destructive gases, metals can corrode and weaken, and coatings can deteriorate. Some materials may change properties unpredictably in response to the high radiation fields, fluctuating temperatures, and other environments to which nuclear weapons are subject.

In the absence of developing new nuclear weapons, experts must work to extend the life of existing units and understand how their constituent materials and components age. Scientists conduct a comprehensive program of weapon surveillance (close examination), laboratory experiments, and maintenance and refurbishment of components. Data from all activities are used to refine computational models, some of which serve as electronic surrogates for underground testing. These combined activities, which require the efforts of

Stockpile

Chemist Sarah Chinn and postdoctoral researcher Brian Mayer conduct accelerated aging studies on polymers.

chemists, materials scientists, engineers, physicists, and computer scientists, are called stockpile stewardship. The Stockpile Stewardship Program has been enormously successful to date and has permitted the directors of Lawrence Livermore, Los Alamos, and Sandia national laboratories to annually assess the status of the stockpile and conclude that currently a need does not exist for nuclear testing.

Livermore chemist Bob Maxwell notes that relying solely on routine surveillance of nuclear weapons provides little insight into possible future changes in materials and components that could affect safety or performance. "Inspecting or testing components doesn't help us predict beyond today," he says. "For example, a test of HE material taken from a stockpiled unit may tell us the material is capable of detonating this month but does not necessarily give us confidence in its performance a decade from now."

To gain added confidence, Livermore experts lead numerous efforts in NNSA's Enhanced Surveillance Campaign, aimed at producing informed estimates about how nuclear weapon materials and components will likely change over the next one to two decades. Results from enhanced surveillance efforts are fundamental to life-extension programs, which entail refurbishing or replacing parts to extend the time that a specific weapon system can safely and reliably remain in the stockpile. "We must look 15 to 20 years in the future because it can take that long to fix a problem, given the current lean nuclear weapons infrastructure," explains Bill McLean, manager of Livermore's Enhanced Surveillance Campaign.

For several years, a key thrust of enhanced surveillance centered on studying the properties and aging of plutonium pits found in every modern nuclear weapon. In 2006, the two NNSA nuclear design laboratories—Lawrence Livermore and Los Alamos—issued a joint report stating that "subtle age-induced changes in the atomic structure and composition of plutonium do not, in themselves, limit the lifetime of U.S. weapon pits," and "the majority of plutonium pits for most nuclear weapons have minimum lifetimes of at least 85 years." That finding has permitted Livermore stockpile stewards to shift the focus of their attention to obtaining a better scientific understanding of how other weapon materials and components age and interact during the decades they remain in the stockpile.

Some Livermore enhanced surveillance experiments artificially age materials and components by subjecting them to high temperatures or intense gamma or neutron radiation. Other efforts focus on developing new diagnostics and nondestructive tests. Data obtained from

Managing the Nation's Ever-Shrinking Nuclear Arsenal

The nation's current nuclear stockpile consists of sea-based, land-based, and air-carried systems. For decades, the performance of the complex nuclear explosive package as well as the nonnuclear components in these weapon systems was confirmed with underground tests conducted at the Nevada Test Site. Since the nuclear test moratorium was adopted in 1992, the U.S. has deployed no new weapons, while thousands of existing weapons have been retired or dismantled.

Under the 2002 Moscow Treaty on Strategic Offensive Reductions, the U.S. has been reducing the number of its operationally deployed nuclear weapons to between 1,700 and 2,200 by 2012. In April 2010, U.S. President Barack Obama and Russian President Dmitry Medvedev signed a new arms reduction pact that pledges to reduce the number of operationally deployed, strategic nuclear weapons in both countries and commits the nations to adopt new procedures for verifying which weapons each country possesses. Under this treaty, called New START, both countries will be limited to 1,550 ready-to-use, long-range nuclear weapons. In the future, as the number of U.S. weapons shrinks, fewer weapons will be available for disassembly, underscoring the importance of nondestructive testing of existing weapons and science-based studies of materials and components.

The New START force reductions are a key step in implementing the Obama administration's strategy to reduce nuclear dangers, which is described in the 2010 Nuclear Posture Review (NPR). NPR emphasizes as one of its five major findings the need for the nation to sustain a safe, secure, and effective nuclear arsenal as long as nuclear weapons exist.

Stockpile stewardship is a responsibility of the National Nuclear Security Administration (NNSA), which was established by Congress in 2000 as a semi-autonomous agency within the Department of Energy. The Stockpile Stewardship Program includes science and engineering experiments and computer simulations to study the mechanisms of how nuclear weapon components age. NNSA assesses each nuclear weapon to detect or anticipate potential problems that may come about as a result of aging. As part of that effort, each weapon receives routine maintenance and surveillance (a thorough examination). In addition, the agency extends nuclear warhead lifetimes through the refurbishment of critical components and safely dismantles and disposes of units that have been retired.

NNSA nuclear weapons laboratories—Los Alamos, Lawrence Livermore, and Sandia—assess the health of the current stockpile, design the components and systems for the life-extension programs, and certify the life-extended models when they enter the stockpile. Over the past decade, NNSA has funded new experimental capabilities at the laboratories, including the National Ignition Facility at Livermore and the Dual-Axis Radiographic Hydrodynamic Test Facility at Los Alamos. One of the most far-reaching efforts was instituting the program now known as Advanced Simulation and Computing, which permits the computational "testing" of components and entire systems, and which has impelled a transformation of the nation's supercomputing industry.

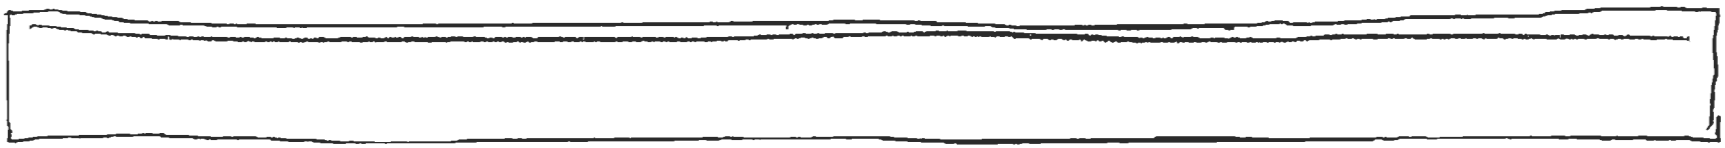
Background



- **NWC approved creation of a Joint Reliable Replacement Warhead Project Officers Group (RRW POG) on 23 March 2005**

- **NWC memorandum dated 11 April 2005 establishes a RRW POG**
  - Oversee a laboratory design competition for an RRW
  - First deployment on SLBM
  - 18 month study
  - Assess technical feasibility, design definition and cost
  - At the conclusion of the study, the RRW POG will present the preferred RRW design options and recommendations to the NWCSSC for approval
  - Requested Lead Project Officer brief NWCSSC on study plan in July 2005 including goals, strategy, and milestones

UNCLASSIFIED
UNCLASSIFIED

Reliable Replacement Warhead Study Goals

DEDICATION

This handbook is dedicated to Dr. Mark M. Mills who conceived the Pinon Project and developed in detail the initial plan. Dr. Mills lost his life in a helicopter accident at the Eniwetok Proving Grounds on April 6, 1958 while making preparations for the execution of the experiment.

2121

PREFACE

This report comprises a handbook which was intended to be used by technical representatives from the United Nations Scientific Committee on the Effects of Atomic Radiation during a demonstration of a low fission to fusion yield explosion at the Eniwetok Proving Grounds. The handbook includes the operational concept and detailed technical descriptions of the methods of measurement which were to be used to determine the total energy release and the fission energy release. The total energy release was to be measured by rate of fireball growth measurements, and is described in the section entitled Fireball Determination of Total Yield prepared by Dr. Lewis Fussell of Edgerton, Germeshausen and Grier, Inc. The fission yield was to be determined by a radiochemical method and is described in Chapter III prepared by Dr. Roger Batzel of the University of California Radiation Laboratory.

This demonstration shot, designated Pinon, was cancelled on July 26, 1958. However, because the techniques described here had not been published previously it was considered desirable to publish the handbook.

GERALD W. JOHNSON
Technical Director

2122

FOREWORD

In 1954 the United States had already begun research to find means of drastically reducing the proportion of fission yield required in the thermonuclear explosion. This was an effort to develop nuclear explosives whose residual radioactivity could be confined more nearly to the area of blast and thermal damage, and to reduce greatly the amount of radioactive fallout which would be created from such explosions and given world-wide distribution. In July, 1956, the United States announced that it had achieved initial success in this program and in test firings had found that, with further development, weapons of drastically reduced fission yield could be produced.

The United States has with high priority continued the development of weapons of greatly reduced fission yield in proportion to total yield. A large portion of the current test series (Hardtack) is being devoted to making possible a material increase in the number of reduced-fission type weapons that can be produced.

On April 25, 1958, the United Nations, on behalf of the United States, offered to nations represented on the U. N. Scientific Committee on the effects of atomic radiation an invitation for their representatives to observe a demonstration of the firing of a weapon of greatly reduced fission yield. This demonstration will provide opportunity for the U. N. Observers to witness the firing of such a device and to make a determination, through instrumentation and laboratory analyses, of the weapon's total and fission yield.

It is the purpose of this handbook to describe briefly the operational procedure to be followed for the U. N. observance, the instrumentation to be used, and the analyses to be made.

2125

have been derived through correlation of fireball-growth parameters with the total energy-release of fission bombs as determined by radiochemical means. On the other hand, theoretical studies have given the scaling constants in terms of the gamma (ratio C_p/C_v of the specific heats) for air at elevated pressures and temperatures; comparison of the two methods has actually thrown much light upon these characteristics of the medium in regions of strong shock.

It was shown, prior to the first atomic explosion at New Mexico, that the energy release may be expressed by

$$E = K\rho_o R^5 t^{-2} \qquad (1)$$

where R is the radius of the spherical shock wave in an ideal medium, t is the time after the explosion, ρ_o is the atmospheric density, and K is a dimensionless parameter dependent upon the gamma of the medium inside the fireball. This relation was published by its originator, Sir Geoffrey I. Taylor[1], in a pair of articles that also compared the theoretical prediction with the experimental observations obtained during the New Mexico (Trinity) shot of 1945.

The observations obtained for the first several test shots of the USAEC showed that equation (1) was generally not satisfied until the latter phases of visible shock propagation; but that after a preliminary period of deviant growth it did indeed settle down and obey equation (1) for a time interval long enough to permit the empirical evaluation of the parameter K, in terms of the radiochemical yield. From this observation it follows that the gamma of air remains approximately constant for a considerable range of fireball temperatures and pressures.

When the quantities in equation (1) are expressed in CGS units, the first determination based on about six shots was K = 1.740. After a few years it appeared that the value K = 1.709 gave a better fit with the radiochemical data. This value continues to be good to this day, when applied to the prescribed portion of the hydrodynamic-growth curve.

3. Taylor Theory

Taylor considers the total energy release to consist of two parts:

---

[1] G. I. Taylor, Proc. Roy. Soc. 201A, 159, 175 (1950).

2129

$$\text{the kinetic energy,} \quad K.E. = 4\pi \int_o^R \frac{1}{2} \rho u^2 r^2 \, dr$$

$$\text{and the heat energy,} \quad H.E. = 4\pi \int_o^R \frac{pr^2}{\gamma - 1} \, dr \ .$$

He starts with the equations of motion and continuity and the equation of state of a perfect gas. He determines the boundary conditions in terms of the Rankine-Hugoniot relations, which describe the conditions at the shock front. He finds it necessary to use approximations for these relations. The approximations are excellent as long as the pressures are very large compared with the ambient pressure. He concludes, on page 163, that the total energy release is given in equation (1) and that K is the sum of two integrals, each depending only on gamma.

Two errors may be noted in his derivation. On page 162, his equation 16a, the coefficient $(2\gamma/\gamma + 1)$ is inverted but is corrected in equation 16b. On page 161 a more fundamental error occurs, when he expresses the velocity of sound in air in terms of the variable parameter gamma; he should have used the value $\gamma_o = 1.40$. It turns out that this causes but a small error in the final result. It should also be noted that in calculating the energy release of the New Mexico shot, Taylor assumed an ambient air density of 1.25×10^{-3} g/cc, considerably greater than the true value 1.006×10^{-3}.

Taylor evaluates his integrals by means of step-by-step numerical integration, assuming several different values of gamma. These are summarized in his Table 3, page 180. He also derives some approximate formulae to facilitate these numerical calculations. We have re-stated his integral expressions, using $\gamma_o = 1.40$, and have evaluated them using the approximate methods.

The calculated values of K are found to be:

γ	K (Taylor)	K (re-calculation)
1.20	1.727	1.740
1.30	1.167	1.175
1.40	0.856	0.856

Several sources of data are available, from which the probable magnitude of gamma may be estimated. An estimate is all that can be made,

2130

since the actual temperatures in the fireball interior can only be surmised; the surface is certainly much cooler, and we can observe only the surface. The published data may be found in the literature.[2,3,4,5] These data are summarized in the curves given in Figure 1. Although there is some scatter to the data, it is clear that gamma goes through a broad minimum, and is of the order 1.2. Thus Taylor's theoretical scaling constant K = 1.740 differs from the experimental value K = 1.709 by only 2 percent, and we use the experimental number in evaluating all USAEC test shots. The energetic equation is, then,

$$E = 1.709 \rho_o R^5 t^{-2} \text{ (ergs)} \quad . \tag{2}$$

In practice the USAEC has measured the fireball diameter, rather than the radius, and has used a different set of units throughout. Expressing D in meters, t in milliseconds, ρ_o in grams/liter, and E in kilotons, relation (2) may be rewritten:

$$E = 1.272 \times 10^{-8} \rho_o D^5 t^{-2} \text{ kilotons} \tag{3}$$

where we use the conversion factor, one kiloton = 4.2×10^{19} ergs.

This conversion factor, although somewhat arbitrary, has been used consistently.[6]

4. Expected Diameter/Time Curves for Piñon

It has been shown that the energy release from a nuclear explosion in an ideal medium is proportional to D^5/t^2, where D is the diameter of the symmetric shock front, and t is the time since detonation, at which this diameter obtains. In his theoretical derivation Taylor uses a quantity A, which is proportional to $D^{5/2}/t$; similarly we have found it useful to determine a parameter $\phi = D/t^{2/5}$ which is, like Taylor's A, approximately constant for a given shot. The deviations of ϕ from a constant are indicative of extraneous effects (such as varying gamma and also of large masses in the vicinity of the immediate explosion); the constancy of ϕ and the length of the interval over which it is constant lends confidence in the result. Further, a statistical analysis of the scatter of the experimental points in the constant-ϕ region can be used to establish confidence limits for the yield of the explosion.

Figure 2, a log-log plot of the expected diameter-vs-time data for yields of 1, 3, and 10 megatons, shows continuously increasing diameters, and slight deviations from straight lines. These deviations are magnified in the ϕ vs t plot of Figure 3; it is clear that ϕ becomes constant for the interval immediately preceding shock-breakaway, and this interval is used for scaling purposes. After breakaway the shock front is invisible (although it continues to grow with constant ϕ for a while longer), and the fireball itself lags behind. The fireball edges become indistinct and diffuse, and measurements are valueless as far as yield determinations are concerned. An ambient air density ρ_o = 1.15 grams/liter has been assumed in drawing these curves.

The trend of the data, in the early stages prior to constant-ϕ growth, is typical of shots which are exploded with only small amounts of material in the immediate vicinity of the detonation. When large masses must be consumed in the early phases, the growth pattern may be altered drastically; nevertheless it will settle down to the same constant ϕ.

5. Growth into Inhomogeneous Atmosphere

The high-yield nuclear explosion results in a fireball of large physical size. During the period in which yield measurements are to be made the top of the fireball may reach an elevation of about 3,600 ft, where the density of the air is about 90 percent of that at sea level. Thus the fireball

2133

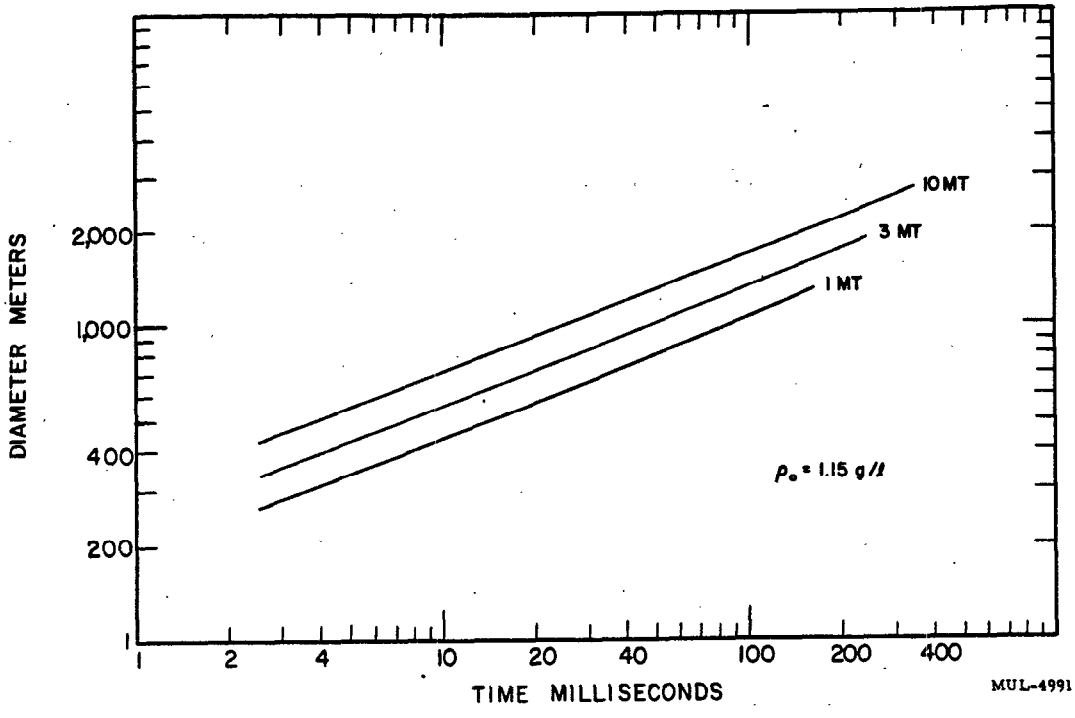

Fig. 2. Fireball growth, diameter vs time – surface shots, ρ_o = 1.15 g/liter.

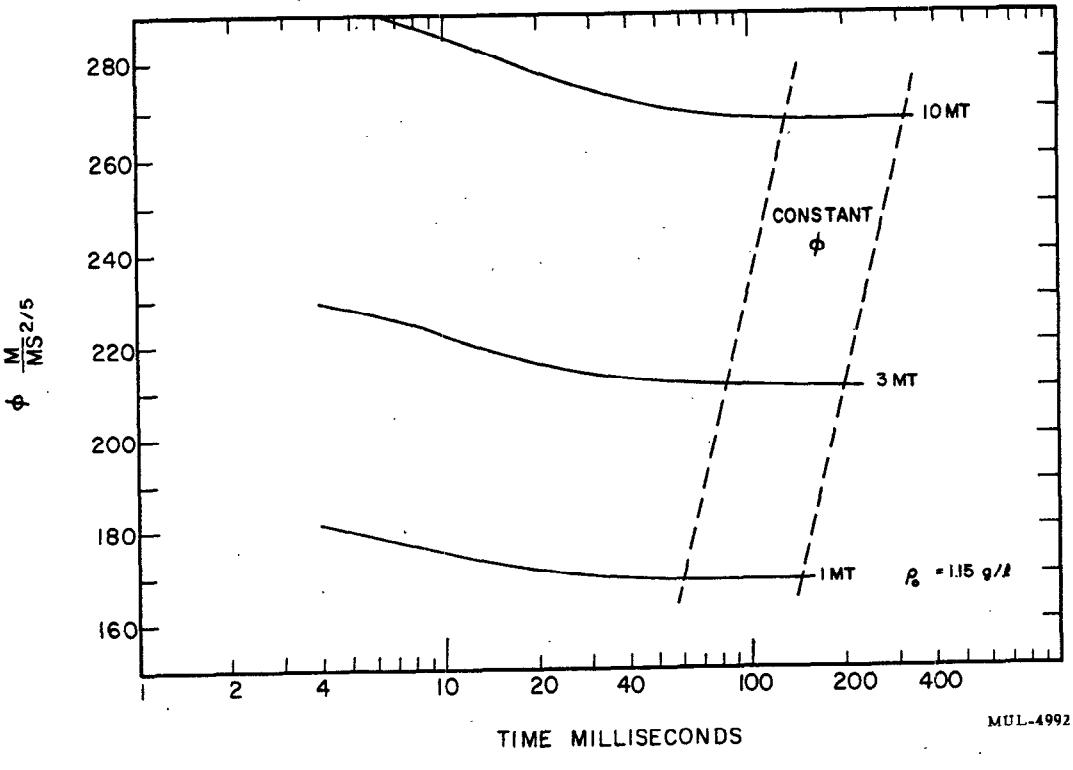

Fig. 3. Fireball growth, ϕ vs time – surface shots, ρ_o = 1.15 g/liter.

2134

can grow more rapidly, and to a greater extent, in the vertical direction than in the horizontal. The result will be a fireball shaped something like half an egg, rather than a perfect hemisphere.

The appropriate air density is that occurring at the center of the fireball area, such that half the area is above, and half below, the chosen altitude. For a hemisphere the altitude for center-of-area occurs at one-half the radius; we apply the same criterion to the distorted fireball, and use a different value of air density for each frame that we measure.

This effect does not alter the validity of the scaling laws; it simply introduces another step that must be taken in the analysis of the data and requires detailed data on the variation of air density with elevation.

6. Ground Reflection Effect

The effect of the rigid water surface must be considered for the Piñon shot, which is to be detonated within a few feet of sea level. The acoustic impedance of water is about 150,000 grams/cm^2/sec, whereas that of air is only 44. The result is that very little energy goes into the water; instead it is reflected almost perfectly back into the fireball and reinforces the shock front that was directed upward initially. The fireball becomes a nearly perfect hemisphere (excluding the effects of the inhomogeneous atmosphere which were just discussed), and the hemisphere represents half of a fireball having twice the apparent energy. Thus the factor $F = 0.50$ is introduced into the scaling equation, and the total yield for a surface burst is given by

$$E = 0.5\, K \rho_o D^5 t^{-2} \quad . \tag{4}$$

7. Measurements Required

It has been shown that four quantities must be measured in order to determine the total fireball energy release:

a) diameter of the fireball,

b) time after burst at which the measured diameter obtains,

c) air density (specific gravity) as function of altitude, and

d) ground-reflection factor.

The diameter of the image of the fireball, formed by the camera lens upon the film, will be measured in the analysis procedure. In order to relate this image to the size of the fireball itself, it is necessary to determine the

2135

magnification factor of the optical system. This factor is equal to the ratio

$$\frac{\text{Distance, camera to plane perpendicular to optic axis containing the fireball diameter}}{\text{Lens focal length}}$$

Since the camera is operated at a slightly tilted angle, τ, the desired optic-axis distance equals the horizontal (ground) distance multiplied by cos τ. It is thus necessary to measure the horizontal distance, L, the focal length, f, and the angle of tilt, τ; once measured these quantities will remain constant for all frames exposed in a given camera. The USAEC measurements are each good to about 0.2 percent, and facilities will be provided to check them to something like 1.0 percent.

The time scale, relating each exposed frame to the time after detonation, will be determined from timing marks placed upon the film while the camera is being exposed. These marks will establish the time after detonation to better than 0.2 percent, and the observer-check will also be good to 0.2 percent.

The air density requires measurements of barometric pressure, temperature, and relative humidity, all three as functions of altitude. These quantities will be measured by means of weather balloons, released on Eniwetok Island shortly before detonation, which will telemeter the meteorological data to the ground. An independent measurement of the ground-level data will be made at the Control Point adjacent to the photo tower on Parry Island; this will utilize a Cenco mercury barometer and a standard sling-psychrometer. These instruments will be available for check-reading by the Observers, prior to and at shot time. From these readings the air density at ground level may be determined to a precision of about 0.2 percent; check values at various altitudes may be derived from this number through the use of the standard atmospheric data (such as those adopted by the NACA), to better than 0.5 percent.

The ground-reflection factor will be taken as equal to 0.50, and no measurements are contemplated.

8. Precision of Measurements

In addition to the individual measurement errors described above, one expects a reading error during the analysis of the films. For each frame

2136

encountered infrequently. For the Piñon shot the images will be approximately hemispherical. The fireball edge will be only moderately sharp, because of scattering in the 20-mile photographic path; scattering may also result in poor exposures of low contrast. Furthermore, natural clouds will probably obscure portions of the fireball, since it will grow to a considerably greater height than the normal low-lying cloud cover. These factors introduce the necessity for exercising some degree of judgment in measuring the fireball diameters.

The orientation of the film on the comparator stage is such that the images will appear to be on their sides, with the horizon vertical. The image of the selected picture is centered, making use of the micrometers and the rotational adjustment, so that the base of the fireball coincides with the vertical diameter of the circular grid pattern. It will undoubtedly be necessary to adjust the illumination for both stages, and in some cases to switch the upper stage light on and off to aid in locating the fireball edge in reference to the grid.

The observer can usually bracket the average diameter quickly by noting the greatest and the least circles of contact. These limits can be narrowed by running the eye around the intermediate circles, finally interpolating to arrive at a best estimate of the average or effective diameter. Experience and practice are required to make this determination quickly and consistently, and without undue fatigue. It is always best, in our experience, to have each picture measured by several persons; in the event of disagreement between them a short discussion usually suffices to reach a joint reading agreeable to everyone.

Before moving the film to read another frame, it will be necessary to measure with the micrometer the distance from the film-speed mark to the trailing sprocket hole. These measurements only need to be precise to about 0.03 inches, or one-tenth of a frame, and a visual estimate may suffice instead of a measurement. They will enable the calculation of the time for the particular picture.

25. Calculation of Total Yield

Measurements and calculations are best worked out in tabular, systematic form. We usually record all measurements and calculations on vellum, which may be reproduced in any desired quantities easily and

2160

quickly. One sheet of paper will summarize the magnification parameters:

horizontal distance: L
camera tilt: τ
optic-axis distance: $L \cdot \cos \tau$
camera focal lengths: f
camera magnifications: $L \cdot \cos \tau / f$, and
the Hauser magnifications for each objective.

Another sheet will summarize the meteorological data, and will tabulate air density ρ_z and the fifth-root of the density, as functions of altitude; the fifth-root data will also be plotted on graph paper against altitude.

Four additional sheets, one for each film, will tabulate for each picture measured:

the time and image diameter,
the corresponding object diameter, D
the parameter $\phi = D \cdot t^{-2/5}$, and also
$\phi \rho_z^{1/5}$.

Tables giving $t^{-2/5}$ as a function of t, will be provided to aid these last two determinations, and the density chosen will correspond to an altitude equal to one-fourth the diameter.

The computed parameter ϕ will be plotted against log (time) to determine the interval over which it is essentially constant. Finally an average figure will be determined for $\phi \rho_z^{1/5}$, over the indicated time interval and over all four cameras; this value will be raised to the fifth power and multiplied by $\frac{1}{2} \times 1.272 \times 10^{-8}$ to obtain the total energy release in kilotons.

2161

CHAPTER III

RADIOCHEMICAL DETERMINATION OF FISSION YIELD

A. THEORY

The fission yield of a device can be measured by radiochemical techniques by using macroscopic tracer of sufficient amount to allow a measure of the fraction of total debris collected in a sample. From this bomb fraction and the absolute number of fissions collected in a sample, the total fission yield can be measured.

The bomb fraction tracer is placed in such a manner as to insure that the material will mix completely with the fission products and be distributed uniformly with the fission products throughout the post-shot cloud. Aircraft equipped with units designed to collect representative samples of debris on filter papers are flown through the cloud.

The samples are removed from the aircraft by remote handling techniques, the radiation levels measured and the samples packaged and returned to the laboratory for dissolution and analysis. Fractions of the solution containing the filter paper are then taken for measurement of the bomb fraction and the absolute number of fissions. Uranium in the form of U_3O_8 is used as the tracer. Molybdenum 99 has been chosen as the fission product to be determined. The total fissions are given by

$$\text{Total fission} = \frac{\text{Initial uranium}}{\text{Uranium in sample}} \times \text{Fissions in sample.}$$

Since one megaton TNT equivalent is defined as 10^{15} calories and the prompt energy per fission is 179 Mev, 1.45×10^{26} fissions are equivalent to one megaton.[10]

B. TECHNIQUES

PREVIOUSLY DELETED

1. Bomb Fraction Tracer

The bomb fraction tracer to be used is [redacted] uranium partially depleted in U^{235} in the form of uranium oxide (U_3O_8). The uranium oxide has a bulk density of about 2.5 g/cc and will be packaged in approximately 100-pound containers.

[b] J. Terrell, W. E. Scott, J. S. Gilmore, and C. O. Minkkinen, Item 55-136 (Presented at the American Physical Society Meeting, Sept. 3, 1953, Albuquerque, New Mexico).

The beta proportional counters (Figure 15) used to determine Mo^{99} disintegration rates are calibrated using Pb^{210} - Bi^{210} - Po^{210} samples of known disintegration rates obtained from the National Bureau of Standards. Pertinent data for each standard are provided by the National Bureau of Standards. These Ra D+E samples are counted in the same position relative to the counter as the Mo^{99} is to be counted. A thin ($7mg/cm^2$) aluminum absorber is placed close to the counter to absorb any α radiations from Po^{210} and β radiations from Pb^{210}. The observed counting rate is corrected for absorption by air gap, absorber, and 3.4 mg/cm^2 aluminum counter window, back-scattering from the Pd-Ag mount, and self-absorption of the PbO_2 electro deposit (see Appendix III for sample calculation). The corrected counting rate is divided by the known absolute disintegration rate of the standard sample to give the efficiency, i.e., the solid angle of the counter for a weightless sample mounted on a weightless mounting.

Previously, a carrier-free sample of Mo^{99} was prepared and a measured portion evaporated carefully on a thin Mylar (organic polymer) film supported on a frame. Another measured portion of the active solution was added to a known amount of inactive molybdenum in solution as Mo(VI). The solution was well mixed and heated to 90°C for 15 minutes. Then $PbMoO_4$ was precipitated, washed twice with water, once with acetone, and dried for one hour at 130°C. After cooling to room temperature, samples of varying weight were prepared on thin aluminum dishes. All samples were mounted on thick aluminum holders and counted in the proper geometry. Figure 16 shows the results of these measurements.

One may now correct the observed Mo^{99} counting rate for the effects of self-scattering, back-scattering, self-absorption, and absorption due to air gap and counter window in the same manner as for the Ra D+E standard. The aliquot mounted on Mylar is taken as a good approximation to a weightless sample on a weightless backing.

Given the absolute disintegration rate of a sample of Mo^{99} separated from the bomb debris, the following sequence of calculations is performed;

1. The disintegration rate is extrapolated back to the time of detonation, using the known half-life of 66.04 hours.

2. The number of disintegrations per unit time at the time of detonation, is converted into atoms of Mo^{99} through the relationship

$$\text{atoms of } Mo^{99} = \frac{\text{disintegration rate x half-life}}{\ln 2}$$

3. The number of fission events giving rise to the derived number of molybdenum atoms is derived through the relationship

$$\text{numbers of fissions} = \frac{\text{atoms of } Mo^{99}}{\text{fission yield of } Mo^{99}}$$

The short half-life of Mo^{99} may render impossible the direct confirmation of the above series of measurements. However, it has been our experience that the 282 day Ce^{144} is also an excellent fission indicator and will give results similar to those from Mo^{99}. The determination of Ce^{144} must wait for at least two weeks after the detonation to allow the Ce^{143} to decay sufficiently for accurate determination, hence our choice of Mo^{99} for this demonstration.

b. Chemical Separation Procedure. Radiochemical analysis for Mo^{99} is routinely performed using carrier, i.e., a known amount of inert molybdenum added to the active material. Once isotopic exchange has been attained, chemical separations performed on milligram amounts of added carrier molybdenum will serve to separate the radio-molybdenum in exact proportion. When the carrier material is completely purified from extraneous activities, it is precipitated in weighable form and weighed to determine the fraction recovered.

Tracer and carrier molybdenum ions exchange readily in hydrochloric acid medium if nitrate is present to insure the complete conversion of all

molybdenum to Mo(VI).

A measured aliquot of the sample solution is added to a measured aliquot of previously analyzed ammonium molybdate solution. After thorough mixing, the solution is brought to pH 5 with ammonium acetate-acetic acid buffer, and 0.1 M $Pb(NO_3)2$ solution is added to precipitate the molybdenum lead molybdate. The sample is centrifuged and the supernatant is discarded. The precipitate is dissolved in 9 M HCl and the solution is poured through a column packed with anion exchange resin (Dow Chemical Company Resin "Dowex A-1"), previously treated with 9 M HCl. When all the active solution has passed through, the molybdenum is located in an adsorbed band at the top of the resin column. The following solutions are then passed in turn through the column to remove impurities: 10 milliliters (ml.) of 9 M HCl; 10 ml. of 0.1 M HCl; 1 ml. H_2O; 5 ml. of 3 M NH_4OH; 1 ml. H_2O. The molybdenum is then removed from the resin by passing through 15 ml. of 4 M HNO_3. A few drops each of sodium tungstate solution and silver nitrate solution are added to the eluate and the solutions mixed; then sufficient dilute hydrochloric acid is added to precipitate the added silver as silver chloride. The solution is digested in a hot-water bath to coagulate the mixed precipitates of tungstic acid and silver chloride and the precipitates are centrifuged off and discarded. The tungsten and silver precipitations are repeated. A small quantity of a solution containing Fe^{+3}, La^{+3}, Te^{+4} and Zr^{+4} is then added to the supernatant and precipitated with NH_4OH at pH 10 or higher for further decontamination. The precipitate is rejected. More Fe^{+3} and La^{+3} are added to the supernatant (which is ammoniacal) and the resulting precipitate rejected. The supernatant solution is then acidified with acetic acid to pH 5 and 0.1 M $Pb(NO_3)_2$ solution is added to precipitate the molybdenum as lead molybdate. The precipitate is washed with water and acetone and dried.

The dry precipitate is transferred to a weighed aluminum dish, the dish and contents are re-weighed, and the precipitate fixed in place by a few drops of diluted lacquer. The weight of recovered lead molybdate is determined by difference. The small dish is fastened with adhesive tape to a support suitable for insertion into the counting equipment and is counted once or twice daily for several days. The lacquer must be thoroughly dry before the counting is started, since the lacquer solvent exerts a pronounced effect on the counting rate.

2179

This separation procedure for molybdenum has been described by Gunn, Hicks, Stevenson and Levy, Physical Review, 107, 1642 (1957). Analyses are run in triplicate or quadruplicate to minimize experimental errors.

c. Treatment of Data. Each individual counting rate measurement is subject to two corrections. After recording an event, a counting instrument is insensitive for a period known as the "dead time", which we may represent by the symbol τ. Then if there are R events per unit time, the instrument is insensitive for a time $R\tau$ and operative for a time $1-R\tau$ in each unit time. The true counting rate then is $R \times 1/(1-R\tau)$. In the instruments used the dead time τ is so small (5 to 6 μ sec) that at ordinary counting rates the correction may be neglected. There is also a correction (due to the "background" rate of the counter) that is the counting rate in the absence of the sample. Background may be due to cosmic radiation, radioactive contamination of the counter, or electronic noise in the amplifier circuits; it is considered to vary only slowly with time. A measurement of the background rate made shortly before or after the measurement of the sample counting rate will yield a number which is subtracted from the measured rate to give the true counting rate of the sample.

The observed corrected counting rate for a pure sample of Mo^{99} will decrease exponentially with a half-life of 66.04 hours. The activity of the Tc^{99} and Tc^{99m} daughters activities are 99 percent adsorbed by the air gap and counter window and thus can be neglected. The counting rate for each sample can be extrapolated back to the time of the detonation to give an "initial rate" R_o.

The calculations are then as follows:

Let

$$y = \frac{\text{weight } PbMoO_4 \text{ recovered}}{\text{weight of Mo as } PbMoO_4 \text{ added as carrier}}$$

$$a = \frac{\text{volume of aliquot taken for analysis}}{\text{volume of total sample}}$$

f_{SSA} = proper ordinate of Figure 16

t = mg/cm^2 air gap + counter window

2179

$$\mu = \frac{0.693}{42} \frac{cm^2}{mg}$$ absorption coefficient for β radiation of Mo^{99}

g = fraction of disintegrations detected by counter as measured with Ra D+E standard

$$\text{disintegration rate of } Mo^{99} = \frac{R_o e^{\mu t}}{y \cdot a \cdot f_{SSA} \cdot g} = N\lambda$$

where N = Mo^{99} atoms

$$\text{and } \lambda = \frac{\ln 2}{66.04 \cdot 60} = 1.749 \times 10^{-4} \text{ min}^{-1}$$

$$\text{fissions represented by sample, f} = \frac{N\lambda}{1.749 \times 10^{-4} \times \text{fission yield of } Mo^{99}}$$

d. Calculation of Fission Yield. Given the above information on number of fissions and amount of uranium in the sample the fission yield can be calculated as follows:

$$\text{Fission yield in megatons} = \frac{\text{initial uranium x fissions in sample}}{\text{uranium in sample x } 1.45 \times 10^{26} \text{ fissions/megaton}}$$

e. Fission Ratio Determination. With the results of the fireball measurement of total yield and the radiochemical measurement of fission yield, the fission fraction can be calculated as shown:

$$\text{Fission ratio} = \frac{\text{Fission yield in megatons}}{\text{Total yield in megatons}}$$

2180

temperature latitudes with a few months. Thus we will consider materials with half lives of a few months as potential long range hazards. Among the fission products, Sr^{90} is the classic example of a worldwide hazard and Sr^{89} is an example of a long-range but not worldwide hazard.

In the following estimates of amounts of radioactive materials formed, experimental numbers were used where available. For neutron capture in ground and air it was assumed that one neutron per 150 Mev total yield was emitted by the weapon, (taken equivalent to 2×10^{26} neutrons/MT). For an air burst all neutrons were assumed to be absorbed by nitrogen, while for a surface burst half are taken to be captured in ground and half in air. Activities produced in ground are assumed to be mixed in the fireball and fall out like fission products.

The following potentially hazardous radioactive materials have been considered.

A. Half lives longer than 1 year:

Sr^{90}: [redacted] DoE b(3)

[redacted] At 5% one obtains .16 Megacuries Sr^{90} per Megaton fission (Mc/MT fission). Sr^{90} is discussed in order to compare clean and fission weapons.

C^{14}: Formed in 95% of all air captures. This gives:

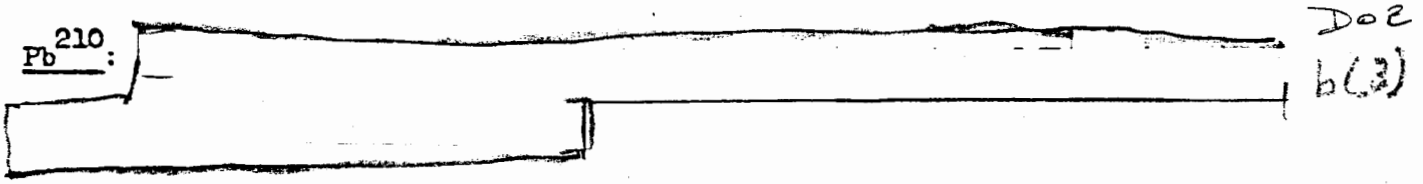
.02 Mc/MT for air burst

.01 Mc/MT for surface burst.

Co^{60}: May be produced in up to ~.1% of neutron captures in ground, leading to 10^{23} atoms/MT for surface burst. [redacted] DoE b(3)

SECRET

Taking this higher figure we obtain



.12 Mc/MT.

Fe^{55}: Produced in ~.5% of ground captures or 5×10^{23}/MT for surface burst.

.4 Mc/MT.

Pb^{210}:

3 curies/MT.

Cl^{36}: For surface detonation over sea water will produce about 60c/MT.

Ca^{41}: For surface detonation on typical ground will produce about 4c/MT with a maximum of about 240c/MT for a surface burst on limestone.

Cs^{134}: For surface detonation on typical ground may be formed in ~.01% of ground captures of 3×10^{3}c/MT.

B. Half lives less than one year:

Sr^{89}: Formed in about 5% of U^{235} fissions or 30Mc/MT fission, but only in about 3% of fissions for standard two stage weapons.

Ca^{45}: Formed by neutron capture in ground -- in about .05% of captures in average ground, .2% in concrete and 3% in limestone. For detaonations on concrete we have

.27 Mc/MT.

SECRET

~~SECRET~~

Note that the production of Ca^{45} will vary markedly with the Ca content of the surface on which the weapon is detonated.

DOE
b(3)

W^{185}: [redacted] In addition about 25Mc of W^{181} may be expected but this is probably appreciably less hazardous than the W^{185}.

P^{32}: May produce from ~.05% of neutron captures in average ground. This leads to about .5 Mc/MT but may vary considerably with phospherous content of soil.

Fe^{59}: From iron in weapons have produced 4×10^{22} atoms per MT or .2 Mc/MT.

Da

SECRET

It will be seen that all the clean radioactive products are unlikely to be a worldwide hazard for energy releases, $\lesssim 10^5$ megatons. Thus they are probably of no great concern in the present rate of testing weapons and we shall consider only the hazard associated with their use in wartime, i.e., we assume that the radioactivity is injected over a short period of time.

Of the long lived isotopes produced by clean bombs it is likely that C^{14} is the most hazardous. Estimates may be made from the radiocarbon studies. Libby takes a carbon inventory averaged over the earths surface of .45 gm/cm^2 of carbon in the biosphere and atmosphere (a similar number would obtain for atmosphere plus part of biosphere plus top of ocean). This gives 2.25×10^{18} gm of available carbon on the earth's surface. If from NBS Handbook 52, we take maximum permissable amount of C^{14} in body at 25μc[1] (for large populations) and body mass as including about 10 kg C; then the maximum permissable ratio of C^{14}/to C in biosphere is 2.5×10^{-3} μc C^{14} per gram of C. This corresponds to a total C^{14} production of 5.6×10^3 Mc or a yield of 3×10^5 Mt.

Measurements exist on the increase in C^{14} activity due to weapons tests. On the above scale, about 50 Mt of neutrons have been released to the air. We would predict from this a production of 1 Mc of C^{14} and an increase of C^{14} in atmosphere and biosphere of about .5 $\mu\mu$c/gm. This corresponds to .02 disintegrations per sec per gm of C, which is about 7% of the natural rate. An increase of about 10% in the C^{14} concentration in the atmosphere has been observed -- thus indicating that our estimates are reasonable.

It may be noted that detonation of 3×10^5 Mt could increase the C^{14} content of the atmosphere by a factor 10^3 above natural levels. Conceivably an increase of this magnitude could produce non-physiological hazards such as perturbation of weather by increasing conductivity of the air. However it appears

[1]Note that this and most subsequently quoted levels would increase the radiation level in a critical organ by a factor 10 above the natural background.

SECRET

unlikely that this particular effect could be important. The natural C^{14} in the air contributes at the most (at sea level over water) only 10^{-4} of the ion pairs which produce the air conductivity. Thus increase of the C^{14} levels by 10^3 would increase air conductivity by only $\lesssim 10\%$. Much larger variations occur naturally, with altitude, and air over earth vs. air over water.

For Sr^{90}, Anderson and Langham have summarized fission megatons required to produce hazardous levels of Sr^{90}. For a world average, 3×10^4 Mt fission would lead to about 1 μc/kgm Ca or 3×10^3 Mt to .1 μc/kgm Ca.

DOE
b(3)

(Which number is most similar to the 25 μc C^{14}?) Variability of Sr^{90} distribution and capture has led some to recommend that these yields should be divided by about a factor 10 to have a safe level of Sr^{90} everywhere (outside the locality of detonation).

The chief hazard of Co^{60} may lie in its use as a trace element of importance to some organisms or simply as a general source of γ radiation from the ground. One may estimate the latter danger as follows: Suppose the Co^{60} is deposited uniformly over the earth surface where it has a mean life against removal by weathering of ~ 1 year. If a dose, to exposed flesh, of 1.5 r in one year is considered roughly comparable to the large population figures, we estimate (from figure 9.120 of Effects of Nuclear Weapon) that this corresponds to about 10 curies/mi^2 or a total yield of about 2×10^5 Mt. This indicates that Co^{60} could be directly a hazard comparable to the inevitable C^{14}, and its production should be kept low in clean weapons. It may be argued that a mean life of 1 year against weathering is much too large, but on the other hand there will no doubt be concentrations in the fallout.

An estimate may also be made on the hazard of ingested Co^{60}. If one takes $10 \mu gm/cm^2$ of available Co on earth surface, 5×10^{-4} gm of Co^{60} in a person, a maximum permissable amount of Co^{60} in body of .3 μc, and assumes equilibrium between Co^{60} and ordinary Co in biosphere he finds 2.5×10^5 Mt required to produce a hazardous level. However, in view of the apparently poor absorption of Co and its short effective half life (as reported in Handbook 52) it would appear unlikely that equilibrium can be established in the Co^{60} lifetime. Nevertheless it would appear wise to devote further study to Co^{60}.

The remaining long lived isotopes of table I appear less hazardous than C^{14}, by an order of magnitude or more. Fe^{55} appears harmless unless there are efficient mechanisms for direct consumption of Fe. This conclusion can be reached by considering Fe^{55} in equilibrium with available Fe in the same manner that Sr^{90} (relative to Ca) was treated by Libby. Pb^{210}, Cl^{36}, Ca^{41}, Cs^{134} are created in too small quantities to be hazardous.

Of the short lived isotopes, Ca^{45} and W^{185} appear most worthy of attention. P^{32} does not appear as hazardous as Ca^{45} -- because of its shorter half life.

The hazard of Ca^{45} may be compared with that of Sr^{89} since these have similar half lives. It may be expected that 1 curie of Ca^{45} produced by a bomb is about as hazardous as 10 curies of Sr^{89}. This factor 10 is arrived at through the following factors. Sr is discriminated against relative to Ca in entry into human bones by a factor (10). The energy of the Ca^{45} β^- is (1/6) the energy of the Sr^{89} β^-. The half life of Ca^{45} is (3) times that of Sr^{89}. This longer half life will give the Ca^{45} a longer time to reach bones so that perhaps an added factor (2) advantage is obtained. $10 = (10)(1/6)(3)(2)$.

Thus the hazard due to Ca^{45} production as in Table I is about twice that due to Sr^{89} from a 5% fission weapon. For a similar detonation over Limestone these figures give Ca^{45} predominating over Sr^{89} by a factor of about 30.

A quantitative comparison between damage due to Sr^{89} and Sr^{90} is difficult to make. Probably energy deposited by Sr^{89} in bones is $\approx$ 10% of the Sr^{90} energy.. However it is delivered 100 times as fast. It appears that under adverse conditions the Ca^{45} formed in a 5% fission weapon could be more damaging than the Sr^{90}.

W^{185} is, an isotope deserving of considerable attention.

If one assumes that W behaves like Mo in the body, then the saving feature appears to be that only 2×10^{-4} of the ingested W^{185} (Mo) will reach bone, the critical organ, (NBS Handbook 52). The energy per W^{185}

November 9, 1954

TO: Distribution

FROM: George I. Bell

SUBJECT: CONTROL OF RADIOACTIVE CONTAMINATION FROM LARGE YIELD WEAPONS.(U)

SYMBOL: T-649

The characteristics have been investigated of some large yield weapons [redacted] it is felt that one must use a fuel which contains a substantial amount of Li^6 and which is compressed by an efficient implosion system. Two detailed calculations have been made. However, no general survey has been made to explore the yield as a function of implosion system and Li^6 concentration.

Two graphs have been prepared to show how this [redacted] compares with fission product activity. They are somewhat simplified in that the involvement of many half lives and gamma energies has been ignored and only the dominant (and more or less average) decay [redacted] has been considered. The predominant gamma ray energy is 0.41 Mev, somewhat less than that for an average fission product decay.

77. A memo to Assistant and Associates Directors, Division Leaders, Department Heads, Business Manager, and C. L. Tyler from N. E. Bradbury about Technical Associate Director's Responsibilities, dated March 6, 1951. (Doc # DIR-DRAFT) 4 pages

78. A memo to ADWD, Leaders of? ? E, J, F, T, and W Divisions, Chairman, Fission Weapon Development Committee from Darol Froman about Request for Data on Effort and Program Information, dated March 22, 1951. (Doc # TAD-218) 2 pages

79. A document about A Separate Thermonuclear Division from Darol Froman, dated March 20, 1951. (Doc # SAB200085580000) 5 pages

80. A letter to Chairman Gordon E. Dean from Edward teller about concerning future of the Thermonuclear Program, dated April 20, 1951. (Doc # ADWD-260, SAB200085590000) 2 pages

81. A document about A New Site for Thermonuclear Development, dated April 20, 1951.(Doc # ADWD-261) 13 pages

82. A document about Partial Statement Made by Hans Bethe at Princeton Meeting, dated June 16-17, 1951. (Doc # SAB200085620000) 1 page

83. A document to N. E. Bradbury from Gordon Dean about discussing the Status At the Los Alamos PD. (Doc # SAB200085630000, NR S-107 2616372 GR492) 4 pages

84. A memo to Edward Teller from N. E. Bradbury about Responsibilities as Assistant Director for Weapon Development, dated September 24, 1951. (Doc # SAB200085640000) 1 page

85. A memo to N. E. Bradbury from Edward Teller about Comments on Draft Memo of March 6, 1951, dated March 7, 1951. (Doc # SAB200085550000) 1 page

86. A memo to Norris E. Bradbury from Lothar W. Nordheim about Comments on the Organization of the Thermonuclear Work, dated March 23, 1951. (Doc # ADWD-218, SAB200085570000) 2 pages

87. A letter to Dr. J. Robert Oppenheimer from N. E. Bradbury about confirming their Tentative Arrangement, dated June 1, 1951. (Doc # DIR-625, SAB200085600000) 2 pages

88. A memo to Darol Froman from N. E. Bradbury about the Princeton Meeting, dated June 6, 1951. (Doc # DIR-626, SAB200085610000) 1 page

89. A memo to Technical Council Members from Edward Teller about the Super Bomb and the Laboratory Program, dated October 13, 1949. (Doc # ADWD-2-7, SAB200085650000) 5 pages

90. A memo to Members of the Technical Council from J. H. Manley about the Future Laboratory Program, dated October 13, 1949. (Doc # TAD-73, SAB20008566) 5 pages

91. A letter to Dr. John H. Manley from Edward Teller about the Two Distinct Models of the Booster that will be tested of the Feasibilities of Thermonuclear Reactions dated December 13, 1949. (Doc # ADWD-2-, SAB200085670000) 3 pages

92. A letter to Dr. Luis Alvarez from Edward Teller about Radiation Laboratory asking for Help, dated February 8, 1950. (Doc # ADWD-2, SAB200085680000) 1 page

93. A memo to Carson Mark from Hans Bethe about Calculations Concerning the super Weapon, dated June 2?, 1950. (Doc # LAB-T-202, SAB200085690000) 4 pages

94. A document about The Need and Philosophy of Fixing upon a Thermonuclear Development Program, dated March 15, 1951. (Doc # SAB200085700000) 3 pages

95. Notes for Darol Froman by S. Ulam about Some of the Important Projects Necessary for a Rational Thermonuclear Program. (Doc # SAB200085710000) 1 page

96. A Rough Draft from N. E. Bradbury, H. A. Bethe, D. K. Froman, J. C. Mark, L. W. Nordheim and E. Teller, dated June 7, 1951. (Doc # SAB200085720000) 6 pages

97. A memo to C. L. Tyler from N. E. Bradbury about Los Alamos Scientific Laboratory Thermonuclear Program, dated July 13, 1951. (Doc # DIR-643, SAB200085730000) 2 pages

98. A document from Darol Froman about Some Ideas about the LASL Thermonuclear Program, dated June 12,1951. (Doc # TAD-262, SAB20008574000) 11 pages

132. A memo to R. S. Warner, Jr. from H. W. Russ, Subject: Unknown, dated November 12, 1946. (Doc # A-84-019 17-5, SAC200103950000) 2 page

133. A memo to Harlow W. Russ from Marshall G. Holloway about a memo of 12th of December to E. Jette, dated December 16,1945. (Doc # A-84-019 17-5, SAC200103960000) 1 page

134. A letter to Commanding General of Manhattan Engineer District from R. S. Warner, Jr. about Little boy Procurement Program, dated October 23, 1946. (Doc # A-84-019 17-5, SAC200103970000) 2 pages

135. A letter to Dr. Eric Jette from E. E. Wilhoyt, Jr., Subject: Unknown, dated November 1, 1946. (Doc # A-84-019 17-5, SAC200103980000) 1 page

136. A memo to DP-21 (J. Smith, 903-6723) from Charles J. Beers, Jr. about Nuclear Explosive Safety Study of the B53 Mechanical Disassembly Operations at the USDOE Pantex Plant, dated May 27, 1994. 3 pages

137. A memo to RADM Charles J. Beers, Jr. from NESD about Nuclear Explosive Safety Study Report, dated January 3, 1994. 99 pages

138. A list of records to Jette–Morrison, dated July 2, 1945. (Doc # SAC200088280000) 37 pages

139. A document by Wataru Goishi, Bradley K. Esser, Jesse W. Meadows, Neil Namboodiri, David K. Smith and John F. Wild, LLNL, Livermore, CA & Scott M/ Bowen, Phyllis L. Baca, Loretta F. Olivas, Carmen G. Geoffrion, Joseph L. Thompson and Charles M. Miller, LANL, Los Alamos, NM about Total Radionuclide Inventory Associated with Underground Nuclear Tests Conducted at the Nevada Test Site, 1955-1992, dated September 26, 1994. (Doc # LA-CP-94-0222, SAC200122510000) 294 pages

140. A memo to Richard Contreras from H. R. Leos about FL Container Packing Checklist, Appendix 3, for Existing Pits Visual Inspection Checklist Amendments to Existing Pits Received from Rocky Flats, dated October 1, 1997. (Doc # SAC200133330000) 5 pages

141. A letter to Mr. John R. Kirby from J. C. Yarbrough about Model FL Container Sunlight Controls, dated August 10, 1997. (Doc # 192834, SAC200133340000) 5 pages

142. A letter to Gerald L. Dittman from Steven G. Hallett regarding Thermal Modeling, dated July 28, 1997. (Doc # 192891, SAC200133350000) 2 pages

143. A Special Task Group Report-Beryllium Substitute Materials for BE and BEO in Nuclear Weapons, Volume II, Impact on United States Department of Energy National Defense Programs of Proposed Department of Labor (Occupational Safety and Health Administration) Beryllium Standards, dated May 2, 1978. (Doc # SAA200118380000) 3 pages

144. A letter to James R. Nicks from W. F. Weston regarding Beryllium Requirements and Scrap Projections, dated December 14, 1984. (Doc # 84-RF-3511, SAA200118390000) 3 pages

145. A memo to Ken Sprankle from Richard J. Jiacoletti regarding Beryllium Forecasts and Sustainability Estimates, dated December 26, 1985. (Doc # POD-SAA200118400000) 2 pages

146. A letter to Albert E. Whiteman from J. E. Kinzer regarding Beryllium Five-year Projection, dated December 10, 1985. (Doc # 85-RF-3366, SAA200118410000) 3 pages

147. A letter to T. C. Jones from Seymour Sack regarding SRD Report "Beryllium Supply Updated", dated July 21, 1980. (Doc # SAA200118420000) 4 pages

148. A letter to R. E. Batzel from T. C. Jones regarding Beryllium Metal Costs, dated September 11, 1980. (Doc # SAA200118430000) 4 pages

149. A memo to Mr. Michael Q. Guy from J. E. Hockett regarding Response to your TWX of October 3, 1980, regarding brush Wellman Letter and ALO Proposed Beryllium Program, dated November 3, 1980. (Doc # WX-5-80-630, SAA200118440000) 4 pages

150. A letter to Major General J. K. Bratton from R. D. Baker regarding the LASL Position on Future Availability of Beryllium and Beryllium Oxide, dated August 2, 1979. (Doc # ADNSP/100, SAA200118450000) 7 pages

151. A document About B52 Flying Alert over Goldsboro, N. C. on operation Coverall with two? Weapons Experienced ruptured wing Fuel Tank, Broke up in Flight, and crashed. Bombs were torn from Bomb Bay by Violet aircraft Maneuvers, dated January 24, 1961. (Doc # SAC20117770000) 2 pages

152. A document about Lightning/Nuclear Weapon Accident and Incident Reported by FC/DASA in the Period from Early 1961 to February 1968, dated February 25, 1969. (Doc # RS-1515, SAC200117740000) 10 pages

153. A letter to Field Command and Directors from W. Lee Hancock regarding Weapon Debris from Thule Accident returned to AEC, dated June? (Doc # WDW:PRS (S145-68), SAC200117780000) 2 pages

154. A memo to distribution from J. G. Marsh regarding Classification Guidance, Greenland B-52 Weapons Accident, dated February 26, 1968. (Doc # SAC200117730000, 3414 NA, File 16.b) 6 pages

155. A letter to Dr. Norris about the future of the Los Alamos Scientific Laboratory, dated August 14, 1956. (Doc # SAB200144950000) 3 pages

156. A document by Raymond Pollock about A Short History of the U.S. Nuclear Stockpile: 1945-1985, dated January 2, 1991. (Doc # LA-11401, SAB200115710000) 30 pages

157. A document by Joseph S. Howard II and Edward I. Whitted about The Future of Non-Strategic Nuclear Forces. Are these Capabilities Still Needed? Dated April 30, 1991. (Doc # LA-12063-MS, SAC200057210000) 74 pages

158. A document by Joseph S. Howard, Edward J. Palanek, John L. Richter, Richard R. Sandoval, Frank L. Smith, Richard H. Stolpe, CDR Larkin E. Garcia and LTC L. Warren about Modular Weapon Systems and Insertable Nuclear Components, A Compendium of Requirements, Technology, Applications, and Utility, dated September 1983. (Doc # LA-9866-MS, SAB 200090150000) 127 pages

159. A memo to Mr. Oppenheimer from C. S. Smith and I. C. Schoonover about Gun Fabrication-lan-Supplement to Document Dated June 13, 1945, dated June 28, 1945. (Doc # LA-4000,REV.7, 9/94, SAB200115990000) 4 pages

160. A memo to Steve Yan from J. W. Liebenberg about Introductory Words on H1501 (A) Tests, dated February 14, 1992. (Doc # SAC200108720000, NWSSGR 92-1) 10 pages

161. A document to Col. D. J. O'Connor from H. T. Season, Jr. about? Product Change Proposal Support, dated October 13, 1995. (Doc # SAB200086430000) 2 pages

162. A document about B57 Retrograde alternation Proposal, dated April 3, 1992. (Doc # SAC20008945000) 4 pages

163. A memo to Gene Grewis from C. C. Burks about Nuclear Safety of B57-1/2. B61-0/1/2during Logistics Operations, dated April 3, 1992. (Doc # SAC20008946000) 3 pages

164. A rough draft about Technical Manual-Nuclear Weapons Retrofit Order ALT 914, dated April 27, 1992. (Doc # NWSSGR 92-2, SAC200108730000) 15 pages

165. A letter to H. T. Season from C. A. Yarnall about Final Product Change Proposal (PCP) No. 3-92, dated May 18, 1992. (Doc # SAC20008948000) 6 pages

166. A rough draft by T. P. Seitz, E. E. Ives, and H. T. Season regarding B57 Special Study Report, dated September 21, 1992. (Doc # RS5115/92/00016, SAC200089470000) 35 pages

167. A document by H. A. Bethe about Analysis of Joe-4, dated September 11, 1953. (Doc # T-527, A-89-038 29-30, SAB200088600000) 49 pages

168. A document about FY91 through FY93 Process Development Plans and Budgets, Weapons Systems Development, dated September 1990. (Doc # MHSMP-90-36, SAB200050030000) 10 pages

169. A document by Dale P. Hilleary and James M. Lightfoot aboutW48 Disassembly using a Thermal Shock Method, dated April 1989. (Doc # MHSMP-89-12, SAB200050020000) 37 pages

170. A document about Interim Development Report for the TX-53 Assembly and TX-53 Bomb, Engineering Development AEC Atomic Weapon Data-Division 7144, dated April 1962. (Doc # SC-4621(WD), RS 3423/571) 171 pages

171. A document by F. C. Alexander, Jr. regarding Early Thermonuclear Weapons Development: The Origins of the Hydrogen Bomb, Dated May 1969. (Doc # RS 3434/100, SC-WD-68-334, SAC200087100000) 24 pages
    a. A document by the Information Research Division, 3434, regarding History of the Early Thermonuclear Weapons Mks 14,15,16,17,24, and 29, dated June 1967. (Doc # RS 3434/10, SC-M-67-661, SAC200087110000) 59 pages
    b. A document about Final Evaluation Report MK IV MOD O FM Bomb by the Mk IV Evaluation Committee, dated September 13, 1949. (Doc Report # SL.82, SAC200087120000) 113 pages
    c. A Monthly Progress Report of Sandia Laboratory, dated September 18, 1949 through November 1, 1949. (Doc Report # SL-97, SAC200087140000) 88 pages

d. A Historical document Undergoing Classification Review by Frederick Reines about Scientific Director's Report of Atomic Weapon Tests at Eniwetok, Sandstone Handbook of Nuclear Explosions, dated August 1, 1949. (Doc 3 JOL-65-845, SAA200036480000) 100 pages

e. A document of Volume III by B. R. Suydam about Scientific Director's Report of Atomic Weapon Tests at Eniwetok, The Greenhouse Handbook of Nuclear Explosions, Part I- Theory, dated March 17, 1951. (Doc # SAA200036480000) 51 pages

172. A document of Family Committee, Minutes of Meeting, which was held on Friday, March 10, 1950 at 10:00AM in Room A-204, document date is March 10, 1950. (Doc # LAMD-262, SAA200069260000) 4 pages

173. A document of Family Committee, Minutes of Meeting, which was held on Thursday, March 16, 1950 at 1:15 PM in Room A-204, document date is March 16, 1950. (Doc # LAMD-263, SAA200069270000, ADWD-117) 5 pages

174. A document of Family Committee, Minutes of Meeting, which was held on Thursday, March 23, 1950 at 1:15 PM in Room A-204, document date is March 23, 1950. (Doc # LAMD-272, GMX-417, SAA200069280000) 10 pages

175. A document of Family Committee, Minutes of Meeting, which is held on Thursday, March 30, 1950 at 1:15 PM in room A-204, document date is March 30, 1950. (Doc # LAMD-278, GMX-420, SAA200069290000) 7 pages

176. A document of Family Committee, Minutes of Meeting, which was held on Thursday, April 6, 1950 at 1:15 PM in Room B-117, document date is April 6, 1950. (Doc # LAMD-288, GMX-423, SAA20006930000) 11 pages

177. A document of Family Committee, Minutes of Meeting, which was held on Thursday, April 20 1950 at 1:15 PM in Room B-117, document date is April 20, 1950. (Doc # LAMD-289, ADWD-2-124, SAA200069820000) 13 pages

178. A document of Family Committee, Minutes of Meeting, which was held on Thursday, April 27, 1950 at 1:15 PM in Room B-117, document date is April 27, 1950. (Doc # LAMD-306, ADWD-1-129, SAA200069310000) 9 pages

179. A document of Family Committee, Minutes of Meeting, which was held on Thursday, May 4, 1950 at 1:15 PM in Room B-117, document date is May 6, 1950. (Doc # LAMD-308, ADWD-1-133, SAA200069320000) 12 pages

180. A document of Family Committee, Minutes of Meeting, which was held on Thursday, May 11, 1950 at 1:15 PM in Room B-117, document date is May 11, 1950. (Doc # LAMD-309, ADWD-136, SAA200069330000) 13 pages

181. A document of Family Committee, Minutes of Meeting, which was held on Wednesday, May 17, 1950 at 1:15 PM in Room B-117, document date is May 17, 1950. (Doc # LAMD-311, ADWD-139, SAA200069340000) 9 pages

182. A document of Family Committee, Minutes of Meeting, which was held on Thursday, May 25, 1950 at 1:15 PM in Room B-117, document date is May 25, 1950. (Doc # LAMD-319, ADWD-141, SAA2000069350000) 13 pages

183. A document of Family Committee, Minutes of Meeting, which was held on Thursday, June 1, 1950 at 1:15 in Room B-117, document date is June 1, 1950. (Doc # LAMD-323, ADWD-146, SAA200069360000) 18 pages

184. A document of Family Committee, Minutes of Meeting, which was held on Thursday, June 8, 1950 at 1:15 PM in Room B-117, Document date is June 8, 1950. (Doc # LAMD-327, ADWD-148, SAA200069370000) 17 pages

185. A document of Family Committee, Minutes of Meeting, which was held on Thursday, June 22, 1950 at 1:15 PM in Room B-117, document dated is June 22, 1950. (Doc # LAMD-332, ADWD-153, SAA2000069750000) 13 pages

186. A document of Family Committee, Minutes of Meeting, which was held on Thursday, July 6, 1950 at 1:15 PM in Room B-117, document date is July 6, 1950. (Doc # LAMD-344, ADWD-157, SAA200069380000) 7 pages

187. A document of Family Committee, Minutes of Meeting, which was held on Thursday, July 13, 1950 at 1:15 PM in Room B-117, document date is July 13, 1950. (Doc # LAMD-352, ADWD-160, SAA200069390000) 6 pages

188. A document of Family Committee, Minutes of Meeting, which was held on Thursday, July 20, 1950 at 1:15 PM in Room B-117, document date is July 20, 1950. (Doc # LAMD-355, ADWD-163, SAA20006940000) 4 pages

189. A document of Family Committee, Minutes of Meeting, which was held on Thursday, August 3, 1950 at 1:15 PM in Room B-117, document date is August 3, 1950. (Doc # LAMD-375, ADWD-17?, SAA200069830000) 7 pages

190. A document of Family Committee, Minutes of Meeting, which was held on Thursday, August 5, 1950 at 1:15 PM in Room B-117, document date is August 5, 1950. (Doc # LAMD-376, ADWD-174, SAA200069840000) 7 pages

191. A document of Family Committee, Minutes of Meeting, which was held on Thursday August 10, 1950 at 1:15 PM in Room B-117, document date is August 11, 1950. (Doc # LAMD-379, ADWD-176, SAA200069850000) 8 pages

192. A document of Family Committee, Minutes of Meeting, which was held on Saturday, August 26, 1950 at 9:00 AM in Room B-117, document date is August 26, 1950. (Doc # LAMD-399, ADWD-180, SAA200069860000) 6 pages

193. A document of Family Committee, Minutes of Meeting, which was held on Thursday, September 7, 1950 at 1:15 PM in Room B-117, document date is September 7, 1950. (Doc # LAMD-408, ADWD-187, SAA200069870000) 6 pages

194. A document of Family Committee, Minutes of Meeting, which was held on Thursday, September 21, 1950 at 1:15 PM in Room B-117, document date is September 21, 1950. (Doc # LAMD-420, ADWD-194, SAA200069880000) 6 pages

195. A document of Family Committee, Minutes of Meeting, which was held on Thursday, October 5, 1950 at 1:15 PM in Room B-117, document date is October 5, 1950. (Doc # LAMD-445, ADWD-197, SAA200069890000) 14 pages

196. A document of Family Committee, Minutes of Meeting, which was held on Thursday, October 19, 1950 at 1:15 PM in Room B-117, document date is October 19, 1950. (Doc # LAMD-451, ADWD-203, SAA20006990000) 11 pages

197. A document of Family Committee, Minutes of Meeting, which was held on Thursday, October 26, 1950 at 1:15 PM in Room B-117, document date is October 26, 1950. (Doc # LAMD-463, ADWD-206, SAA200069910000) 9 pages

198. A document of Family Committee, Minutes of Meeting, which was held on Wednesday, November 15, 1950 at 1:15 PM in Room B-117, document date is November 15,1950. (Doc # LAMD-470 C.38A, ADWD-217, SAA200069920000) 7 pages

199. A document of Family Committee, Minutes of Meeting, which was held on Thursday, December 7, 1950 at 1:15 PM in Room B-117, document date is December 7, 1950. (Doc # LAMD-494, ADWD-223, SAA200069930000) 10 pages

200. A document of Family Committee, Minutes of Meeting, which was held on Thursday, December 21, 1950 at 1:15 PM in Room B-117, document date is December 21,1950. (Doc # LAMD-508, ADWD-230, SAA200069940000) 7 pages

201. A document of Family Committee, Minutes of Meeting, which was held on Thursday, January 11, 1951 at 1:15 PM in Room B-117, document date is January 11, 1951. (Doc # LAMD-531, ADWD-235, SAA200069950000) 7 pages

202. A document of Family Committee, Minutes of Meeting, which was held on Thursday, January 18, 1951 at 1:15 PM in Room B-110, document date is January 11, 1951. (doc # LAMD-538, ADWD-237, SAA200069960000) 7 pages

203. A document of Family Committee, Minutes of Meeting, which was held on Saturday, February 17, 1951 at 9:00 AM in Room B-117, document date is February 17, 1951. (Doc # LAMD-569, ADWD-242, SAA200069970000) 11 pages

204. A document of Family Committee, Minutes of Meeting, which was held on Thursday, March 1, 1951 at 9:00 AM in Room B-117, document date is March 1, 1951. (Doc # LAMD-584, ADWD-247, SAA200069980000) 4 pages

205. A document of Family Committee, Minutes of Meeting, which was held on Monday, March 19, 1951 at 9:00AM in Room B-117, document date is March 19, 1951. (Doc # LAMD-604, ADWD-3-13, SAA200069990000) 7 pages

206. A document of Family Committee, Minutes of Meeting, which was held on Saturday, March 24, 1951 at 1:15 PM in Room B-117, document date is March 24, 1951. (Doc # LAMD-614, ADWD-252, SAA200070000100) 5 pages

THE END

Typical Range of Controlling Parameters for Firing System Design

Characteristic	Minimum	Maximum
Electrical		
Input Voltage	24V	36V
Output Voltage (Operating)	400V	6000V
Output Current	600 Amps	640,000 Amps
Voltage Regulation	± 2%	± 10%
Loads	Single	Multiple
Charge Time	300 ms	5 seconds
Arm Time	1 second	20 years
Output Energy	.5 joule	5790 joules
Reliability	.992	.9995
Normal Environment		
Operating Temperature	-65°F	+170°F
Exposure Temperature	-80°F	+200°F
Shock	100g	18,000g
Vibration	.05 g^2/Hz	2 g^2/Hz
Angular Acceleration	—	289,000 rad/sec^2
Spin Rate	—	16,350 rpm

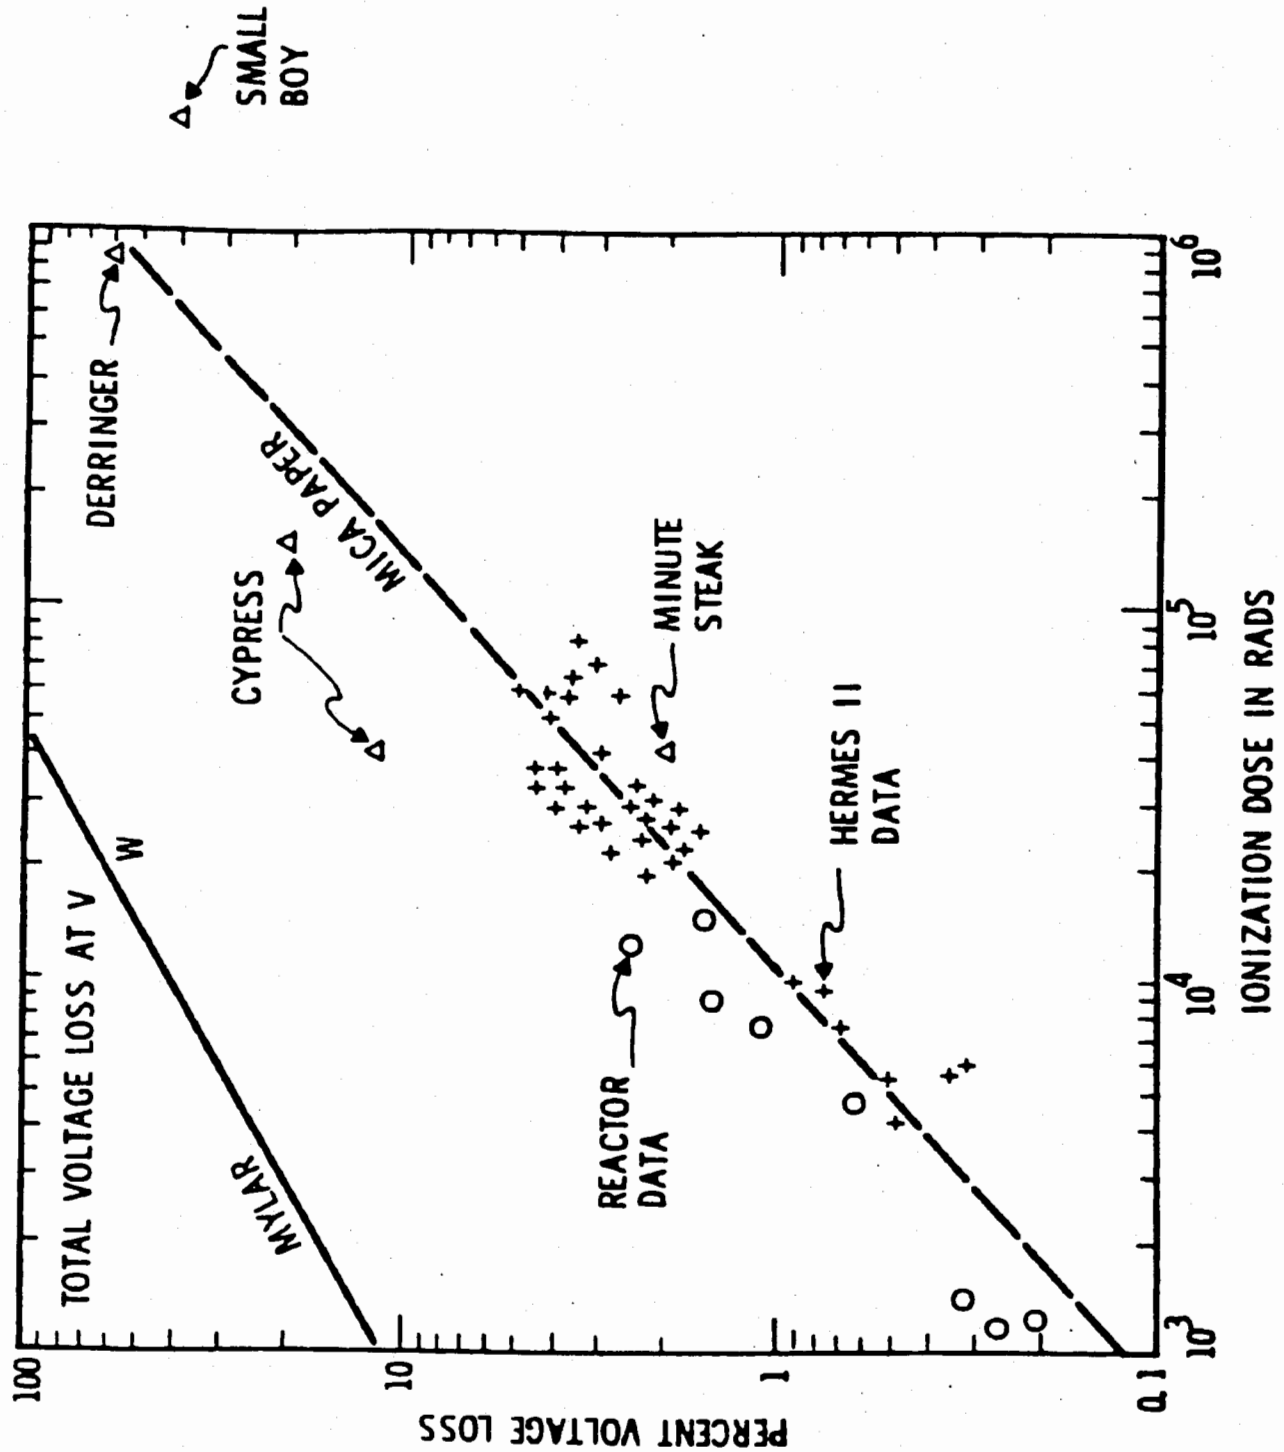
WR-708, 1995 edition

UNCLASSIFIED



Firing Set Types (U)

CDU — Capacitor Discharge Unit

In its simplest form, the CDU consists of a device for supplying the energy to charge a capacitor upon receipt of arming signals and also a switch of some sort for discharging this energy through the detonators upon receipt of a firing signal.

Firing Set Types (U)

FE — Ferroelectric

The FE firing set consists of an explosive plane wave generator and a poled ferroelectric ceramic element. A pressure pulse produced by detonation of the explosive in the plane wave generator causes the release of bound charge from the ceramic element in the detonator load. This technology is also used as the power source in explosive neutron generators.

UNCLASSIFIED
UNCLASSIFIED

THEORY OF OPERATION PRE-ARMED FE

UNPOLED

Polycrystalline Multidomain Ferroelectric Ceramic

POLING PROCESS

Domains aligned (as allowed by crystallographic directions) by impressing external electric field

POLED CERAMIC

Dipoles remain aligned in absence of disturbing independent variable. Bound surface charge remains due to internal electric field

SHOCK DEPOLING PROCESS

Shock wave randomizes dipoles (domains) eliminating internal field, thus freeing bound charge to external circuit.

UNCLASSIFIED

UNCLASSIFIED

Firing Set Types (U)

FM — Ferromagnetic

The FM firing set basically consists of an explosive charge, a ring of ferromagnetic cores and excitation and load windings. Mechanical energy in an explosively driven pressure pulse is transduced into electrical energy in the load winding as the magnetic cores are demagnetized by the shock wave.

UNCLASSIFIED

UNCLASSIFIED

Firing Set Types (U)

CMF — Compressed Magnetic Field

The CMF or "Lobo" firing set converts chemical energy stored in explosive to electro-magnetic energy through magnetic flux compression. A CMF firing system also includes an injector to introduce an initial magnetic flux into the compression volume just prior to the compression event. This injector can be a CDU, FE, FM, or SFE.

UNCLASSIFIED

Test Moratorium - 1958 to 1961

In March 1958, Soviets declared moratorium

In October, negotiations on CTBT began & Eisenhower announced 1-yr U. S. moratorium

May 1960 U-2 incident scrubbed planned summit

Kennedy Administration resumed talks

August 1961, citing French test, Soviets resumed testing

Soviets conducted over 50 tests in the last 3 months of 1961

UNCLASSIFIED
UNCLASSIFIED

The Limited Test Ban Treaty - 1963

Limited nuclear tests to underground

Original signatories were US, Soviet Union, and UK

US ratified 10/63

More than 100 parties now

France ceased above ground tests in 1974,
China in 1980

UNCLASSIFIED

UNCLASSIFIED

The Nonproliferation Treaty - 1968

Eisenhower proposed "Atoms for Peace" in 1953

IAEA established in 1957 to promote and monitor

Nuclear Nonproliferation Treaty was negotiated from 1965 and signed in 1968

NPT Review Conferences every 5 years

After 25 years (1995) a majority vote will determine indefinite or another fixed extension

In exchange for peaceful use of atomic energy, signatories agree to safeguards

UNCLASSIFIED

UNCLASSIFIED

Biological and Toxin Weapons Convention

Outlaws development, production, stockpiling of all biological or toxin weapons and requires destruction of existing stocks

No specific verification provisions

Signed in 1972 and ratified by the US in 1975

Nixon ended US program in 1969 and destroyed stocks

Soviet incident at Sverdlovsk in 1979

UNCLASSIFIED

UNCLASSIFIED

SALT I - 1972

Interim Agreement on Strategic Offensive Arms

Limited launchers (silos and sub tubes) to the then current number

US - 1710 SU - 2347

Limit on heavy launchers (SS-9 and later SS-18)

Five year duration

US ratified in Oct 1972

Reagan repudiated SALT I and II in May 1986

UNCLASSIFIED

UNCLASSIFIED

ABM Treaty - 1972

Johnson and McNamara tried to convince Kosygin at Glassboro to limit ABM systems - June 1967

US announced Sentinel program in September1967

ABM talks were postponed by Soviet invasion of Czechoslovakia in 1968

Nixon changed concept to Safeguard, protecting ICBMs and Washington, DC

Treaty prevents defense of territory, limits to 2 sites with 100 interceptors, limits LPARS

Forbids mobile ABMS or sea, air, or space systems

OPP, Krasnoyarsk, SCC, capabilities questions

UNCLASSIFIED

UNCLASSIFIED

Threshold Test Ban Treaty - 1974

Signatories are the US, Soviet Union, and UK

Limits nuclear tests to 150kT

Verification by NTM (seismic)

A two page treaty

Joint Verification Experiment in 1988

US ratified in 1989

UNCLASSIFIED

UNCLASSIFIED

Peaceful Nuclear Explosives Treaty - 1976

Limited peaceful nuclear explosives to 150kT

Permitted maximum aggregate yield of 1.5 MT, with on site monitoring for yields above 150kT

Plugged a loophole in the TTBT

UNCLASSIFIED

UNCLASSIFIED

START Treaty - 1991

Signed July 31, 1991, 5 months before the end of SU

Lisbon Protocol, signed May 1992, committed Russia, Ukraine, Belarus, and Kazakhstan to START (and NPT)

START limits SNDVs and deployed warheads:

	START	US forces*	Soviet forces*
SNDVs	1600	2246	2500
ICBM & SLBM Warheads	4900	8210	9416
Total Warheads	6000	10563	10271
Heavy ICBM Warheads	1540	------	3080
Mobile ICBM Warheads	1100	------	618
Throw-wt ICs & SLs (metric tons)	3600	2631	6626

*as of 9/90

UNCLASSIFIED

UNCLASSIFIED

The President's Nuclear Initiative-1991

Sept 1991

- Eliminate ground launched tactical nuclear weapons
  - Lance and AFAPs
- Withdraw tactical nuclear weapons from surface ships, subs and P-3 bases
  - B-57, SLCM, B-61
- Stand down strategic bombers from alert
- Stand down MMII
- Cancel mobility for PK and SICBM
- Cancel SRAM II
- Propose joint elimination of MIRVed ICBMs

Jan 1992

- Build only 20 B-2s
- Cancel SICBM
- Halt production of ACM
- Halt production of W88 for Trident II

UNCLASSIFIED
UNCLASSIFIED

START II - 1993

Treaty between the Russian Federation and US, signed by Bush and Yeltsin January 3, 1993, codifed agreements of the Washington summit of June 17, 1992.

START II builds on START - and requires START

	START	START II Ph1	START II Ph2
Start Warheads	6000	3800-4250	3000-3500
ICBM & SLBM Warheads	4900	no sublimit	no sublimit
MIRVed ICBM Warheads	N/A	1200	0
SLBM Warheads	N/A	2160	1700-1750
Heavy ICBM Warheads	1540	650	0
Mobile ICBM Warheads	1100	1100	1100

Phase one to be complete 7 years after entry-into-force, Phase two by 2003

Books of interest

The Making of the Atomic Bomb, Richard Rhodes, 1986.
Pulitzer prize winner, follows the scientific discoveries that led to the bomb, particularly good at the personalities involved, finishes with vivid descriptions of Hiroshima and Nagasaki. Excellent and entertaining.

At the Highest Levels, Michael R. Beschloss and StrobeTalbott, 1993.
Intimate details of the end of the Cold War, as seen at the top.

Lenin's Tomb, David Remnick, 1993.
Details the end of the Soviet Union from the viewpoint of the Russian people and their legacy. Choppy, but a very human picture of the great event.

The Wizards of Armageddon, Fred Kaplan, 1983.
Follows the policy and strategy decision regarding nuclear weapons, much emphasis on the early RAND personalities. Very good and readable.

UNCLASSIFIED
UNCLASSIFIED

Nonproliferation Initiative

What Constitutes a Weapon of Mass Destruction

- Indiscriminate nature of use
- Effect not confined to Belligerents
- Excessive injury -- "cruel and unusual"
- Inability to defend against effectively
- Use would overwhelm medical and evacuation resources
- Notion of "terror"

ARMS CONTROL IN THE ANCIENT WORLD

1269 BC	Earliest known peace treaty (Egypt and the Hittites), cemented by the marriage of Ramses II to a Hittite princess.
1100 BC	Philistines restrict the use of iron by the Israelites (1 Samuel 13:19-20).
700-800 BC	"...and they shall beat their swords into plowshares..neither shall they make war anymore" (Isaiah 2:2-4).
546 BC	Following the first recorded arms control conference, a "cessation of armaments" ends 72 years of hostilities in the Yangtse River Valley in Honan Province, China.

UNCLASSIFIED

UNCLASSIFIED

ARMS CONTROL IN THE ANCIENT WORLD (CONT'D)

400-500 BC	Athens and Sparta agree to dismantle fortifications although during the negotiations the Athenians hedged their bet by continuing to build their ramparts "high enough to be defended" (Peloponnesian War, Thucydides). Note that, according to the Aristophanes, the women of Athens and Sparta, under the leadership of Lysistrata, tried a different approach to forcing an end to hostilities!
450 BC	Socrates to Glaucon -- no use of poisoned weapons or poisoned water (The Republic, Plato).
300-400 BC	No weapons concealed in wood, no barbed or poisoned points, no points "blazing with fire" (India's Book of Man).
202 BC	After the battle of Zama, Carthage is required to surrender all war elephants and all but 10 triremes to Rome (Book XXX, Livy).

UNCLASSIFIED

UNCLASSIFIED

Why Not Zero?

Many nations and individuals want us to completely eliminate weapons -- attractive philosophy but dubious policy:

There may be things worse than nuclear weapons (e.g. biologics)

UNCLASSIFIED

UNCLASSIFIED

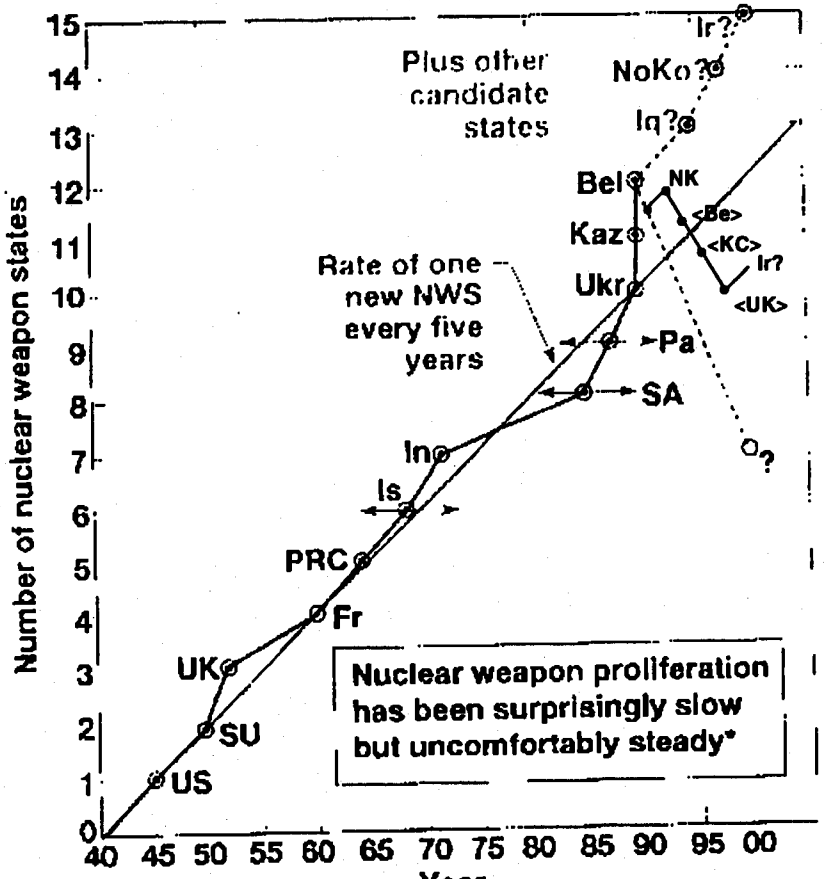
There have been some Nonproliferation Successes

-- Sweden abandoned its programs in the 1970s.

-- South Africa stopped its programs in 1992 (6 weapons).

-- Argentina and Brazil renounced their programs.

-- Taiwan and South Korea abandoned their programs in the 1980s.



-- Iraq's program "put on hold" by Desert Storm and UN Resolution 687 and 715.

-- Belarus, Kazakhstan, and Ukraine (?) have agreed to return the FSU weapons to Russia.

UNCLASSIFIED

UNCLASSIFIED

How many nuclear weapons states will there be in the year 2000?

Nonproliferation Initiative

Goals of Proliferation Controls (non → counter)

-- **REMOVE MOTIVATION** FOR POSSESSION OF NUCLEAR WEAPONS

-- **INTERDICT DEVELOPMENT AND ACQUISITION**

-- **DETER EMPLOYMENT** OF KNOWN OR SUSPECTED STOCKPILES OF NUCLEAR WEAPONS

-- **ELIMINATE INFRASTRUCTURE** BY PERSUASION, INTERNATIONAL SANCTIONS (E.G., Res 687)

-- PROACTIVELY **DESTROY FACILITIES** (E.G., Osirak)

UNCLASSIFIED

UNCLASSIFIED

Incorporation of Nonproliferation into US National Security Policy

A successful nonproliferation strategy must address the underlying security concerns that drive the quest to obtain advanced weapons and must encompass contingency planning to deal with these weapons should prevention fail.

National Security Strategy of the United States
August 1991

UNCLASSIFIED

UNCLASSIFIED

Secondary Impacts of Nonproliferation Initiatives

o NPT//NPT Extension Conference (1995):
  -- New and more intrusive inspections regimes
  -- An increased call for transparency
  -- More downward pressure on the stockpile from the "have nots"
  -- Continued pressure against nuclear testing

o Negotiations on controls on fissile materials:
  -- Codify in-place current US and Russian practices
  -- Inspection regimes and transparency
  -- Possible attempts to restrict tritium production

o Export Controls
  -- Heightened concern over "dual use" systems and commodities

PHASE 1 CONCEPT FORMULATION

(Φ1)

SECRET

UNCLASSIFIED

SECRET

UNCLASSIFIED

Phase 1 - Weapon Conception

DOE

Continuing studies by DOE agencies. Studies may be informal and independent from DoD or may be conducted jointly with DoD. May result in the focusing of sufficient DoD interest in a modification of a present weapon or in the development of a new type weapon to warrant formal study.

DoD

Continuing studies by DoD agencies. May be independent of the DOE or may be conducted jointly with DOE. Sufficient attention may become focused on an item to warrant a formal program study. DoD requests DOE to make a program study on a new idea for a weapon or component or may initiate its own study.

UNCLASSIFIED

SECRET

UNCLASSIFIED

Phase 2A - Design Definition and Cost Studies

A DOE design team will normally be selected and a Project Officer Group will be formed. The POG will conduct trade-off studies to identify baseline design(s) which best balances resources and requirements. Review and revise draft MCs and STs. Establish tentative development and production schedule and division of responsibilities. A Weapon Design and Cost Report will be prepared.

Phase 3 ENGINEERING DEVELOPMENT
(Φ3)

SECRET
UNCLASSIFIED
SECRET
UNCLASSIFIED

SECRET
UNCLASSIFIED

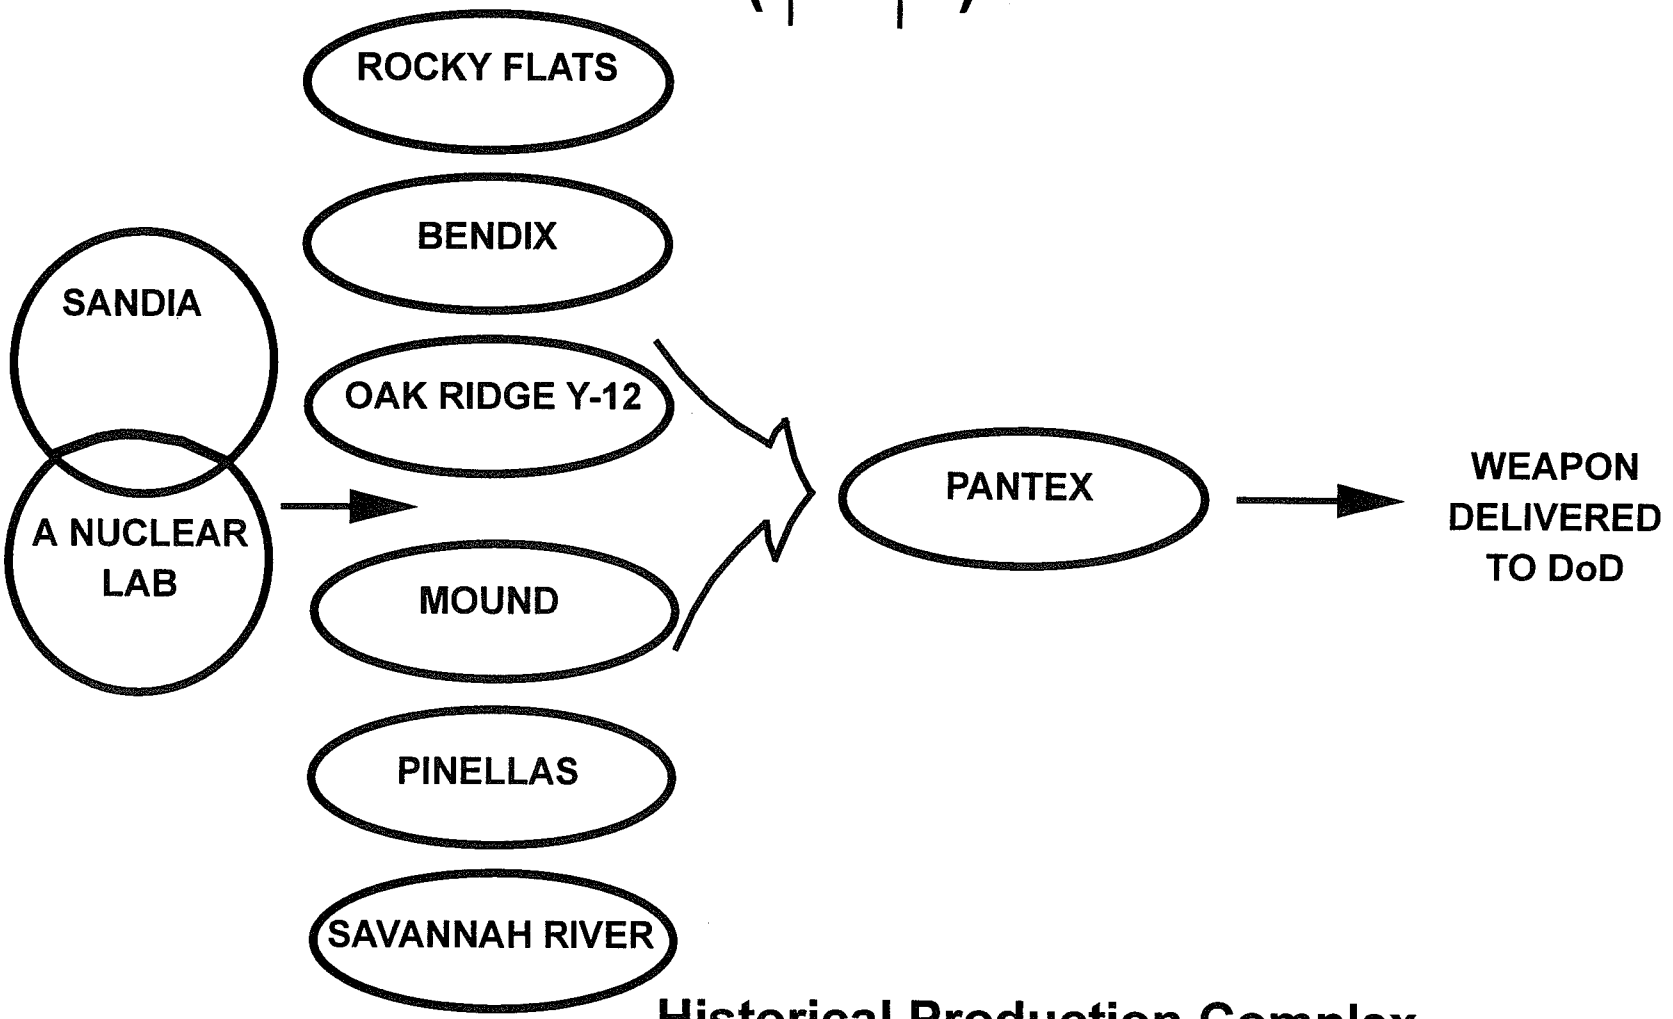
Phase 3 - Development Engineering

DOE

Launches a development program based on required military characteristics. Produces prototypes for DOE and DoD evaluation.

Provides development specifications to DoD as they become available.

Determines the developmental design release date and submits a final report on the development design to the DoD.



DoD

Maintains liaison with DOE field agencies and conducts independent evaluation of prototypes as considered necessary.

Studies the development specifications of the weapon design and gives appropriate guidance to the DOE.

UNCLASSIFIED
SECRET

Phase 4-6 PRODUCTION
(Φ4-Φ6)

- Historical Production Complex
- Reconfiguration Will Impact

SECRET UNCLASSIFIED
SECRET UNCLASSIFIED

SECRET
UNCLASSIFIED

Phase 4 - Production Engineering

DOE

Proceeds with production engineering of weapon, tooling, and layout of manufacturing facilities, without waiting for formal comments of DoD on the developmental design. Such guidance is integrated when received. Further prototype evaluation is performed during this phase.

Prepares product specifications for production release and furnishes these specifications to the DoD for review.

DoD

Reviews product specification.

Maintains liaison with appropriate DOE agencies on product design changes and specifications and gives appropriate guidance to DOE.

Continues evaluation of prototypes as considered necessary.

Phase 5 - First Production

DOE

Initiates manufacture of weapons according to product specifications by production tools, without waiting for DoD's comments on product specifications. DOE performs own evaluation and on basis of preliminary evaluation releases weapons to DoD for testing, training, and other purposes. Makes final evaluation and approves weapon model as suitable for standardization.

DoD

Completes operational suitability tests and makes independent evaluation of production type weapons. If weapon as designed, produced, and approved by DOE is satisfactory, approves the weapon as standard.

SECRET
UNCLASSIFIED

SECRET

UNCLASSIFIED

Phase 6 - Quantity Production and Stockpile

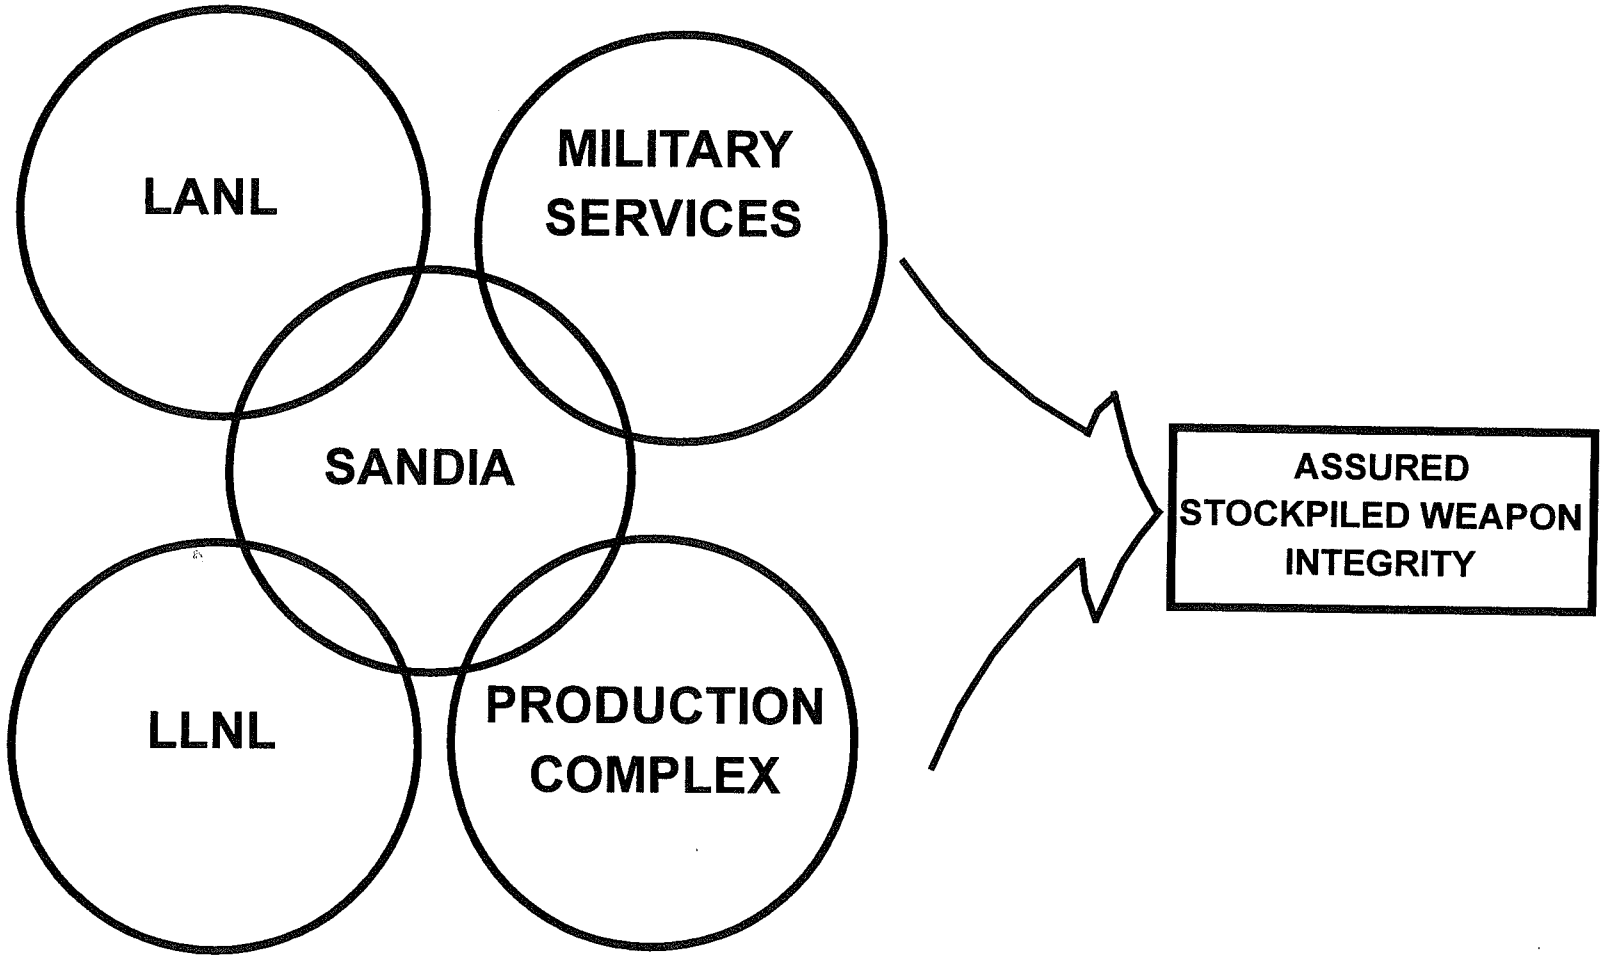
DOE

Brings various production facilities up to full production pursuant to DoD requirements. Maintains production, inspection and quality control programs to ensure that each article produced meets specifications.

Maintains quality assurance and functional surveillance programs to ensure the continued quality of weapons in stockpile, in accordance with current agreements with respect to stockpile operations. These programs and the data obtained thereof will be made available to the DoD.

DoD

Maintains liaison with DOE agencies at production facilities. Continues appraisal of weapon performance.



Maintains liaison with DOE to review performance and technical advances in anticipation of modernization changes.

Reviews DOEs quality assurance and functional surveillance programs and results and submits appropriate comments and recommendations to the DOE. Maintains functional surveillance program in accordance with current agreements with respect to stockpile operations.

Phase 6 Activities

Nuclear Weapon Operations (cont.)

UNCLASSIFIED
SECRET

Command and Control

- Provides critical link and positive control by the President
- Designated communications systems
- Specific authentication procedures and codes

Training

- Ensure maximum unit and force readiness
- Exercises are still conducted

Personnel Reliability and Assurance Program

- Ensures highest possible standards of individual realiability
- DoD (PRP) DOE (PAP)

SECRET
UNCLASSIFIED

Phase 6 Activities

Logistics Activities

Transportation

- Logistic movements (DOE and DoD)
- Operational movements (DoD)
- Safety and Security are important considerations

Storage

DOE DoD Security Areas

Maintenance

- Normally accomplished by the custodial service
- Accomplished at weapon storage area maintenance facilities or in maintenance trucks (USAFE)
- LLCE--boost reservoirs, neutron generators, RTGs

SECRET UNCLASSIFIED
SECRET UNCLASSIFIED

Phase 6 Activities

Accident/Incident Activities

Nuclear Weapon Accident--unexpected event involving:

- **Accidental or unauthorized launching, firing, or use by US forces or U.S. supported allied forces of a nuclear capable system**
- **An accidental, unauthorized, or unexplained nuclear detonation**
- **Non-nuclear detonation or burning of a nuclear weapon or nuclear component**
- **Radioactive contamination**
- **Jettisoning of a nuclear weapon or nuclear component**
- **Public hazard, actual or perceived**

Nuclear Weapon Significant Incident--unexpected event involving:

- **Evident damage to a nuclear weapon**
- **Immediate action for safety or security**
- **Adverse public reaction**
- **A situation that could lead to a nuclear weapon accident**

Accident/Incident Response Preparation

- **DoD (EOD) and DOE (ARG) personnel continuously trained**
- **EOD manual and ARG procedures kept updated**
- **Joint DoD/DOE Accident/Incident training exercises held**

UNCLASSIFIED
SECRET
SECRET
UNCLASSIFIED

Phase 6 Activities

Technical Inspections

Performed by Service or Field Command, Defense Nuclear Agency teams

Conducted at least annually

Used to recertify nuclear capable units

Emphasis on safety as well as operational requirements

SECRET UNCLASSIFIED

UNCLASSIFIED SECRET

Phase 6 Activities

<u>Stockpile Quality Assurance and Reliability Testing</u>

Begun after the system has been in the field for a year

Consists of two types of testing:
- Stockpile Laboratory Testing (SLT)
- Stockpile Flight Testing (SFT)
- Used to include Stockpile Confidence Testing (SCT), but the UGT Moratorium has effectively canceled them

Each year test units chosen at random from the active stockpile

Test units disassembled at Pantex Plant
- Non-nuclear components tested via SLT and SFT
- One nuclear physics package testing non-nuclearly at physics lab

All but one test unit rebuilt and returned to the field

Each Service tests non-DOE system components

~~SECRET~~ UNCLASSIFIED

UNCLASSIFIED ~~SECRET~~

Phase 6 Activities

Weapon Modification and Retrofits

Can be done in the field or at Pantex Plant

Modifications and retrofits usually incorporate new technology to increase weapon safety and/or reliability

SECRET UNCLASSIFIED

GLOSSARY

ABM	Anti Ballistic Missile
ACDA	Arms Control and Disarmament Agency
ADM	Atomic Demolition Munition
AEC	Atomic Energy Commission - then ERDA, now DOE
AF&F	Arming, Fuzing and Firing
AFAP	Artillery Fired Atomic Projectile
AFWL	Air Force Weapons Laboratory - now Phillips Laboratory
AK	Adaptation Kit
α	Alpha (Neutron Multiplication Rate)
ALCM	Air Launched Cruise Missile
AL	Albuquerque Operations Office
AMAC	Aircraft Monitor and Control
ASDP	Assistant Secretary (DOE) for Defense Programs
ATSD (AE)	Assistant to the Secretary of Defense for Atomic Energy
AWLPG	AL Workload Planning Guidance
Barn	Unit of cross section - 10^{-24} cm^2
Boosting	The use of deuterium/tritium to increase primary yield
Burnt Orange	The colors of a well-known outstanding university
CAT (A,B,C,D,E, or F) PAL	Permissive Action Link - code controlled open switch in the weapons arming circuit. Characteristics as defined in the "General Characteristics" of PAL definition
CD	Command Disable (locally initiated disablement of a nuclear weapon. Not, certficate of deposit, but can be command destruct

SECRET
UNCLASSIFIED
UNCLASSIFIED
SECRET

SECRET
UNCLASSIFIED

CDU	Capacitor Discharge Unit
CEP	Circular Error Probable; circle within which 50% of the weapons are expected to hit
Channel	The space around the secondary and between the primary and secondary but inside the radiation case
CHE	Conventional High Explosive (means non-IHE)
CINC	Commander-in-Chief
CNWDI	Critical Nuclear Weapon Design Information - a DoD category of Secret RD information or higher pertaining to sensitive weapon design information; not, Caught Naked While Driving Intoxicated
Critical Mass	The minimum amount of fissionable material capable of supporting a chain reaction under precisely specified conditions
CTB	Comprehensive Test Ban
DAB	Defense Acquisition Board
DASMA	Deputy Assistant Secretary for Military Applications
Depleted Uranium	Uranium which has had much of the isotope U^{235} removed; essentially U^{238}
Destruct	Normally refers to the intentional destruction of a weapon by the high order detonation of the weapons HE at a single point
Disablement	Usually nonviolent actions taken on weapon hardware to prevent normal use. Disablement and destruct normally differ in degree
DMA	Directory of Military Application - now DASMA
DNA	Defense Nuclear Agency
DoD	Department of Defense
DRAAG	Design Review and Acceptance Group
EBW	Exploding BridgeWire (Detonator)
EMP	Electromagnetic Pulse

UNCLASSIFIED
SECRET

UNCLASSIFIED

SECRET

EMR, EMI	Electromagnetic Radiation, Electromagnetic Interference
ENDS	Enhanced Nuclear Detonation Safety
Enhanced Electrical Safety	Embodiment of the exclusion region, strong-link, weak-link, unique signal concept (ENDS)
EOD	Explosive Ordnance Disposal
EP	Earth Penetrator
ER	Enhanced Radiation - usually neutron enhancement
ERDA	Energy Research Development Administration - was AEC, now DOE
ESD	Environmental Sensing Device
FEBA	Forward Edge of Battle Area - now FLOT
FLOT	Forward line of troops
FPU	First Production Unit
FRD	Formerly Restricted Data. Same as RD for foreign nationals
FRP	Fire Resistant Pit
Fuze	Component or subsystem that triggers the firing set. Use of fuse will likely bring abuse on you from old fuzing heads
FY	Fiscal Year
GLCM	Ground Launched Cruise Missile
HE	High Explosive
HOB	Height of Burst - vertical distance from the Earths surface to the point of burst
ICBM	Intercontinental Ballistic Missile
IFI	In-Flight-Insertion (mechanism)
IHE	Insensitive High Explosive - some form of TATB
INC	Insertable Nuclear Capsule
INF	Intermediate Range Nuclear Forces

UNCLASSIFIED

SECRET

UNCLASSIFIED
SECRET

Interstage Area	The space between the primary and secondary
Intrinsic Radiation	Naturally occurring neutron and gamma radiation present at the surface of a weapon
IOC	Initial Operational Capability
JAIEG	Joint Atomic Information Exchange Group
JCAE	Joint Committee Information Exchange Group
JCS	Joint Chiefs of Staff
JTA	Joint Test Assembly
kT	Kiloton equivalent of TNT hydrodynamic yield
LANL	Los Alamos National Laboratory
Lay-down	A form of weapon delivery and/or fuzing. Parachute delivered bomb from very low altitudes with delayed groudburst using a timer fuze
Limited Stockpile Item	A stockpiled weapon which has not been accepted as a "standard" item and for which the DoD has requested additional development
LLC	Limited Life Component; component which must be periodically replaced due to aging
LLNL	Lawrence Livermore National Laboratory
LPO	Lead Project Officer
LRNTF	Long Range Theater Nuclear Forces
MA	Military Application (DOE) - usually refers to the DASMA office or staff
MAR	Major Assembly Release; SNL prepared, AL approved statement that war reserve weapon material is satisfactory for release on a designated date to the DoD for specified use qualified by exceptions and limitations
MIR	Major Impact Report
MIRV	Multiple Independently Targetable Reentry Vehicle

SECRET
UNCLASSIFIED

Mk#	Mark Number. The system of certifying nuclear weapons and RV/RBs, cars, and other assorted goods (like TV programs!) For nuclear weapons - now replaced by W for Warhead and B for Bomb or other
MLC	Military Liaison Committee - historically was the coordinating and interchange of information focus between DoD and DOE
MRR	Minimum Residual Radiation - now RRR
MRV	Multiple Reentry Vehicle
MT	Megaton, million tons equivalent TNT. Also metric tons - 1000 kilograms

SECRET
UNCLASSIFIED

OMA	Office of Military Application - now office of DASMA
OMB	Office of Management and Budget
One Point	The detonation of the weapon HE at a single point

SECRET
UNCLASSIFIED

SECRET
UNCLASSIFIED

Oy	Oralloy - Oak Ridge Alloy. Uranium enriched in the isotope U^{235} to 93.5%
OSD	Office of the Secretary of Defense
PL	Phillips Laboratory (formerly Air Force Weapons Lab)
PAL	Permissive Action Link - coded use control feature
PA&E	Program Analysis and Evaluation, OSD, (not program annihilation and elimination)
P&PD	Production and Planning Directive
P&S	Production and Surveillance
PM-NUC	Program Manager - Nuclear Munitions (Army program office for nuclear-no longer active)
POC	Programs of Cooperation
POG	Project Officers Group
POM	Meeting of the POG
Primary	The "fission" device
Pu	Plutonium, a reactor produced fissionable material obtained by bombarding U^{238} with neutrons
QA	Quality Assurance - DoD uses QART—Quality Assurance, Reliability Testing
QRA	Quick Reaction Alert; weapon system deployed in a state that would allow its employment in a stated minimum specified time
RB	Reentry Body - Navy term for RV
RD	Restricted Data; all data concerning design, manufacture, or utilization of nuclear weapons and the production of special nuclear material which has not been removed by the Atomic Energy Act of 1954
Rolomite	A Sandia designed ESD sensor
RRR	Reduced Residual Radiation - reduced fission devices—formerly MRR (Minimum Residual Radiation)
RTG	Radioisotopic Thermoelectric Generator

RV	Reentry Vehicle Army, Air Force - Navy calls them RBs, definitely not a recreational vehicle
SAC	Strategic Air Command
Secondary	The "thermonuclear" device
Sec Def	Secretary of Defense
Shake	10^{-8} seconds
SLBM	Submarine Launched Ballistic Missile
SLCM	Sea Launched Cruise Missile
SNL	Sandia National Laboratories
SNM	Special Nuclear Material - Pu, Oy
SP	Strategic Programs - Navy SLBM office
Specified Command	Combat command with a broad and continuing mission - usually a single service such as the Strategic Air Command
SRAM	Short Range Attack Missile
SS Material	Source Strength Material - DOE audits one kilogram quantities (includes depleted and natural uranium)
SSPO	Strategic Systems Program Office - now SP
Standard Stockpile Item	A nuclear weapon which meets the approved military characteristics to DoD"s satisfaction
Stockpile Nuclear Test	QA test of a system withdrawn from the stockpile. That rare instance that a stockpiled weapon is tested downhole at NTS - a stockpile "confidence test"
STS	Stockpile-to-Target Sequence
TATB	Triamino-Trinitro-Benzene; see IHE
TTR	Tonopah Test Range - Sandia's testing range at Tonopah, Nevada

SECRET
UNCLASSIFIED
UNCLASSIFIED
SECRET

SECRET

TREE	Transient radiation effects on electronics
Tritium	Third isotope of hydrogen, radioactive gas used to boost weapons
TTBT	Threshold Test Ban Treaty
Tu	Tuballoy - natural uranium. Sometimes also includes depleted uranium, i.e., essentially U^{238}
V– γ Map	A contour depicting permissible velocity and reentry angle combinations for a missile RV/RB
Unified Command	A combat command with a broad and continuing mission composed of forces of two or more services under a single commander
USANCA	U.S. Army Nuclear and Chemical Agency
USDR&E	Under Secretary of Defense for Research and Engineering
WR	War Reserve nuclear weapons material (in DOE or DoD custody) intended for employment in the event of war
Weapons Grade Pu	Plutonium which has 6% or less Pu^{240} content; Pu^{239} is the good stuff
WDCR	Weapon Design and Cost Report
WES	Warhead Electrical System
WS^3	Weapon Secure, Safe, Storage
WSV	Weapons Storage Vault (Weapons Security Vault)
X-unit	A device used to provide energy to initiate nuclear system detonators

Terminology

Asymmetric fission	-	**division of excited nucleus into two unequal fragments with masses about 100 & 140 ama.**
Binary	-	**division at scission point into two parts.**
Cross-Section	-	**probability that a certain reaction between a nucleus and an incident particle or photon will occur, as in a neutron and U^{235} (measured in "barns")**
Fission Fragment	-	**fragment after scission but before prompt neutron emission**
Fission Product	-	**fragment after prompt neutron emission**

	2.017340
236.0526 amu ⟶	235.8334 amu atomic mass unit

MASS DEFECT OF .219 amu

n = 1.00867 amu
p = 1.00728 amu
e = .00055 amu

$$(.219 \text{ amu}) \quad \left(931.4 \frac{\text{MeV}}{\text{amu}}\right) \simeq 204 \text{ MeV}$$

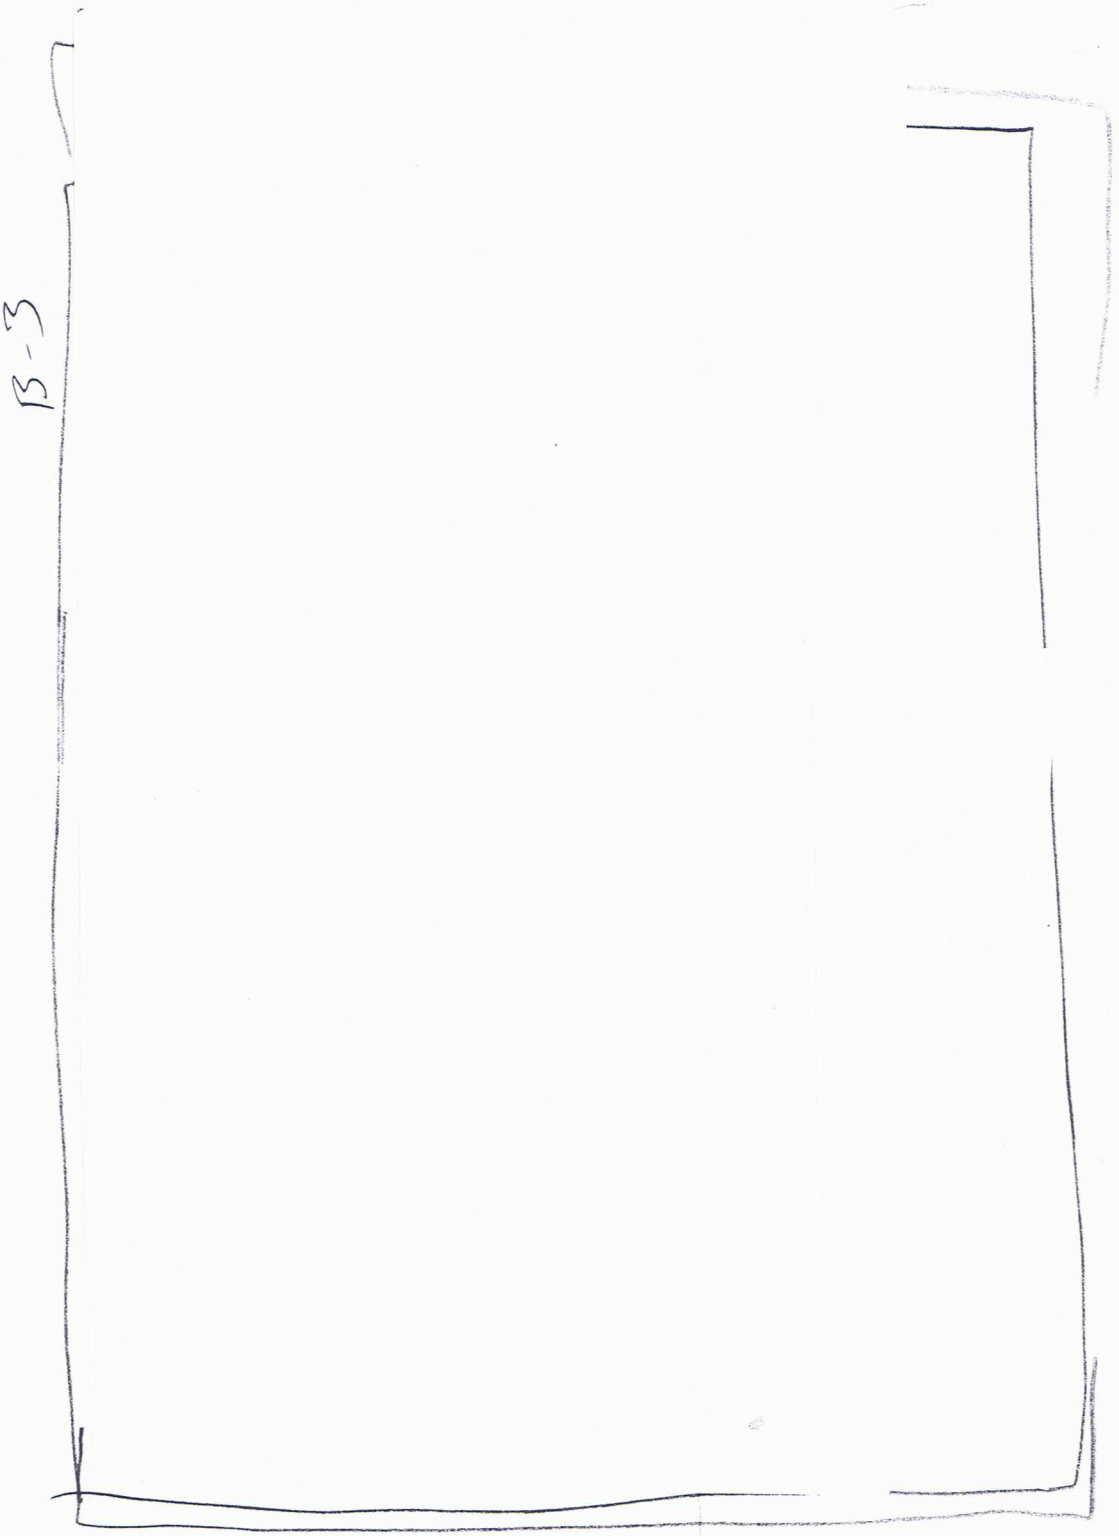
THE EXAMPLE STARTED WITH

$$_{54}Xe^{139} \xrightarrow{3\,ß} {}_{57}La^{139} \quad \text{AND} \quad {}_{38}SR^{95} \xrightarrow{4\,ß} {}_{42}Mo^{95}$$

FISSION CHAIN

SECRET UNCLASSIFIED
UNCLASSIFIED SECRET

THEORETICAL FISSION ENERGY



- THERE ARE $\frac{6.025 \times 10^{23}}{235.0439}$ ATOMS PER GRAM OF $_{92}U^{235}$
- THEREFORE, 1 kg OF $_{92}U^{235}$ HAS 2.5634×10^{24} ATOMS
- HENCE, @ 180 MeV PER FISSION 1 kg OF $_{92}U^{235}$ WOULD PRODUCE 4.6141×10^{26} MeV IF EACH ATOM WERE FISSIONED.
- CONVERTING TO KILOTONS
- $(4.6141 \times 10^{26}\ \text{MeV})\ (3.824 \times 10^{-26}\ \frac{\text{kT}}{\text{MeV}}) \simeq 18\ \text{kT}$

"A Shake"

- **Fission mean free path - how long before it clobbers an atom like URANIUM**
- **Average velocity - how fast it is going**

- $\tau = \dfrac{\textit{fission mean free path}}{\textit{average velocity of neutron}}$

These values are derived experimentally and are related to the fission cross section and velocity of the neutron.

- $\tau = 10^{-8}$ **Seconds or 1 shake**
  (real fast like the shake of a lamb's tail)

UNCLASSIFIED
SECRET

We Care About Neutrons

- An efficient way to fission U^{235} or Pu^{239} is with neutrons.
- The fission of one atom of U^{235} or Pu^{239} releases approximately 200 MeV.
- To create an explosion by fission, a bunch of neutrons are required.
- The more neutrons--the more fission, i.e., We Care About Neutrons!
- Remember that each fission gives off integral numbers of neutrons--about 2-4, but over a bunch of fissions, we measure an average (i.e., 2.54 etc.) and this varies with input neutron energy.

  υ = average number of neutrons

- The whole idea of sustaining the fission process is to get these fission neutrons to go fission more U^{235} or Pu^{239}.
  - If all the neutrons escape without fissioning anything, then the reaction fizzles! (The population becomes extinct.)
  - If at least one of the 2 to 4 neutrons fission something every generation, then we have a steady state condition--a reactor.
  - If most of the neutrons fission another atom etc., etc., we have a run-away condition--a nuclear explosion.

SECRET UNCLASSIFIED
UNCLASSIFIED SECRET

We Care About the Neutrons that Escape

- We call the escapees "lost neutrons," and the abbreviation is *l* (the letter after k).
- So the number of neutrons available for population growth is the average number per fission (u), i.e., 2.54 minus the lost ones.
- Someone called this k.
- Therefore: k = u - *l*
  - for every neutron causing fission in one generation k will cause it in the next generation.

SECRET
UNCLASSIFIED

UNCLASSIFIED
SECRET

We Care About the Multiplication

- Now let's look at a bunch of fissions and bunch of neutrons.
- If we start with some number of neutrons (one or more), let that number equal n.

n = number of neutrons at beginning of a generation

- Remember, k= number of neutrons available for Round 2...
- And k times n equals number of neutrons at the next generation.
- Don't forget we've used up the original neutrons (n) in the first fission process..
- The gain of neutrons is thus:

$$n \bullet k - n$$

(number of neutrons we started with)•(average number in a fission of Round 2 (etc.)) minus the ones we used up in the previous round.

SECRET
UNCLASSIFIED
UNCLASSIFIED
SECRET

UNCLASSIFIED
SECRET

Determine Growth Rate

- We still care about neutrons, but we really care about the rate (speed) that they are produced.
- The rate is the $\frac{\text{change in the number of neutrons}}{\text{change in time}}$
- Mathematically this is represented

$$\frac{Dn}{Dt} \longrightarrow \frac{dn}{dt}$$

- To get the rate change, we divide the actual gain in neutrons by time (t)

$$\frac{nk - n}{t}$$

- Therefore $\frac{dn}{dt} = \frac{nk - n}{t}$

UNCLASSIFIED
SECRET

Apply Basic Calculus

- $\frac{dn}{dt} = \frac{nk-n}{\tau} = \frac{n(k-1)}{\tau}$

- *Let* α *"alpha"* $= \frac{k-1}{\tau}$ *substitution gives*

- $\frac{dn}{dt} = n\alpha$; *Rearrange (cross multiply and divide)*

- $\frac{dn}{n} = \alpha\, dt$ *Integrate from zero neutrons* (N_o) *to N neutrons.*

- $N = N_o\, e^{\alpha t}$

  If α *is known, one can calculate the number of neutrons at any time* (t).

UNCLASSIFIED
SECRET
UNCLASSIFIED
SECRET

The Energy Released is Proportional to the Number of Fissions

$\alpha \approx \frac{\mu - \iota - 1}{\tau} \approx \frac{3-1-1}{\tau} \approx \frac{1}{\tau}$ 1 gen / shake for 1 MeV neutron

where: μ = ave# Neutrons
ρ = Post Neutons

$N = N_o e^{dt} \cong N_o e^{\frac{t}{\gamma}} = e^g$ where g = Number of generations

The energy released is proportional to the number of fissions
The numer of fissions is proportional to the number of neutrons

1 fission $\cong 7 \times 10^{-21}$ tons of TNT
At g = 48 we would have $\approx$ 9800 lbs.

Nuclear Effects Generalities

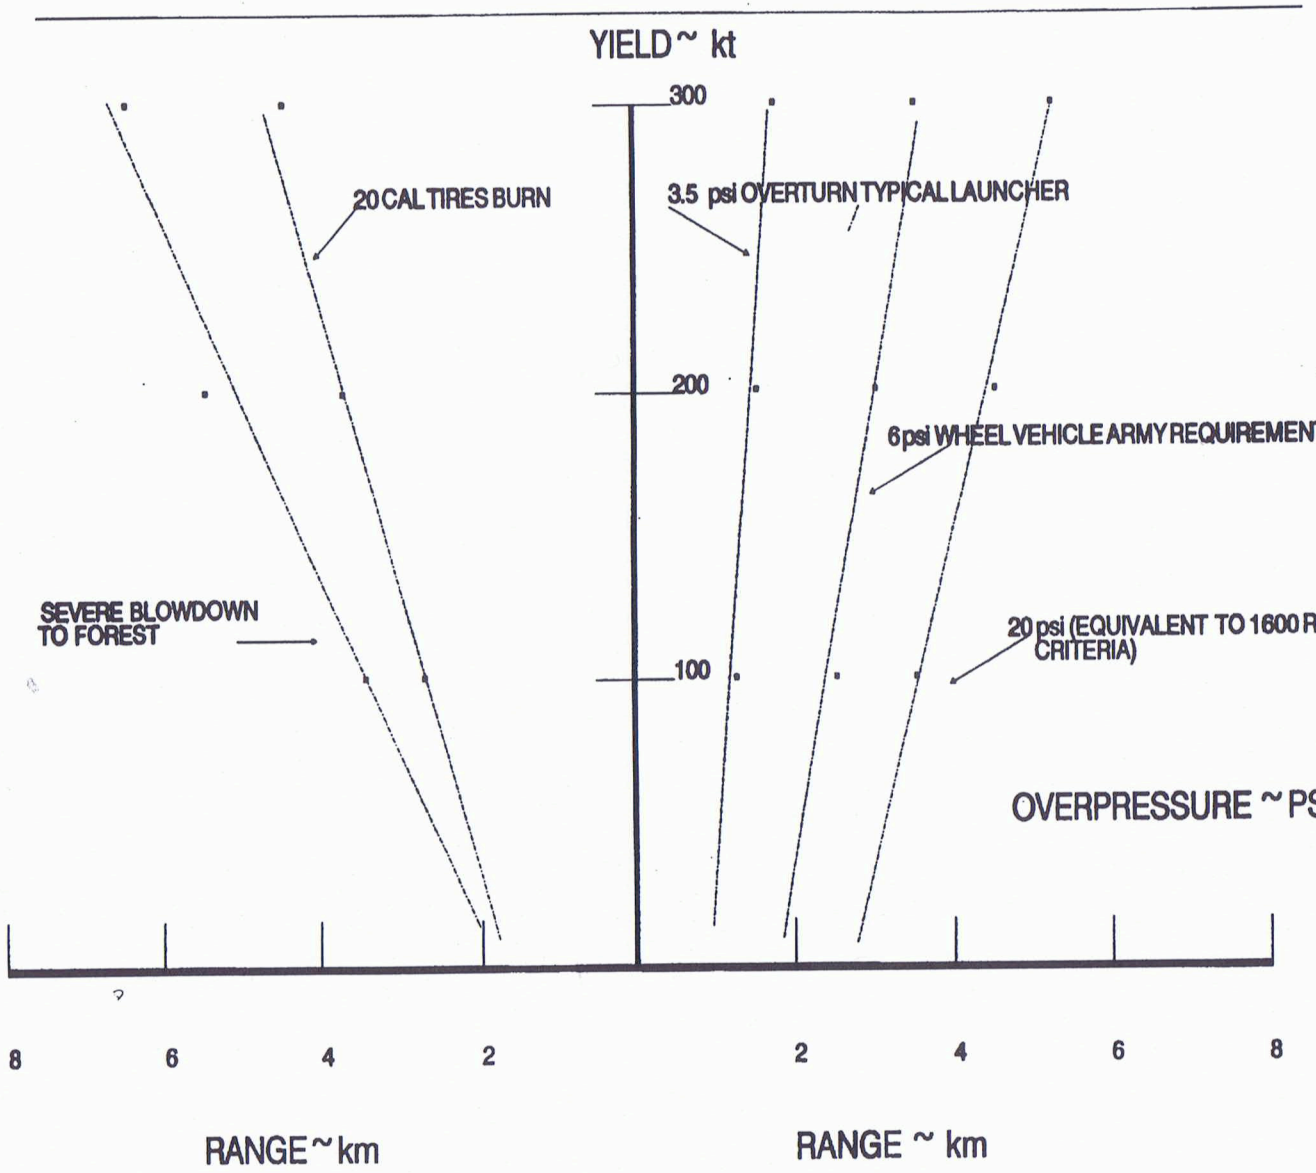
SECRET
UNCLASSIFIED

Subject Generally Divided into 3 areas

- Phenomenology
  - Physics at the weapons source
- Interaction of the nuclear
- Military effects
  - Smashing (over pressure)
  - Turning over (dynamic - winds)
  - Fires (Thermal pulse)
  - Radiation
  - Craters

UNCLASSIFIED
SECRET

SECRET
UNCLASSIFIED



What are Nuclear Effects Calculations Used For?

- Determine how "hard" (radiation, blast, etc.) to make the weapon system (major cost implication)
- Determine the proper yield/accuracy combination
- Placement of weapon system on the battlefield
- Targeting
- Number of nuclear weapons required to achieve an objective
- Safety zones
- Etc.

- Historically, this is an area that has caused much discussion and argument. However, over the years, DNA has developed tools to standardize the methodology and has contributed greatly to the understanding of this area.

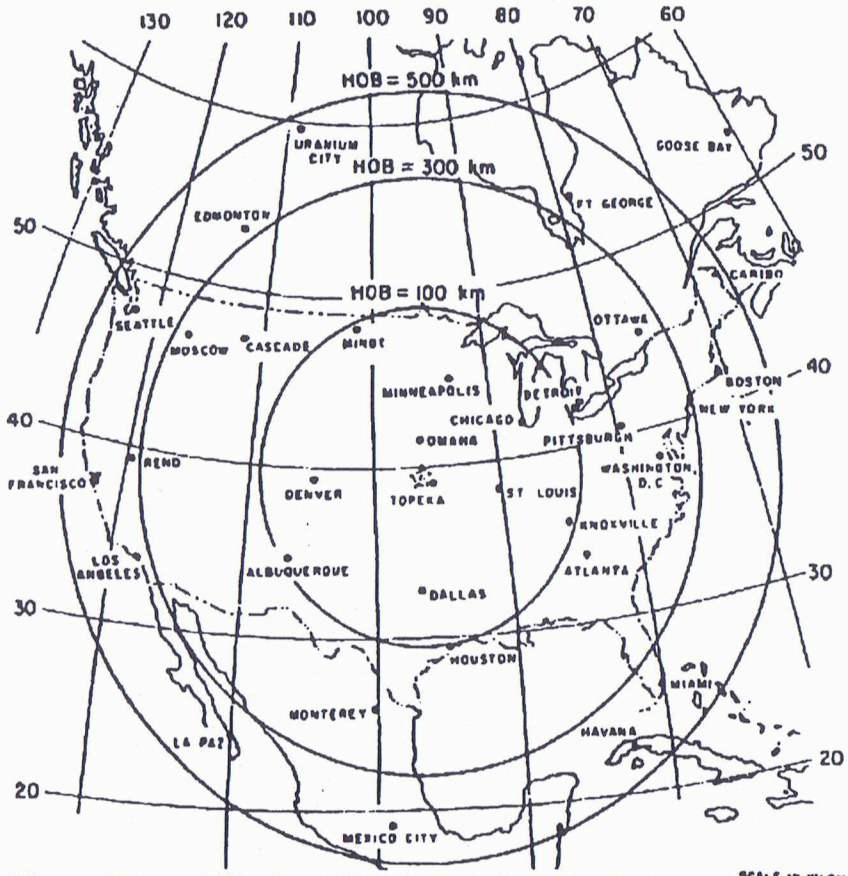
KEY Points



1. Each γ gives a downward traveling compton electron.
2. The electrons are turned by the earth's magnetic field.
3. The relativistic electrons radiate energy downward.
4. The γ 's and EMP radiation travel at the same speed.
   This leads to constructive interference of radiation from all electrons.

[a]Properties of materials marked with asterisks are summarized in data sheets (Section IV).

[b]The weight percent values given in the table are nominal and subject to some variation.

[c]Comp B, Grade A is formulated as a 60/40 RDX/TNT mixture, but high-quality castings usually are higher in RDX content due to the removal of a TNT-rich section at the top of the casting.

[d]There are several cyclotols and pentolites. The most common cyclotol is RDX/TNT 75/25. The most common pentolite is PETN/TNT 50/50.

DOE shares responsibility for safety, security, and control

From the 1983 Memorandum of Understanding between DOE and DoD on Objectives and Responsibilities for Joint Nuclear Weapon Activities

"The obligation of the DoD and the DOE to protect public health and safety provides the basic premise for dual-agency judgment and responsibility for safety, security and control (S ^{2}C) of nuclear weapons. This check-and-balance role shall continue. The DoD and the DOE share the responsibility to:

1) Identify and resolve health and safety problems connected with nuclear weapons. In particular, the DOE has a continuing responsibility to participate with the DoD in the consideration of these health and safety problems for nuclear weapons in DoD custody.

2) Prevent unauthorized use of a nuclear weapon through the use of positive control measure...

3) Determine the adequacy and effectiveness of physical security measures..."

UNCLASSIFIED ~~SECRET~~

Department of Defense Directive

3150.2

Replaces DoD 5030.15...February 8, 1984

SAFETY STANDARDS

1. There shall be positive measures to prevent nuclear weapons involved in accidents or incidents, or jettisoned weapons, from producing a nuclear yield.

2. There shall be positive measures to prevent deliberate prearming, arming, launching, firing, or releasing of nuclear weapons, except upon execution of emergency war orders or when directed by competent authority.

3. There shall be positive measures to prevent inadvertent prearming, arming, launching, firing, or releasing of nuclear weapons in all normal and credible abnormal environments.

4. There shall be positive measures to ensure adequate security of nuclear weapons, pursuant to DoD Directive 5210.41.

SECRET UNCLASSIFIED

UNCLASSIFIED SECRET

DOE Order 5610.10
10/10/90
Nuclear Explosive Safety Standards

a. There shall be positive measures to prevent nuclear explosives involved in accidents or incidents from producing a nuclear yield.

b. There shall be positive measures to prevent deliberate prearming, arming, or firing of a nuclear explosive except when directed by competent authority.

c. There shall be positive measures to prevent the inadvertent prearming, arming, launching, firing, or releasing of a nuclear explosive in all normal and credible abnormal environments.

d. There shall be positive measures to ensure adequate security of nuclear explosives pursuant to the DOE safeguards and security requirements.

e. There shall be positive measures to prevent accidents, inadvertent, or deliberate unauthorized dispersal of plutonium to the environment.

UNCLASSIFIED SECRET
UNCLASSIFIED SECRET

DOE Nuclear Explosive Surety Standard

All DOE nuclear explosive operations shall meet the the following qualitative surety standards to prevent unintended nuclear detonation, fissile material dispersal from the pit, or loss of control. There shall be positive measures to:

- Minimize the possibility of accidents, inadvertent acts, or authorized activities that could lead to fire, high explosive deflagration, or unintended high explosive detonation;
- Minimize the possibility of fire, high explosive deflagration, or high explosive detonation, given accidents or inadvertent acts;
- Minimize the possibility of deliberate unauthorized acts that could lead to high explosive deflagration or high explosive detonation;
- Ensure adequate security of nuclear explosives;
- Minimize the possibility of or delay unauthorized nuclear detonation.

UNCLASSIFIED SECRET

SECRET UNCLASSIFIED

Positive Measures

From DOE Order 5610.10

- Design features, safety rules, procedures, or other controls used individually or collectively to provide nuclear explosive safety.
- Positive measures are intended to assure a safe response in applicable operations and be controllable.
- Examples
  - strong-link switches
  - other safety devices
  - administrative procedures and controls
  - general and specific nuclear explosive safety rules
  - design control of electrical equipment and mechanical tooling physical, electrical, and mechanical restraints incorporated in facilities and transport equipment

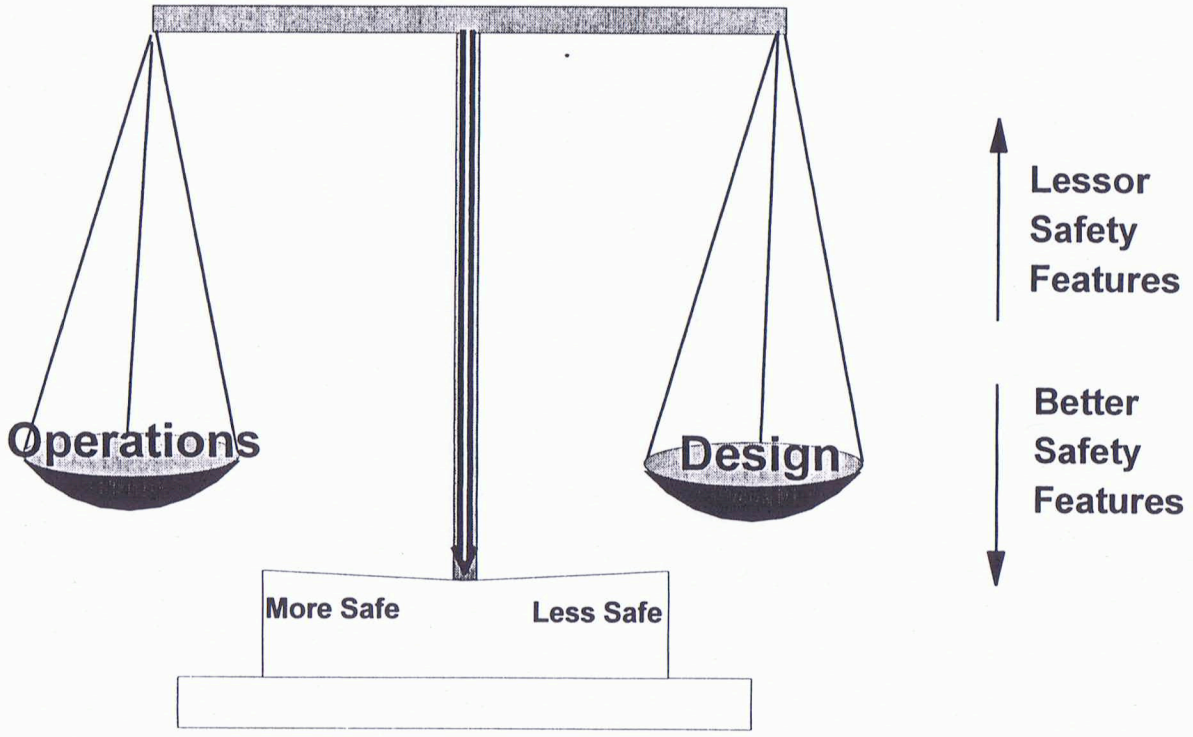
Explanation of normal and abnormal environments



Normal environments (temperature, shock, electrical connections, etc.) are those defined in the weapon or system specifications and intended to be tolerated by the weapon or system. The system is designed to function normally during its entire lifetime if it experiences normal environments.

Abnormal environments are conditions experienced by the weapon or system that are outside the defined normal environments (more extreme temperatures, shocks, voltages, etc.). The weapon or system is not required to function after exposure to an abnormal environment.

Nuclear Weapon Accident--Definition
DOD Directive 5100.52

An unexpected event involving nuclear weapons or nuclear components that results in any of the following:

(1) Accidental or unauthorized launching, firing, or use by U.S. forces or U.S. supported allied forces of a nuclear capable weapon system.

(2) An accidental, unauthorized, or unexplained nuclear detonation.

(3) Non-nuclear detonation or burning of a nuclear weapon or nuclear component.

(4) Radioactive contamination.

(5) Jettisoning of a nuclear weapon or nuclear component.

(6) Public hazard, actual or perceived.

Accidents (mainly air-delivered systems) eventually led to reexamination of the premature nuclear yield criteria and to the present nuclear detonation safety design criteria.

SECRET

UNCLASSIFIED

Need for a Safety Process

- As the deployment dates for sealed pit weapons approached, the Armed Forces Special Weapons Project (AFSWP) and the Services became uncomfortable with their lack of knowledge and understanding of weapon safety designs.

- 1957, AFSWP convened a safety Board to examine the sealed pit weapon systems becoming available.

- Between 1957 and 1960, the Air Force convened joint safety study groups as weapons entered the stockpile.

- A formal, Joint DoD/DOE Nuclear Weapons System Safety process was established in 1960.

1968 -- DoD/DOE Agree on Premature Nuclear Detonation Design Safety Criteria

UNCLASSIFIED
SECRET

- The probability of a premature nuclear detonation due to component malfunctions, in the absence of any input signals except for specified (e.g. monitoring and control), shall not exceed.

(1) For normal storage and operational environments described in the STS, 1 in 10^{9} per weapon lifetime.

(2) For the abnormal environments described in the STS, 1 in 10^{6} per weapon exposure or accident.

UNCLASSIFIED
SECRET

1968 -- DoD/DOE Agree on One-Point Detonation Design Safety Criteria

UNCLASSIFIED

SECRET

UNCLASSIFIED

SECRET

One Point Safety

a. In the event of a detonation initiated at any one point in the high explosion system, the probability of achieving a nuclear yield greater than four pounds TNT equivalent shall not exceed one in one million.

b. One-point safety shall be inherent in the nuclear design, that is, it shall be obtained without the use of a nuclear safing device.

Four Pounds

"The four pounds TNT equivalent evolved from a U.S. Navy requirement based upon personnel exposure in the engine room of an aircraft carrier resulting from a small nuclear yield occuring on the flight deck 50 feet above the engine room (Ref. 5). A study concluded that a detonation giving a nuclear contribution equivalent to 44 pounds of TNT would result in a 50% sickness dose (SD_{50}) of 200 neutron rad to personnel in the engine room. To be conservative, a reliability factor of 10 was applied and the result rounded to four pounds. Another study, conducted in 1967 by the U.S. Army Nuclear Defense Laboratory, concluded that 8.5 pounds TNT equivalent would produce 200 neutron rad at 50 feet. This figure had a reliability factorr of two applied and the result rounded to four pounds, also."

- NUCLEAR WEAPONS SYSTEMS FOR ENDURING STOCKPILE
- AIRCRAFT INTERFACE

UNCLASSIFIED
SECRET

UNCLASSIFIED

SECRET

SANDIA NATIONAL LABS AIRCRAFT COMPATIBILITY DEPARTMENT

- Our charter is to ensure the Department of Energy that a capability exists between US nuclear weapons and the aircraft they are carried on throughout their life in the inventory.
- Our department was established in the early 1960's.
- We work with the military, aircraft contractor, and Sandia's weapon departments in the design of the aircraft/weapon interface.
- We define the requirements the military and contractor must comply with before final design approval can be granted.
- We conduct a wide range of electrical and mechanical tests to verify a capability exists.

UNCLASSIFIED

SECRET

UNCLASSIFIED
SECRET

An Overview of the Evolution of Aircraft Monitor and Control (AMAC) Systems

- The AMAC acronym was created to describe the dedicated "black boxes" that monitor and control nuclear weapons.
- From 1945 to 1961, no standard weapon interface existed. Early bomb technology drove the design of the AMAC Systems.
- Little Boy (B1) and Fat Man (B2) were controlled by an AMAC known as a Flight Test Box (FTB). The FTB could measure battery voltages, turn on radars, and could verify certain components had not failed. Two manually inserted arming plugs were used to arm the weapons prior to pressurization of the cockpit at 8000ft.
- Manually inserted arming plugs were also used on the B3 (production Fat Man) and B4-0 bombs.
- 1950 saw the first bomb (B5) to incorporate a cockpit controlled inflight insertion (IFI) mechanism for enhanced nuclear safety. This device was the forerunner of the Ready/Safe switch, and it required a new AMAC to control this bomb feature.

SECRET
UNCLASSIFIED

UNCLASSIFIED
SECRET

An Overview of the Evolution of Aircraft Monitor and Control (AMAC) Systems

- 1952 saw the first fighter-carried bomb (B7). It had an AMAC controlled retractable fin for ground clearance.
- By 1952 there were three AMAC systems for bomber aircraft and one for fighter aircraft.
- In the late '40s and early '50s AMAC systems were built around the specific needs for the bombs, not the aircraft.
- In 1954 Sandia started a program to standardize AMAC functions for new weapons under development.
- The result of this effort resulted in the T249 AMAC for bomber and fighter aircraft usage.

UNCLASSIFIED
SECRET

UNCLASSIFIED

SECRET

An Overview of the Evolution of Aircraft Monitor and Control (AMAC) Systems

- New bombs designed during the mid to late '50s were made compatible with the T249 rather than building a unique AMAC for a specific bomb.
- AMAC design specifications, defined jointly by the DOE and DoD, first appeared in December 1961.
- AMAC specifications such as Bomber System A, Fighter System A & B, and Aero 6B were the forerunners of todays AMAC systems.
- Today's nuclear-capable aircraft, with the exception of the B-52 ALCM/ACM AMAC Systems, have what is known as a System 1 AMAC interface.
- The System 1 specification first appeared in September 1963.

SECRET

UNCLASSIFIED

UNCLASSIFIED

SECRET

System 1 Offered Many Improved Features in Safety and Compatibility

- A current-limited Monitor State allowing weapon status to be checked without applying Safe power.
- Dedicated weapon status monitor pins for Safe, Arm, Permissive Action Link (PAL), and Weapon Present ID.
- [redacted] (3)
- Category (CAT) B PAL [6/63] and CAT D PAL [8/75] enhanced weapon security.
- Unique Signal Generator (USG) [8/75] enhanced weapon safety in abnormal environments.
- Command Disable (CD) [10/81] provided the ability to render a weapon useless from the cockpit.

SECRET

UNCLASSIFIED

UNCLASSIFIED

SECRET

Conclusion

- All aircraft nuclear weapon interfaces built to date have been analog.
- AMAC systems have transitioned from separate to integrated designs.
- A System 2 AMAC specification, based on MIL-STD-1760, exists that defines a digital interface for possible use in future nuclear weapons.
- The number of nuclear capable aircraft has decreased considerably in recent years.

DSD Manual

The Demilitarization and Sanitization for Disposition (DSD) Manual defines the process to be utilized in the nuclear weapons complex for applying the general guidelines to define and document a demilitarization, sanitization, and/or render-safe process. The process description covers the use of the Demilitarization/Sanitization Table, the Weapon Component Data Sheets, and the issue resolution process.

MMSC Demilitarization/Sanitization

Part Nomenclature	*Demilitarization*	*Sanitization*	*Render Safe*	*Method*
Actuators/Squibs	Yes	No/Yes	Yes	Fire or explosive disposal (some use control items may require sanitization)
Connectors	No	No/Yes	No	None (unless rad hardening potting used, then sanitization required)
Detonators and Cable Assemblies	Yes	Yes	Yes	Fire - shred cable/crush header or explosive disposal (protect# info.)
Foams, cushions compression pads, desiccants, plastics, etc.	No	No/Yes	No	None (shred, melt, or burn if show classified contours or shock mitigation info.)
Mechanical Hardware (O-rings, brackets, bolts, cover plates, rings, etc.	No	No	No	None (part identifier removed if association makes classified)
Neutron Generator, Electronic	Yes	Yes	Yes	Crush (remove rad tube?)
Neutron Generator, Explosive	Yes	Yes	Yes	Fire (mixed waste) or timer driver to explosive disposal/tube to rad waste
Reservoir	Yes	Yes	Yes	Bury (remove rad material if appropriate)
Thermal Battery	Yes	No	Yes	Fire
Timers	No	No	No/Yes	None (fire - remove explosives if appropriate)
Use Control, PAL, CD Hardware	Yes	Yes	Yes	Expend, crush, shred, bury as appropriate

- NEUTRONS INITIATION
- POWER SUPPLIES

UNCLASSIFIED
SECRET

Topics to be discussed

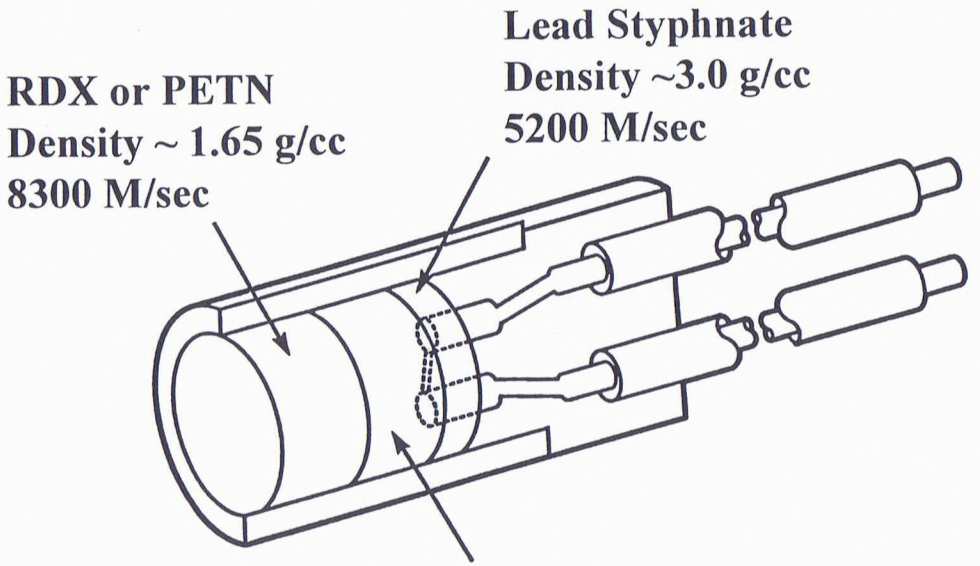
- Review of implosion assembly (IA) operation
- Review of stockpile detonators
- Firing system components
- Operation of explosive firing sets
- Stockpile firing sets
- Nuclear safety
- Production
- Future systems

SECRET
UNCLASSIFIED
UNCLASSIFIED
SECRET

Assumptions for briefing

- Students have an undergraduate background in engineering or science

SECRET
UNCLASSIFIED
UNCLASSIFIED
SECRET

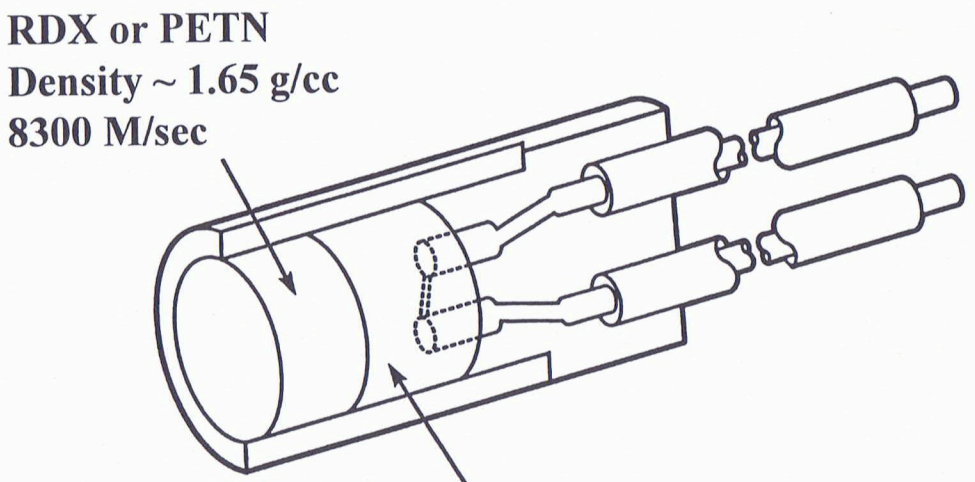


Basics of an Implosion Assembly (IA)

~~SECRET~~
UNCLASSIFIED

UNCLASSIFIED
~~SECRET~~

SECRET
UNCLASSIFIED

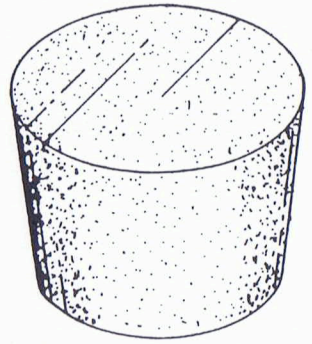


Typical hot wire detonator (Firing current ~ 5 amps)

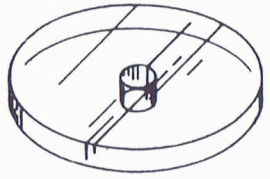
UNCLASSIFIED
SECRET

An exploding bridgewire (EBW) detonator (1.5 X 40 mil gold) initiation requires ~ 300 amps

UNCLASSIFIED
SECRET

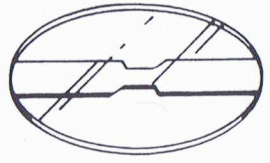


SECRET
UNCLASSIFIED



A basic exploding foil initiator (EFI), slapper detonator, consists of three components

UNCLASSIFIED
SECRET



Secondary Explosive Pellet
(Typically HNS IV)

Insulating disk with
barrel (hole)

Etched metal foil
with insulated flyer

SECRET
UNCLASSIFIED

The Mechanical Safe and Arm Device (MSAD) controls the detonator pellet in the W84 and W87

UNCLASSIFIED
SECRET
SECRET
UNCLASSIFIED

EBW and EFI comparison for detonators which requires approximately the same initiation energy

	Exploding Bridge Wire	Exploding Foil Initiator
Energy	250 mJ	250 mJ
Current	1000 Amps	2,500 Amps
Function time	2.0 μs	0.5 μs
Energy coupled into explosive	~ 20 % of stored energy	~ 5 % of stored energy
Explosive	PETN (0.8 gm/cc)	HNS (1.6 gm/cc)
HE melting point	140° C (100° C degrades)	320° C (doesn't degrade)

* EBWs need recovery; slappers don't.
* Slappers are more environmentally rugged.

UNIQUE DESIGN PROBLEMS IN TRITIUM RESERVOIRS (U)

- *System*
  - Must Deliver In Specified Time
  - Must Be Consistent
  - Satisfy Weight And Space Requirements
  - Fire And Accident Considerations

- *Long Term Degradation*
  - Subject To Hydrogen Embrittlement
  - Subject To Helium Embrittlement
  - Withstand Pressure Increase With Time
  - Subject to Radiation Induced Effects (Loss of Permeability, Stoichiometry)

- *Safety*
  - Must Be Super Safe Against
    - Burst
    - Permeation (Walls, Welds, Stringers)

UNCLASSIFIED
UNCLASSIFIED

Consequences of a stockpile tritium release:

a. Weapon reliability

b. Personnel safety

c. Political/environmental ramifications

UNCLASSIFIED

UNCLASSIFIED

DOE b(3)

UNCLASSIFIED

Helium from tritium decay produces cumulative, irreversible damage in stockpile materials

UNCLASSIFIED

Specifications

- •Narrow chemistry——promotes weldability
- •Grain size——less than ASTM 5
- •Vacuum—arc—remelt (VAR) material
  - Inclusions——ultraclean
  - Ferrete distribution—— < 3% minimize stringers

Acceptance

- •Chemistry
- •Metallography
  - Grain size
  - Ferrite distribution
  - Inclusion
- •Ultrasonics——porosity

For tritium reservoirs, it is necessary to improve the material properties

It is most important to clean all surfaces of undesirables

CLEANING

Why

- To remove residues and oxides which could interface with welding, plating, or heat treating processes
- To remove any metallic materials imbedded into the surfaces permitting the formation of a continuous protective oxide film
- To prevent sources of rusting and corrosion on the surfaces
- To remove contaminants which could react with tritium

How

- Detergent solutions agitated ultrasonically
- Nitric acid solutions for dissolving imbedded copper and iron particles
- Nitric—hydrofluoric acid solutions for dissolving oxide films and imbedded particulate matter, and to etch certain stainless steel alloys
- Freon and alcohol rinsing for removing organic contaminants
- High purity water for rinsing
- High temperature vacuum bake

We take extreme care to verify cleanliness

UNCLASSIFIED

UNCLASSIFIED

CLEANLINESS VERIFICATION

- Monitor the resistivity of the rinse water to verify the absence of ionizable material
- Use analytical rinses to check for organic and inorganic contaminants with infrared spectrophotometer and ion chromotagraphy
- Perform particulate analysis on each reservoir
- Check for imbedded iron particles with a copper sulfate test
- Borescopic examination where applicable
- Visual examination for discoloration, staining, or superficial corrosive attack

Both piece parts and assemblies are cleaned prior to inspection

UNCLASSIFIED
UNCLASSIFIED

Inspection and gaging costs approximate one-third of the piece part costs

INSPECTION AND GAGING

To assure:

- Interchangeability of piece parts
- Fit with next assembly
- Conformation with engineering drawings

We inspect and gage using:

- In process monitoring—feedback
- Open——set up inspection
- Dedicated gages
- Contour gages
- Air gages——non-contact
- Statistical sampling
- Control of numerical machine tapes
- Coordinate measuring machines

To minimize scrap and rework costs, we inspect early in the process

UNCLASSIFIED

468

Mechanical joints are not used for storage of tritium

ASSEMBLY AND JOINING

Joining:

- Weldments
  - Gas-tungsten are——autogenous and wire feed
  - Electron beam——autogenous and wire feed
  - Laser
  - Friction
  - Inertia
  - Resistance forge weld
- Brazes
  - Copper
  - Copper-silver-tin

Inspection and Control:

- Process monitor
- Radiographic
- Ultrasonic
- Dye Penetrant

All pressure rated components are pressure tested

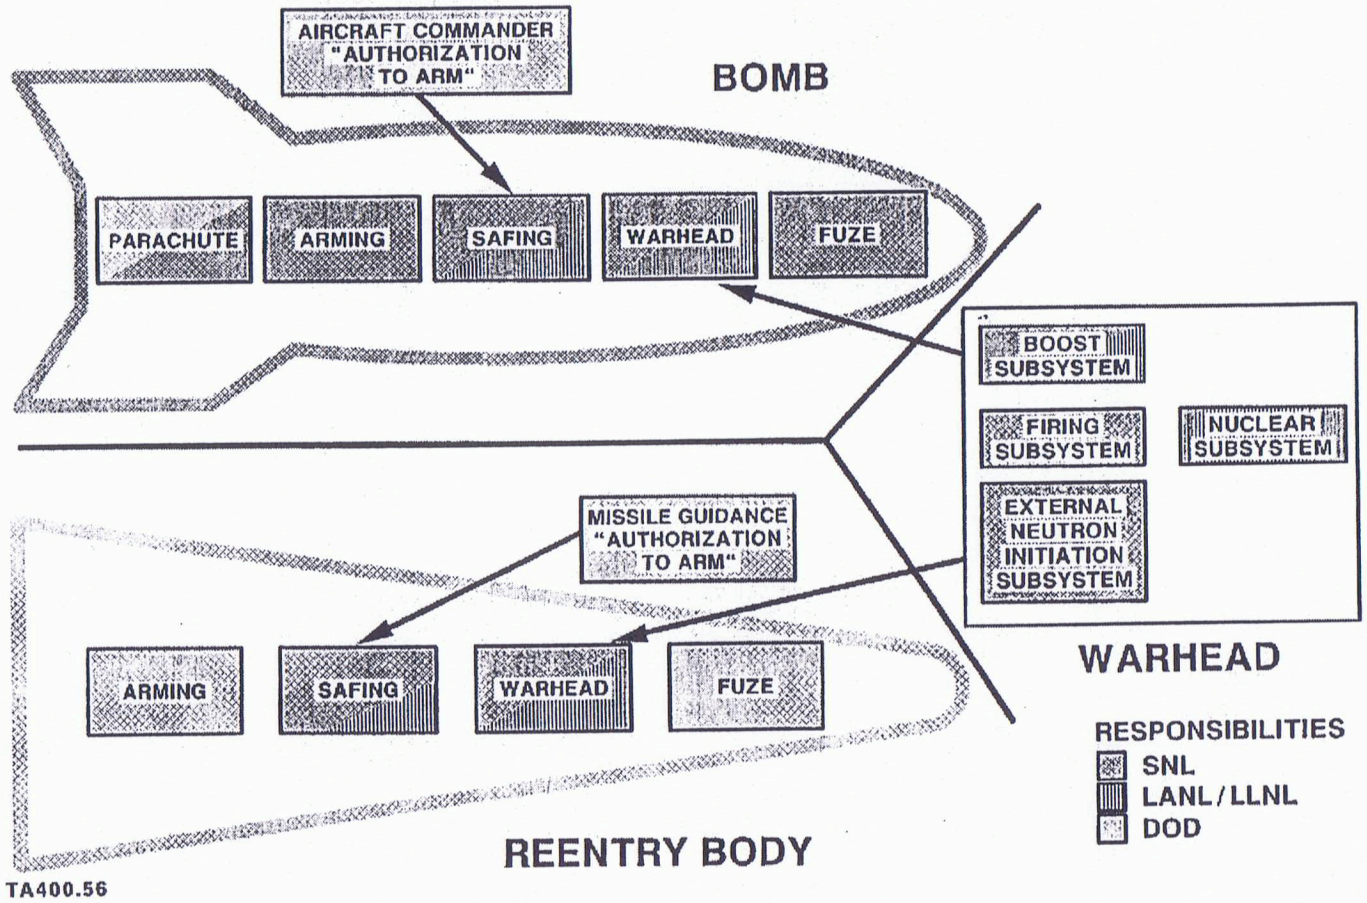
- OTHER FUZING MODES
- ADVANCED FUZING CONCEPTS

AGARD UNCLASSIFIED

Nuclear Weapon Fuzing Technology

- Introduction to Fuzing Components & Systems
- Radar Fuzing
- Contact Fuzing
- Inertial, Barometric, and Timer Fuzes
- Fuzing Systems
- ***Future*** Fuzing Systems
  - SLBM Warhead Protection Program

UNCLASSIFIED
UNCLASSIFIED



What is a Fuze ?

- Mechanism(s) within a weapon responsible for optimizing the location of weapon detonation
- Initiates the final, irreversible phase of weapon detonation
  - Follows "arming" functions, which are
    - reversible
    - time-uncritical
  - Precedes "firing"

SECRET UNCLASSIFIED

Fuzing System Hierarchy

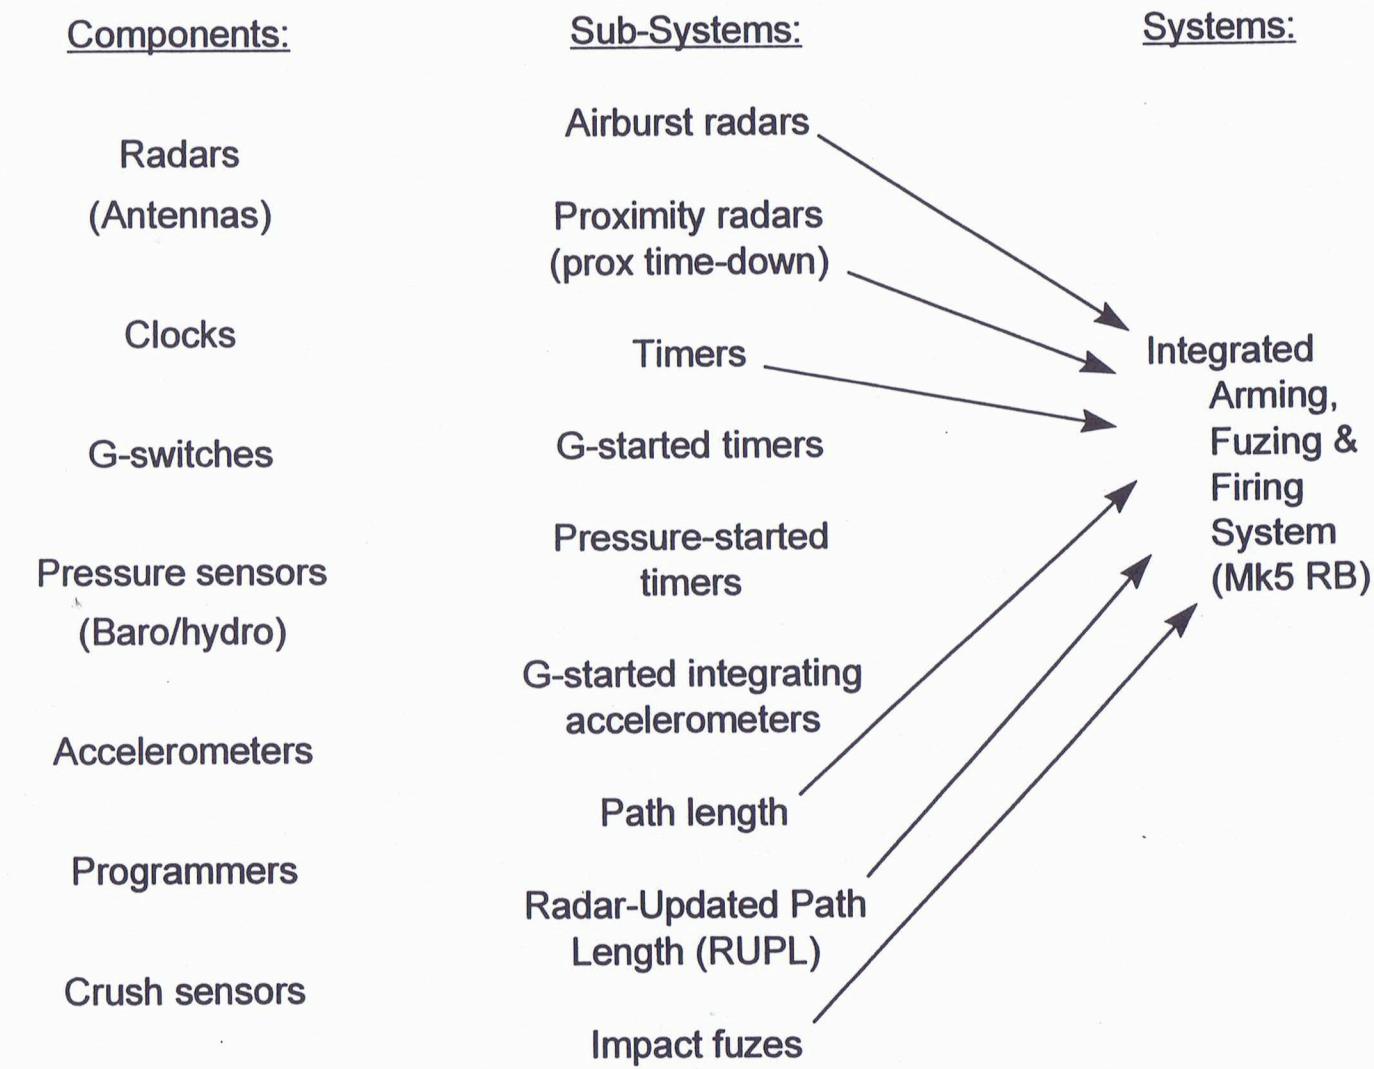
UNCLASSIFIED

UNCLASSIFIED



Fuzing System Hierarchy

UNCLASSIFIED

UNCLASSIFIED

How is a Fuze selected?

Traditional fuzing system priorities:

- Reliable
- Light weight (reentry body)
- Accurate
- Small (reentry body)
- Flexible
- Testable
- Producible
- Inexpensive

UNCLASSIFIED

UNCLASSIFIED

How is a Fuze selected?

Future fuzing systems must be:

- Inexpensive
- Producible
- Reliable
- Accurate
- Certifiable (test & analysis)
- Flexible
- Small (reentry body)
- Light weight (reentry body)

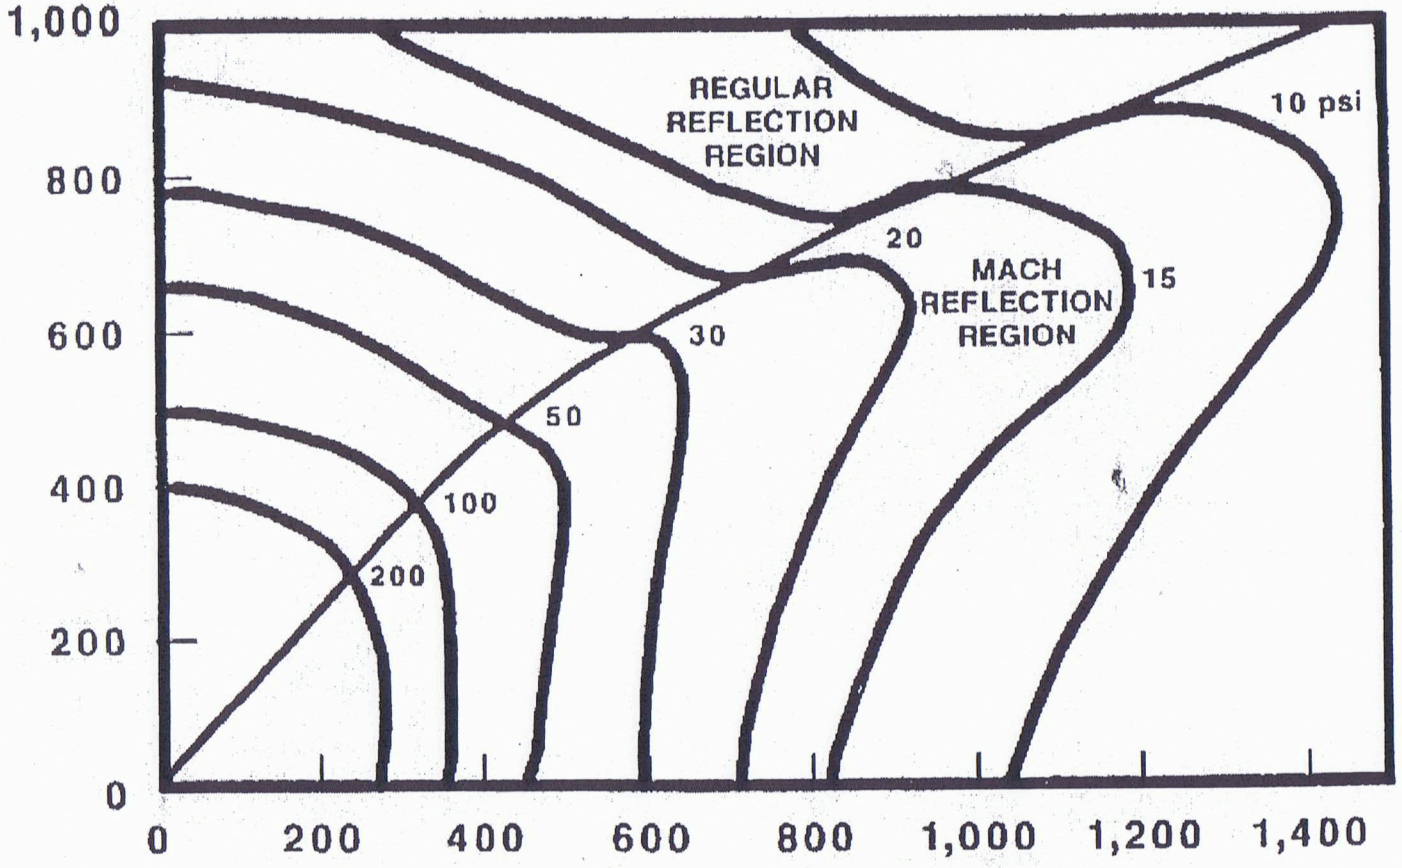
UNCLASSIFIED

UNCLASSIFIED

Radar Fuzing

- Role of radar fuzing
- Basic radar fuze operation
- Radar design issues
- Current technology

UNCLASSIFIED



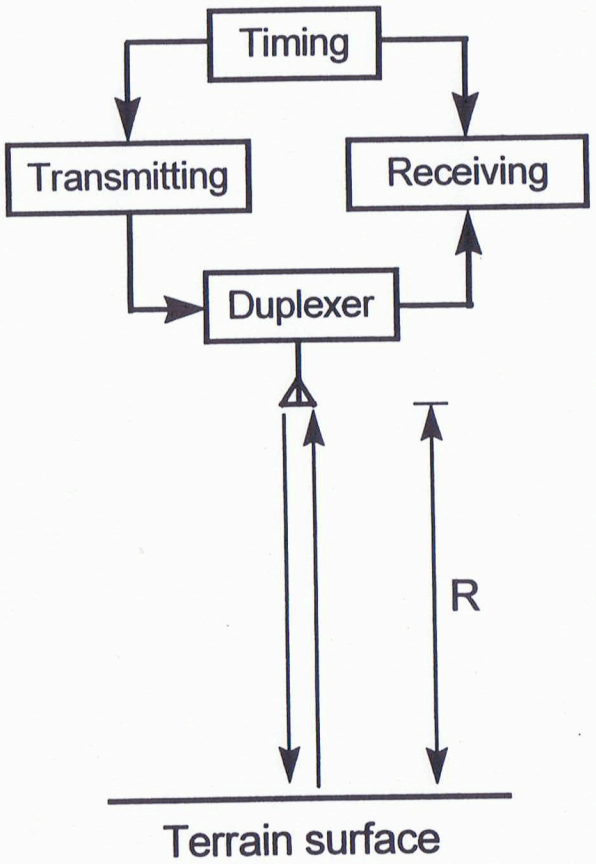
UNCLASSIFIED

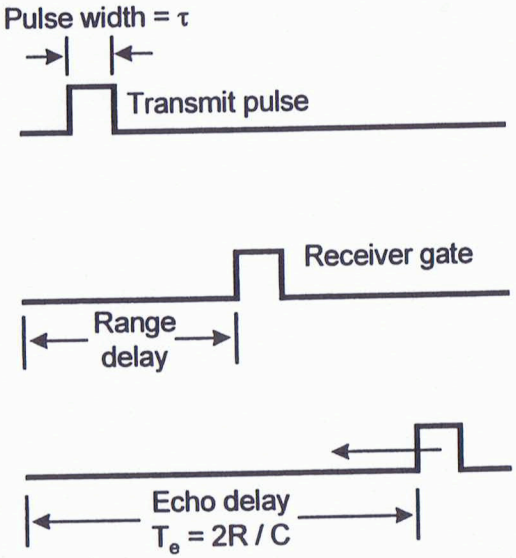
Why use a radar ?

- Height of burst precision to maximize extent of low overpressure levels
  - setability
  - accuracy
- Height of burst control to minimize fallout
- Dependable surface fuzing
  - Ensure detonation prior to collision
- Accurate altitude reference for improving inertial fuze accuracy (radar-updated path length fuze)

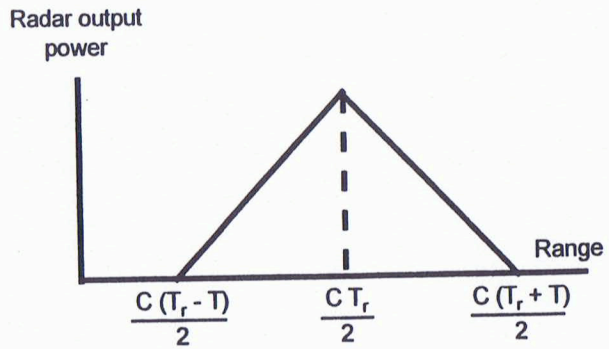
UNCLASSIFIED
UNCLASSIFIED

PEAK OVERPRESSURES ON THE GROUND FOR A 1-KILOTON BURST





REFERENCE: GLASSTONE AND DOLAN, THE EFFECTS OF NUCLEAR WEAPONS, 3RD EDITION US DOD AND DOE, 1977



UNCLASSIFIED

UNCLASSIFIED

Basic Radar Operation

UNCLASSIFIED
UNCLASSIFIED

Radar design considerations

- Immunity to electronic countermeasures
  - prevent premature detection of "radar-like" signals ("spoofing")
  - ensure detection of radar return in presence of RF energy saturation ("dudding")

- Plasma loss (space shuttle "black-out")
  - affects both transmit ***and*** receive
  - varies with: velocity

    altitude

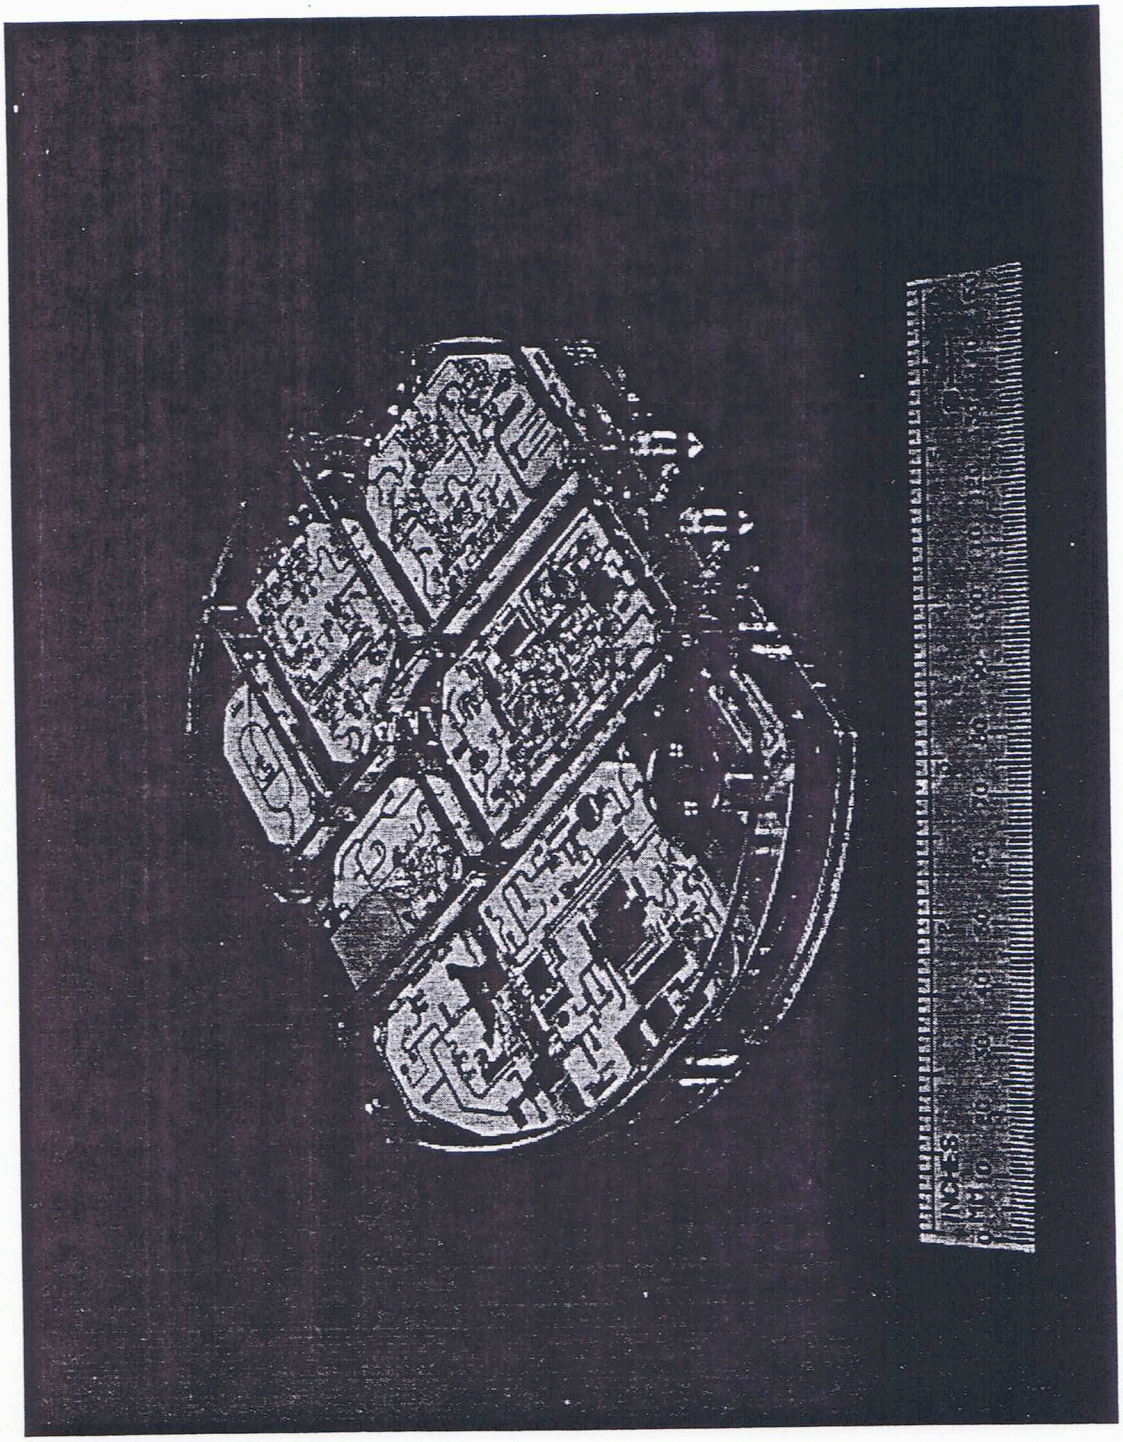
    nosetip and heat shield materials

UNCLASSIFIED

UNCLASSIFIED

UNCLASSIFIED
UNCLASSIFIED

One-way plasma loss vs. frequency for ABRV-3 trajectory



UNCLASSIFIED

UNCLASSIFIED

Radar design considerations, cont'd

- Antenna gain patterns
  - affects both transmit ***and*** receive
  - must accommodate all flight path angles and roll orientations
- Target reflectivities
  - peak reflectivity & angular attenuation
- Frequency
  - Higher frequencies required for proximity fuze narrow pulse width
  - Higher frequencies require less "real estate" for antenna windows
    - Smaller antennas thought to have less impact on reentry body flight
  - Lower frequencies have lower "path loss" requiring less receiver loop sensitivity

SECRET UNCLASSIFIED

SECRET UNCLASSIFIED

Contact Fuzing

UNCLASSIFIED

UNCLASSIFIED

Contact fuze characteristics

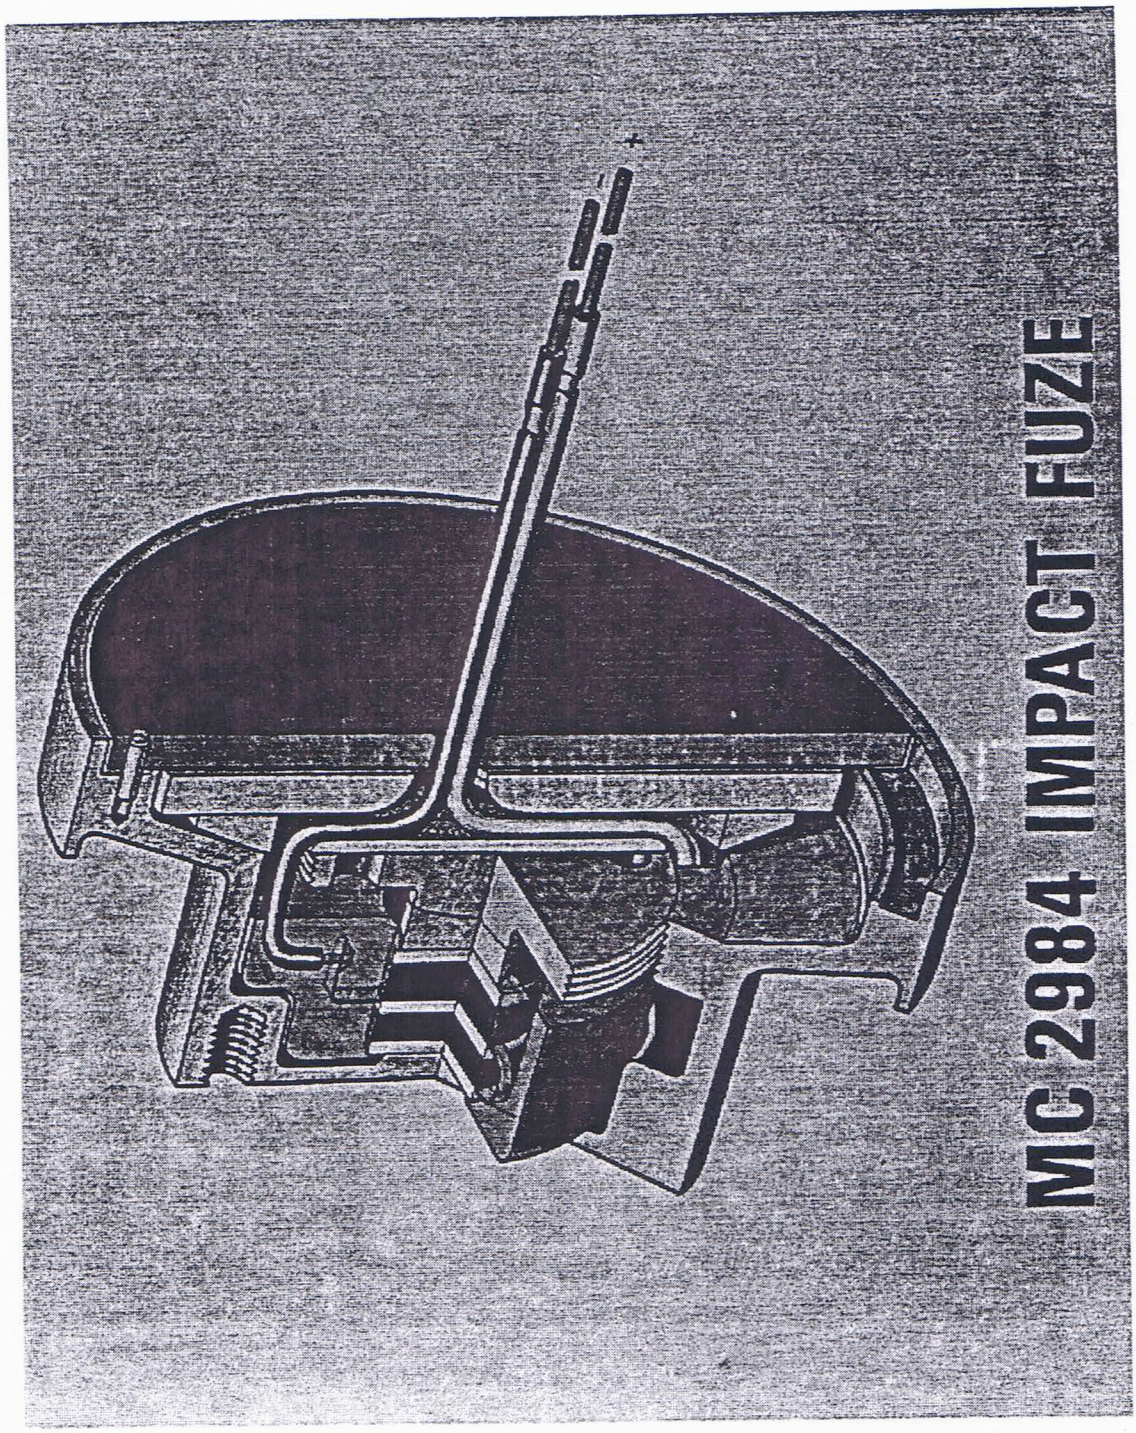
- Output directly triggers firing set for fast operation

  OR

  initiates delay mechnism for weapon designed for impact survivability

- Piezoelectric materials release charge (voltage) when shocked
  - generally not requiring external "poling" or charging

- Use pervasively throughout the stockpile for both selectable and backup fuzing



SECRET UNCLASSIFIED

SECRET UNCLASSIFIED

UNCLASSIFIED

UNCLASSIFIED

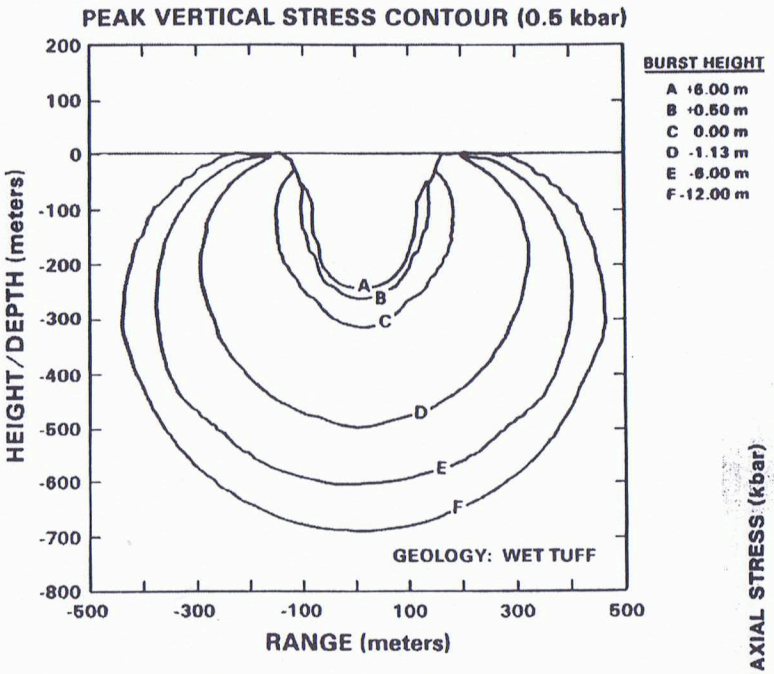
MC 2984 IMPACT FUZE

Contact Fuze Characteristics

- Advantages
  - Very little penalty in weight, cost or volume
  - Desirable as backup to air burst fuzing
  - Radiation hardened and immune to jamming
  - Very reliable as a component
  - Maximizes crater volume and ground motion in comparison to other air burst options

- Disadvantages
  - Reduced "effects radius" for air burst targets
  - Range offset associated with backup role
  - Qualification / testing has been costly
  - Dependability concerns (system reliability)

UNCLASSIFIED
UNCLASSIFIED



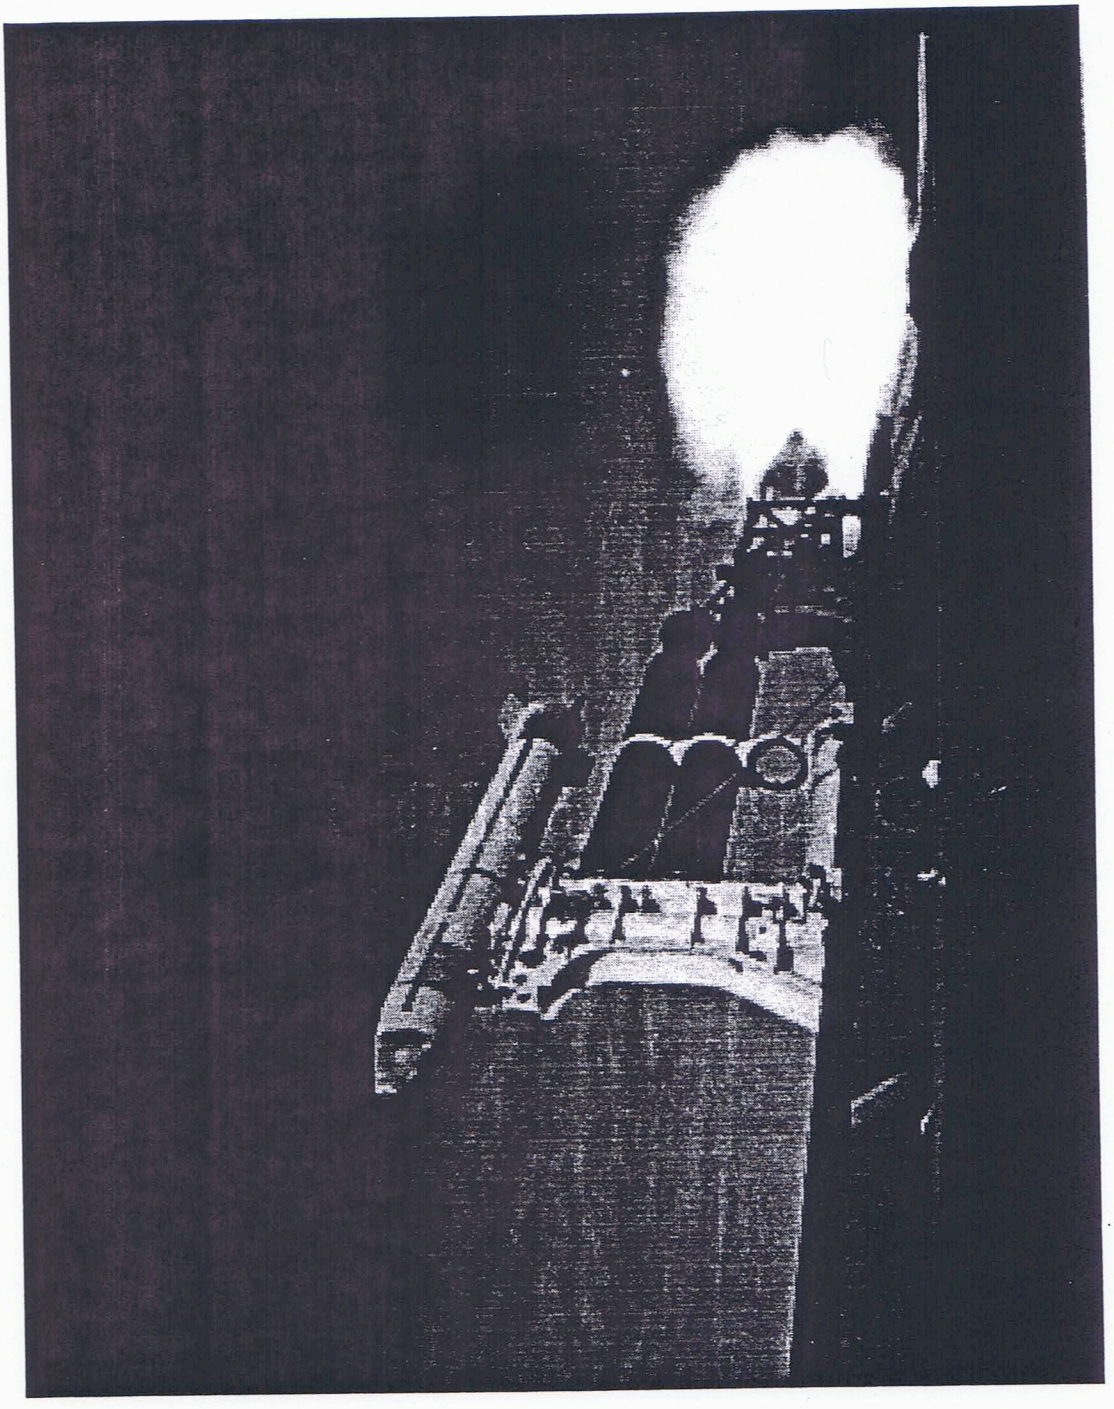
Contact fuzing degree of difficulty

	Component	System
Design	Easy	Easy
Validate	Fairly easy	Very difficult

UNCLASSIFIED

UNCLASSIFIED

Contact vs. Proximity - Ground shock environments



Proximity fuzing consistently results in minimal degradation in ground shock environments when compared to contact

SECRET UNCLASSIFIED

Books of interest

The Making of the Atomic Bomb, Richard Rhodes, 1986.
Pulitzer prize winner, follows the scientific discoveries that led to the bomb, particularly good at the personalities involved, finishes with vivid descriptions of Hiroshima and Nagasaki. Excellent and entertaining.

At the Highest Levels, Michael R. Beschloss and StrobeTalbott, 1993.
Intimate details of the end of the Cold War, as seen at the top.

Lenin's Tomb, David Remnick, 1993.
Details the end of the Soviet Union from the viewpoint of the Russian people and their legacy. Choppy, but a very human picture of the great event.

The Wizards of Armageddon, Fred Kaplan, 1983.
Follows the policy and strategy decision regarding nuclear weapons, much emphasis on the early RAND personalities. Very good and readable.

Some Definitions

Proliferation is the spread of weapons of mass destruction (WMD)-- typically nuclear, biological, and chemical weapons--and the systems which deliver them.

Nonproliferation is the use of the full range of political, economic and military tools to prevent proliferation, reverse it diplomatically, or protect our interest against an opponent armed with WMD or missiles.

Counterproliferation measures are the activities of the DoD across the full range of U.S. efforts to combat proliferation.

Alva Myrdahl's Historical View of Nuclear Weapon Controls

UNCLASSIFIED
UNCLASSIFIED

Nonproliferation Initiative

What Constitutes a Weapon of Mass Destruction

- Indiscriminate nature of use
- Effect not confined to belligerents
- Excessive injury -- "cruel and unusual"
- Inability to defend against effectively
- Use would overwhelm medical and evacuation resources
- Notion of "terror"

SECRET/ UNCLASSIFIED

SECRET/ UNCLASSIFIED

Motivation to Acquire Weapons of Mass Destruction

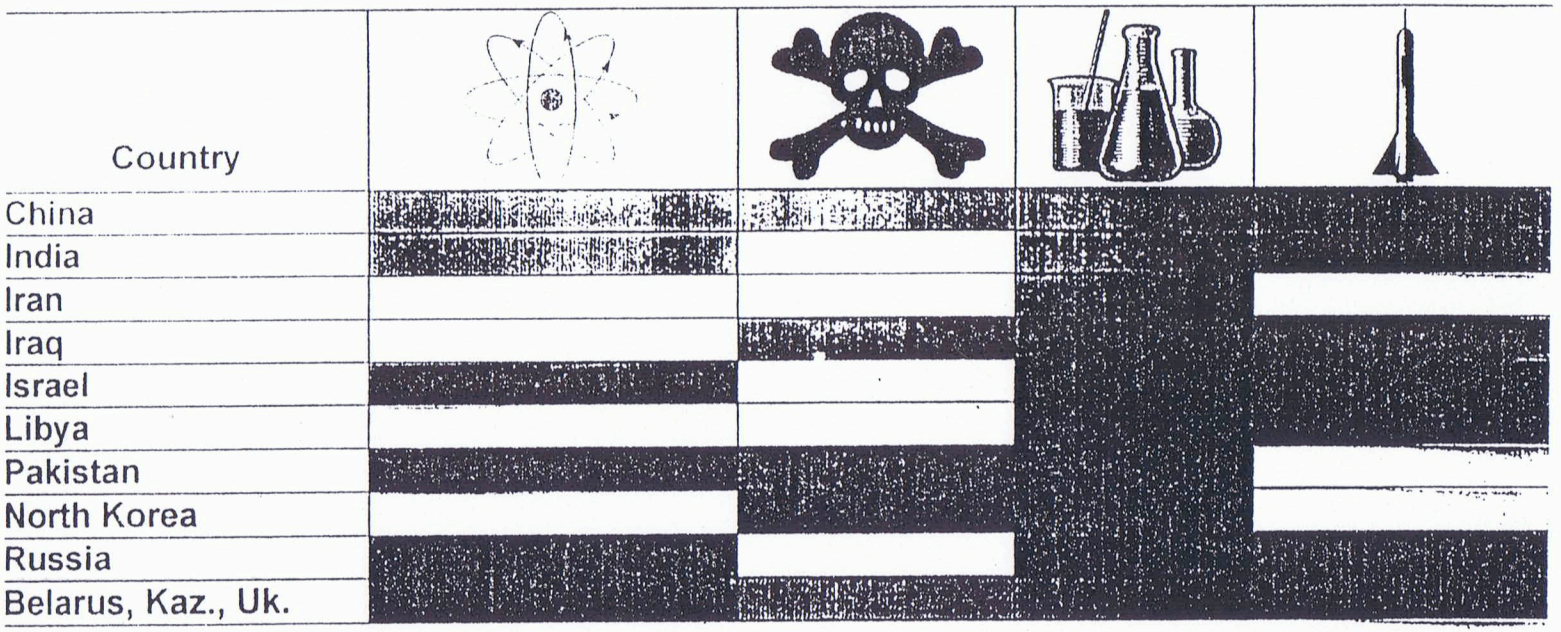
Great Powers have always countered the weapons of other great powers (e.g., USSR in the late 1940s)

Fear that a great power ally will not follow through (e.g., UK, France)

Fear over nuclear capabilities of potential adversaries (e.g., PRC, India, Pakistan, Iran, perhaps US in 1940s)

Fear of adversaries conventional strength (e.g., Israel, perhaps US in 1940s)

Cheaper than conventional defense (e.g., US in 1950s)



Desire for offensive capability (e.g., US in 1940s?)

Status in world or region (e.g., Iraq)

SECRET UNCLASSIFIED

SECRET UNCLASSIFIED

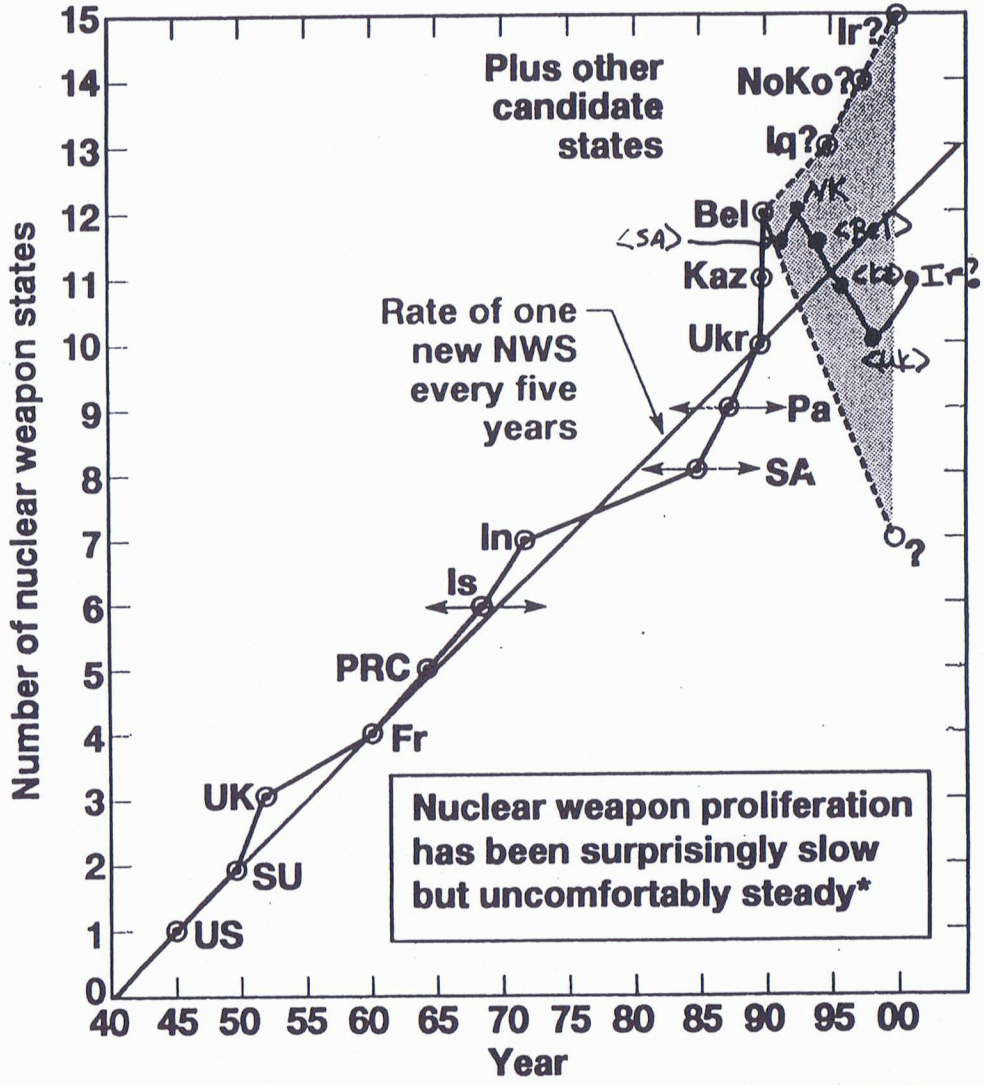
Some Proliferants of Concern

UNCLASSIFIED
UNCLASSIFIED

"Cost Effectiveness" of Weapons of Mass Destruction

The cost of producing, storing and delivering weapons can be estimated as the amount of money to deliver one lethal dose.

For nuclear weapons = $2000



For chemical weapons = $100

For biological weapons = $1

UNCLASSIFIED

UNCLASSIFIED

How many nuclear weapons states will there be in the year 2000?

*Data from news and journal articles in 1992

7B-S/1099-02

UNCLASSIFIED
UNCLASSIFIED

Nuclear Proliferation: A Current Status

- Acknowledged/Declared Nuclear Weapon States
  -- US, UK, China, France, Russia
- Undeclared but widely suspected Nuclear Weapon States
  -- India, Pakistan, Israel
- "Inheritors" of Soviet weapons
  --Ukraine, Kazakhstan, Belarus
- Virtual Nuclear Weapon States (e.g., weapon capabilities but no weapons)
  --Japan, Germany
- Threshold Nuclear Weapon States
  --North Korea
- Aspiring Proliferators
  --Iraq, Iran, Libya, Algeria, various terrorist organizations
- Rollback cases
  --Argentina, Brazil, Sweden, Switzerland, Egypt, Taiwan, South Africa(?)

UNCLASSIFIED

There have been some Nonproliferation Successes

-- Sweden abandoned its programs in the 1970s.

-- South Africa stopped its programs in 1992 (6 weapons).

-- Argentina and Brazil renounced their programs.

-- Taiwan and South Korea abandoned their programs in the 1980s.

-- Iraq's program "put on hold" by Desert Storm and UN Resolution 687 and 715.

-- Belarus, Kazakhstan, and Ukraine (?) have agreed to return the FSU weapons to Russia.

-- NPT indefinitely extended by "pseudo consensus"

SECRET
UNCLASSIFIED

SECRET
UNCLASSIFIED

WMD Technological Capabilities

Nuclear:

5 acknowledged possessors, 30 countries with "capability"

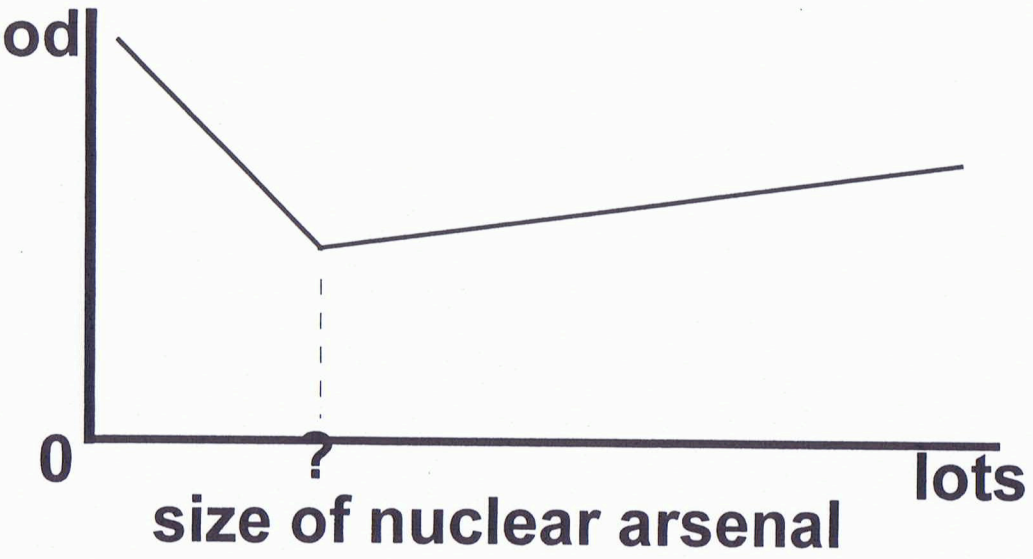
Chemical:

20-24 possessors, 80-90 countries and some subnational entities with "capability"

Biological:

10-12 possessors, virtually every state and several subnational entities are "capable"

(Conventional weapons:



virtually every country possess, 10-40 are major suppliers)

SECRET UNCLASSIFIED

SECRET UNCLASSIFIED

Why Not Zero?

Many nations and individuals want us to completely eliminate weapons -- attractive philosophy but dubious policy:

There may be things worse than nuclear weapons (e.g. biologics)

UNCLASSIFIED
UNCLASSIFIED

Qualitative Level of Proliferation Concern

Cold War (20,000)

START I (10,000)

START II (5,000±1500)

NAS (1,500)

Zero (0)

In the land of the blind, the one-eyed man is king.

Nonproliferation Initiative

Options across the Nonproliferation -- Counterproliferation Spectrum

disincentives ⟷ **incentives**

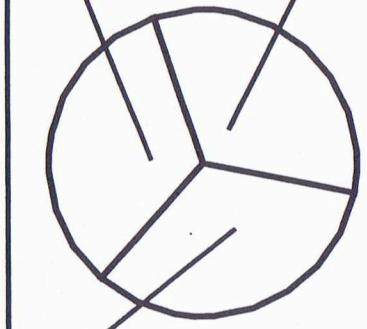
venues

Economics — blockades, sanctions — export controls — foreign aid

Politics — political isolation — int'l organizations — alliances

Military Force — war — peacekeeping — covert operations — military sales — military asst.

confrontation ⟷ **cooperation**



COUNTERPROLIFERATION ⟷ **NONPROLIFERATION**

SECRET
UNCLASSIFIED

Activities Which Accomplish Objectives

Reduce Demand

- International agreements
- Regional security agreements
- Transparency and confidence building
- Responsible behavior by nuclear weapon states
- Penalties for violating international norms
- Minimizing utility

Control Supply

- International Export Control Regimes
- IAEA Safeguards
- Elimination of sources of supply
- Monitoring and enforcement of export controls or embargoes
- Responsible behavior by nuclear weapon states

Mitigate Consequences

- Sanctions and embargoes
- Military activities
- Covert operations

Nonproliferation Initiative

Goals of Proliferation Controls (non → counter)

-- **REMOVE MOTIVATION** FOR POSSESSION OF NUCLEAR WEAPONS

-- **INTERDICT DEVELOPMENT AND ACQUISITION**

-- **DETER EMPLOYMENT** OF KNOWN OR SUSPECTED STOCKPILES OF NUCLEAR WEAPONS

-- **ELIMINATE INFRASTRUCTURE** BY PERSUASION, INTERNATIONAL SANCTIONS (e.g., Res 687)

-- PROACTIVELY **DESTROY FACILITIES** (e.g., Osirak)

Secondary Impacts of Nonproliferation Initiatives

- o NPT//NPT Extension Conference (1995):
  - -- Mandates for movement toward global reductions
  - -- Mandate for a CTB by 1996
  - -- Mandate for "FISS_BAN"
  - -- Mandate for Negative Security Assurances
  - -- Improved Safeguards
- o Negotiations on control on fissile materials:
  - -- Codify in-place current US and Russian practices
  - -- Inspection regimes and transparency
  - -- Possible attempts to restrict tritium production
- o Export Controls
  - -- Heightened concern over "dual use" systems and commodities

UNCLASSIFIED

Issues on the Nonproliferation platter

-- Control over the nuclear arsenal (and direction) of the FSU

-- North Korea--good deal? bad deal?

-- CTBT--linkage to NPT formalized during EXCON

-- China, France--steadfastly continuing to test

-- The Israeli nuclear arsenal

-- The nuclear relationship between India and Pakistan--imminent missile deployment (M11 vs Prithvi)?

-- Iran--a new reactor (Bushehr) for Israel to target?

Weapon Histories Lead to a New Question

- "What is required to sustain a weapon while it is in the stockpile?"
  - The DOE has active programs to:

    Upgrade a weapon's surety

    Maintain a weapon's reliability

    Incorporate new operational features into a weapon

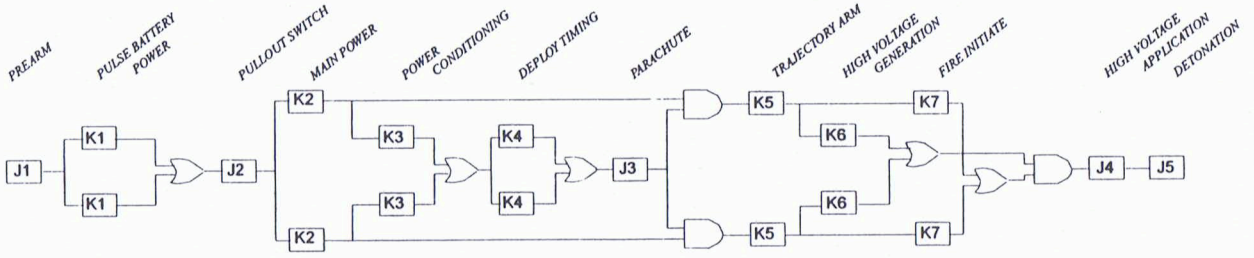
Where The 257 "Actionable" Defect Types Were First Discovered

* Designation in the Historical Summary



** No "Actionable" Defect Types first discovered

UNCLASSIFIED

Reliability Impact Assessed For All Defects

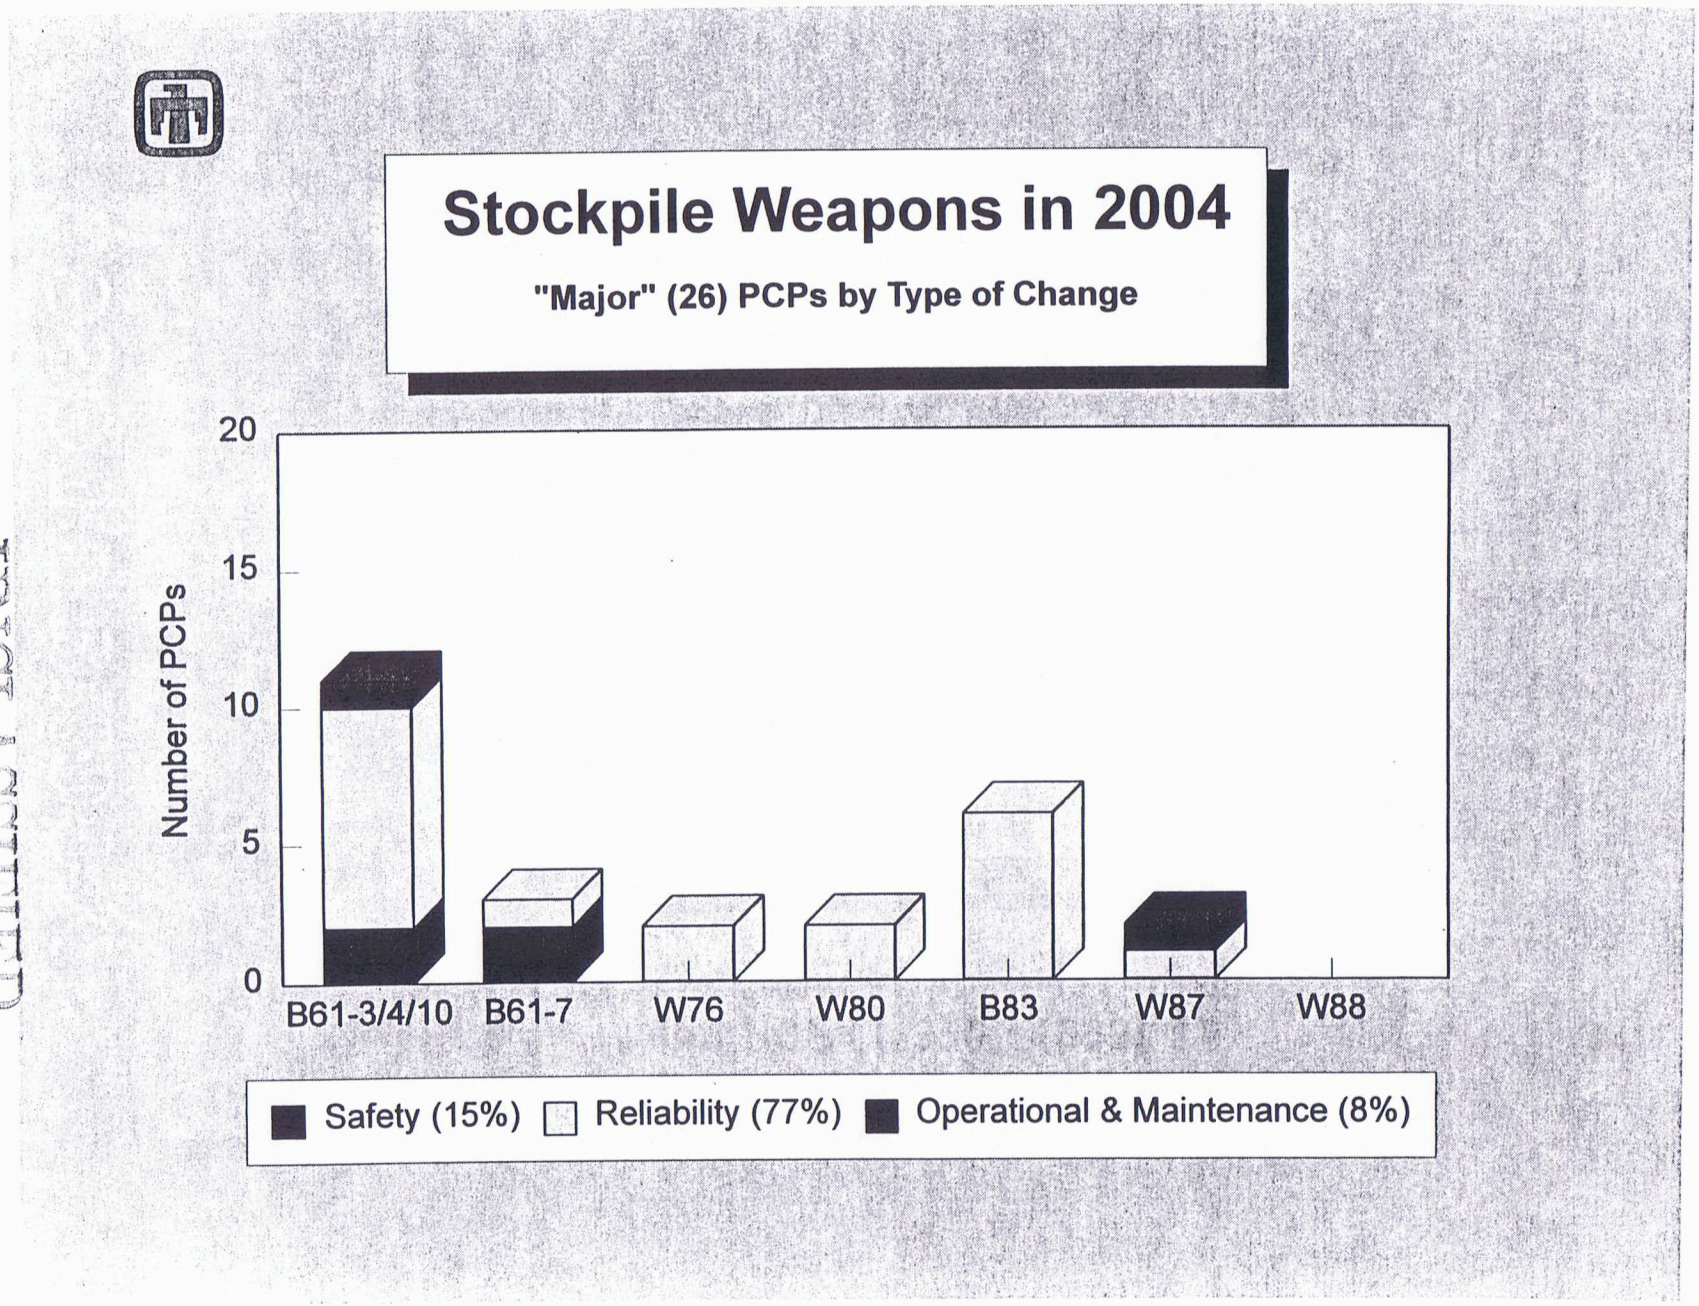
- CONTINUAL PROCESS TO DEFINE WEAPON RELIABILITY -

- Reliability assessment first established during weapon development
  - Reliability model developed

  - Sandia + Physics Lab inputs
- Reliability impact assessed during formal defect investigation (SFI)
  - Data collected from relevant sources
  - Added to existing data base
  - New assessment made (some defects assessed with no reliability impact)

UNCLASSIFIED

PCP Includes MOD & ALT



- Product Change Proposal (PCP)
  - Initiates & authorizes any accountable change to a War-Reserve (WR) weapon & its associated gear or non-WR units
  - Range in importance from Change in Wrench (H1324 for the W71)
  - Normally includes MOD & ALT
- Modification Number (MOD)
  - Assigned to any change to a WR weapon that alters its operational capability
- Alteration Number (ALT)
  - Assigned to any accountable change to a WR weapon & its associated gear or non-WR units

Future Workload Issues

historical data suggest that:

- 1 "actionable" defect will be discovered each year.
- About 2 PCPs will be approved each year - 1 of these will constitute a major change.
